PART I. COMMUNICATION AND ELECTRONICS

PUBLISHED BY THE
AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS
33 WEST 39TH STREET
NEW YORK 18, N. Y., U. S. A.

Copyright 1953 by the American Institute of Electrical Engineers
Printed in U. S. A. by The Mack Printing Company, Easton, Pa.

Preface

The AIEE *Transactions* for 1953 (volume 72) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

Communication Switching Systems
Radio Communications Systems
Special Communications Applications
Telegraph Systems
Television and Aural Broadcasting Systems
Wire Communications Systems
Basic Sciences
Computing Devices
Electrical Techniques in Medicine and Biology
Electronic Power Converters
Electronics
Instruments and Measurements
Magnetic Amplifiers
Metallic Rectifiers
Nucleonics

Part II. Applications and Industry

Air Transportation
Domestic and Commercial Applications
Land Transportation
Marine Transportation
Production and Application of Light
Chemical, Electrochemical and Electrothermal Applications
Electric Heating
Electric Welding
Feedback Control Systems
General Industry Applications
Industrial Control
Industrial Power Systems
Mining and Metal Industry

Part III. Power Apparatus and Systems

Carrier Current
Insulated Conductors
Power Generation
Protective Devices
Relays
Rotating Machinery
Substations
Switchgear
System Engineering
Transformers
Transmission and Distribution

Education
Safety
Research

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index.

Volume 72 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., January 19–23, 1953.
2. Southern District Meeting, Louisville, Ky., April 22–24, 1953.
3. North Eastern District Meeting, Boston, Mass., April 29–May 1, 1953.
4. Summer General Meeting, Atlantic City, N. J., June 15–19, 1953.
5. Pacific General Meeting, Vancouver, B. C., Canada, September 1–4, 1953.
6. Middle Eastern District Meeting, Charleston, W. Va., September 29–October 1, 1953.
7. Aircraft Electric Equipment Conference, Seattle, Wash., September 30–October 2, 1953.
8. Fall General Meeting, Kansas City, Mo., November 2–6, 1953.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Television Coverage of the National Political Conventions

R. W. RALSTON
NONMEMBER AIEE

B. D. WICKLINE
NONMEMBER AIEE

IF ONE were to indicate in a single word the over-all characteristic of the 1952 Democratic and Republic political conventions, it would be difficult to avoid choosing "quantity." From a political standpoint, certainly at no other event in recent history was manifest the number of candidates, the number of delegates, the number of committees, or the number of commentaries by a not inconsiderable group of reporters. However, the most striking application of this word is to the means by which the first large-scale television coverage of these events was provided over such an extended period of time. The concentration of equipment and personnel in Chicago, Ill., during this period was unprecedented for any event, making the television camera as all-pervading as was the microphone at previous conventions. This was most graphically illustrated at the Republican convention after General Eisenhower was selected as candidate. There were cameras at his suite in the Blackstone Hotel, cameras to cover his exit from the hotel as he departed on his trip to the Amphitheatre, cameras along the street as he made his journey, cameras outside the Amphitheatre, ad infinitum.

The provision by Illinois Bell Telephone Company of television facilities for this period represented no exception to the application of this word. As an operating company in the Bell System, it was the company's job to provide all television channels connecting various pickup points, such as the International Amphitheatre, the Conrad Hilton Hotel, and the Blackstone Hotel, to the network terminus in Chicago, and also to provide virtually all other local television channels which were used for indirect connection to the networks. Naturally, this unusually severe requirement introduced many problems not previously encountered. Arranging for the installation and simultaneous operation of 11 microwave equipments at one location, increasing the operating technical forces by a factor of over two—these are but a few examples.

Preliminary plans for the political conventions were formulated immediately after the International Amphitheatre had been officially selected as the site, at which time telecasters indicated to our Commercial Department that two connecting channels would be required. However, these plans were not crystallized until a more detailed résumé of video channel requirements was received early in February 1952. This indicated that approximately 25 channels additional to those in use in the Chicago area at that time would be required during the month of July. Included were 19 channels between the International Amphitheatre—the primary source of convention activities—and the following locations:

1. The Merchandise Mart, location of the studios of television station *WNBQ*, the Chicago National Broadcasting Company (NBC) outlet.
2. The Civic Opera Building, location of the studios and transmitter of television station *WENR-TV*, the Chicago American Broadcasting Company (ABC) outlet; also the transmitter location of station *WNBQ*.
3. The Hilton Hotel, a secondary point of convention coverage.
4. Number 2 Toll Office, the terminating point in the Loop area for video transmission to or reception from the cross-country network.

The remaining six channels extended between various miscellaneous locations in the Loop area.

This was an unprecedented request for service; it would double the number of channels then being provided by our company. However, this requirement was understandable in view of the broadcasters' planning. Each contemplated providing convention coverage for the entire day during the progress of the conventions. This would consist not only of programs originating at the Amphitheatre, but also from the Hilton Hotel, various convention headquarters, and from the network. Consequently each planned to establish an independent master control point at the Amphitheatre through which most of these programs would pass regardless of whether they originated at the Amphitheatre. Editing and switching of pictures would take place here prior to transmission for direct telecast to all network stations providing convention coverage. As is evident, this resulted in a relatively enormous request for channels.

A comprehensive review was then made by the Transmission Engineering Division of our company to determine the most suitable means of furnishing the required service. In general terms, of the 19 channels originating or terminating at the Amphitheatre, it was planned to use special video conductors, together with associated video amplifiers for eight of the channels and to use microwave facilities for the remainder. In regard to other locations, conductors would be used where installed or where a reasonably economic rearrangement would make them available. Microwave channels would be used for the remainder. These plans were then discussed with various organizations within the company to implement the required work.

Cable

Before discussing the problem of providing special video pairs, a brief exposition will be made of our cable facilities for television service. Generally speaking, two types of conductors (pairs) are used with amplifying equipment for providing television service. The first is the polyethylene shielded video (PSV) pair, a special video pair. It consists of two 16-gauge conductors, surrounded by polyethylene string and tape insulation and a double shielding of helically wound copper tape. This make-up provides excellent characteristics for television application such as relatively small loss, very low noise level, and excellent shielding. The PSV pair is placed within a protective sheath along with other conductors of its type and regular telephone pairs, thus constituting what is called video cable.

The second type is the ordinary telephone pair. This has from three to five times the loss of the PSV pair, thus requiring more amplification per channel and providing relatively high susceptibility to interference from other telephone pairs. Statistically speaking, paper pairs have relatively high ambient noise when evaluated according to television requirements. Use of these pairs is rapidly being discontinued as video cable is installed.

Paper 53-90, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted October 23, 1952; made available for printing December 17, 1952.

R. W. RALSTON and B. D. WICKLINE are with the Illinois Bell Telephone Company, Chicago, Ill.

In regard to cable facilities, plans had been formulated independent of the convention for expansion of our PSV pairs in many areas of the city. In the case of the area south of the Loop where the Amphitheatre is located, plans had been made for a substantial increase to provide service to various theaters in the area for theater television, to connect to one of our new toll offices, and to establish service to miscellaneous pickup points in this area. These plans were to be implemented over a broad period. However, because the Amphitheatre was located near the path along which the south expansion would be made, it was decided to expedite its completion by convention time. It would then be necessary to add only a short length of PSV cable from the Amphitheatre to intercept the new PSV pairs in order to establish the convention requirement of eight wire channels between the Loop area and the Amphitheatre. This would avoid an excessive capital expenditure for the convention alone.

Originally, a 4-pair PSV cable had been placed from a central office building in the Loop area as far south as the American League Baseball Park (Comiskey Park) located at 35th Street South; see upper left Figure 1. Two of these pairs were looped through the park and extended farther south and west to the International Amphitheatre at 42nd Street. This provided coverage to both locations.

The plan for expanding facilities south entailed the following:

1. Construction of a small building for housing video amplifiers, to be known as Amplifier Station number 1, located about five miles south of the Loop on the fundamental video wire route. The Amphitheatre lies just a few blocks west.

2. Placement of a 4-pair PSV cable south of Wabash Office directly to the new Amplifier Station, by-passing Comiskey Park.

3. Extension of two of the original four pairs to Amplifier Station number 1, by-passing Comiskey Park. This then provided a total of six pairs to the Amplifier Station.

4. Placement of an additional 6-pair extension from the station to the Amphitheatre.

This provided the necessary eight pairs from the loop area to the Amphitheatre, two of which looped through Comiskey Park and did not extend through the Amplifier Station.

In regard to the Hilton Hotel, a rearrangement and addition to existing facilities was sufficient to provide five pairs into the Hilton Hotel, four of which were video pairs and one paper; see Figure 1.

Just north of the loop area it was necessary to reinforce facilities to serve the studios of *WNBQ* at the Merchandise Mart. The method of providing this addition illustrates some fundamental concepts employed in designing our Chicago Video Cable Network and therefore we feel is of interest. Many pickup points served by our cable pairs are used only a few times a year. In these cases, it is our policy to have flexible cable arrangements permitting some pairs to serve more than one location. Similarly, where a number of pairs serve a location in consistent use but where there are occasionally more severe demands for service, additional

pairs are installed, where possible, on a shared basis with other locations. In consequence of this policy, the addition to Mart facilities involved a number of locations in its vicinity: the Tribune Tower where the studios and transmitter of *WGN-TV* are located, one of our central office buildings near the Tribune Tower (Superior Office), and the Sheraton Hotel. As in the case of the Amphitheatre, a plan for additional facilities had been considered previously but was expedited for the conventions since certain of the locations mentioned would require additional pairs in another year or two.

Originally eight PSV pairs were established to the studios of *WNBQ* at the Merchandise Mart. However, these eight pairs were a part of a 12-pair PSV cable, four of which extended past this location to serve the studio of *WGN-TV*, the Sheraton Hotel, and Superior Office; see Figure 2. The plan for additional facilities included the following:

1. Four PSV pairs previously by-passing the Merchandise Mart were looped through the basement at this location and terminated in a patching arrangement, permitting these pairs to be either routed to the *WNBQ* Studios on the 19th floor or looped through to serve the original locations.

2. A new 6-pair PSV cable was established along another path to serve *WGN-TV* and other locations in its vicinity. Three of these pairs were actually terminated at *WGN-TV*, making a total of 8 pairs, while the remaining three were used to facilitate rearrangements at Superior Office and the Sheraton Hotel.

This permitted simultaneous usage of 12 pairs to the Merchandise Mart, in which case *WGN-TV* would be served by six pairs along the new path. A change in patching would permit routing two *WGN* pairs through the Merchandise Mart basement, thus providing eight pairs to *WGN-TV* and limiting the Mart to the use of ten pairs. This also provided flexibility, thus fulfilling a need which had been felt for some time, that of providing alternate routing for channels in the event of a failure of a particular cable.

At the Civic Opera Building, a tie cable consisting of four PSV pairs was placed between the *WENR-TV* and *WNBQ* locations to permit more flexible use of facilities extending from the Civic Opera Building in the event of an unexpectedly high requirement for either telecaster, see Figure 1.

A rearrangement which was accomplished at one of our central office buildings in the Loop requires some background material. The centralized nature of the Loop Area in Chicago, which contains all of the studios and transmitters of television stations, has permitted us to establish one location—the Franklin Building—through which virtually all television channels are routed, see Figure 2. Prior to the rearrangement to be discussed, all channels were routed through a location on the 16th floor called the Television Control Center (TCC). This center is equipped with special video amplifiers, a patch bay and monitoring equipment which permits control of all channels.

However, before the conventions, a new type of amplifying equipment, the Receiving Line Amplifier, to be discussed in the next section, was made available for use on certain short video channels. This piece of equipment obviated the need of many of the video amplifiers, designated type *A-2*, located at the TCC. Since the capabilities of these *A-2* units were not exploited on short links and also since many additional *A-2*'s were needed during the conventions, it was desirable to replace them with Receiving Line Amplifiers. However, it was found that the losses incurred on some of these short channels merely looping in and out of the TCC (1st floor to 16th floor and back) were sufficient to preclude the use of Receiving Line Amplifiers. For this reason arrangements were made to bring all cables entering the Franklin Building to a patching bay on the first floor, thus permitting channels to either enter or bypass the TCC. It was planned to retain control on channels for monitoring by bridging across the line through a high-impedance amplifier at the first floor to the TCC when required. The reason for citing this rearrangement is that virtually all television channels then in existence were affected by this plan, requiring intricate time-consuming co-ordination work for completion.

Cable rearrangements were also made on television channels extending between the Franklin Building and the number 2 Toll Building to permit more flexible arrangement of pairs between all locations. See Figure 1.

Equipment

Wire

To clarify some of the equipment problems involved, some characteristics of wire video channels will be discussed.

A wire video channel consists of conductors, terminal equipment to permit connection to the broadcasters equipment, suitable amplifying equipment, and a means of equalizing the conductor losses which vary with frequency. At the

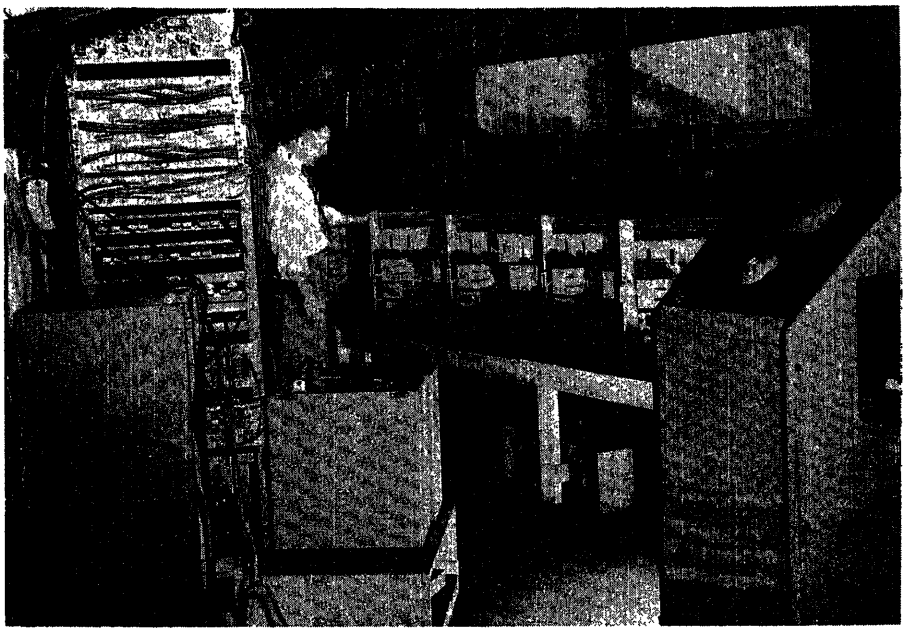

Figure 12. Telephone equipment room at International Amphitheatre. To the left behind cabinet is patch bay showing jacks and plugs. Above this is shown rear of 197 coil installation. 1-B clamper amplifiers appear on top and bottom of bay respectively. Portable monitor and oscilloscope are shown on dolly. Figure 16. Block diagram of telephone equipment room in the International Amphitheatre

originating terminal a means is required to convert from the unbalanced facilities (coaxial cable) of the broadcasters to 2-conductor PSV facilities, each conductor of which has a like impedance to ground (balanced pair). Either a repeating coil, coded *197* type, or a transmitting amplifier may be used for this purpose. The repeating coil, see Figure 3, is a 1 to 1 gain conversion device uniform in response between 60 cycles and 7 megacycles, having one side of the input grounded and the output balanced above ground. The transmitting amplifier has uniform gain characteristics between 3 cycles and 4.5 megacycles. It is used whenever gain is desired, either to increase low signal input or to override high ambient noise such as might exist on paper pairs.

The terminal equipment at the receiving location consists of the repeating coil just mentioned and a *1-B* clamper amplifier; see Figures 4 and 5. The latter consists of an amplifier having a gain of 18 decibels flat to 7 megacycles and a clamper unit which maintains the voltage level of the horizontal synchronizing pulses at a fixed d-c value. This d-c reinsertion is necessary in view of the transformer characteristics of the *197* coil.

Amplification and equalization are accomplished using *A-2* amplifiers; see Figures 6 and 7. Each consists of three components: an input amplifier, an equalizer panel, and an output amplifier. Both input and output may be adapted for connection to coaxial conductors or balanced conductors. In addition, these components may be used in different combinations depending upon the particular need. If it is desired to use the *A-2* system for transmitting purposes where an unbalanced input and a balanced output are required, the input amplifier and equalizer panel are omitted. When the equalizer and the input amplifier are included, the *A-2* is called an intermediate amplifier. The input and output amplifier may make up both gain and equalization on cable losses up to 65 decibels at 4 megacycles. In the case of PSV pairs, this would permit an interval of 4 miles between adjacent amplifiers. To summarize, a wire line channel normally consists of the *197* coil at the originating end, a cable pair, intermediate amplifier, and a coil and clamper at the receiving point.

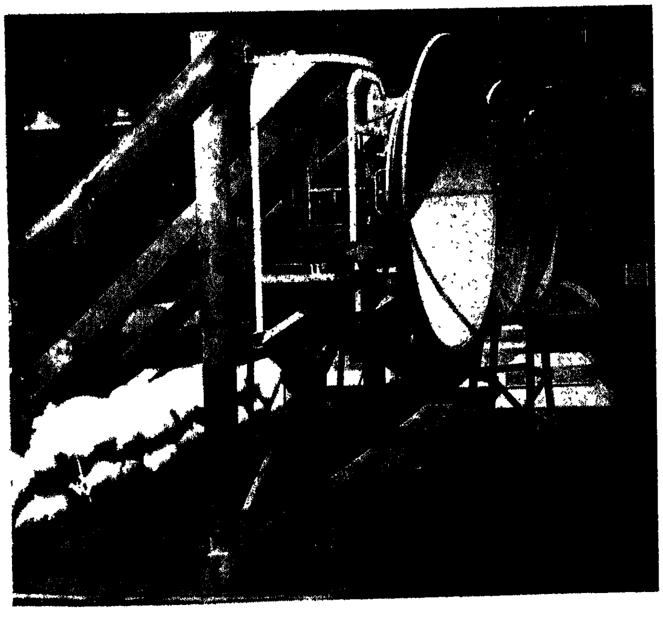

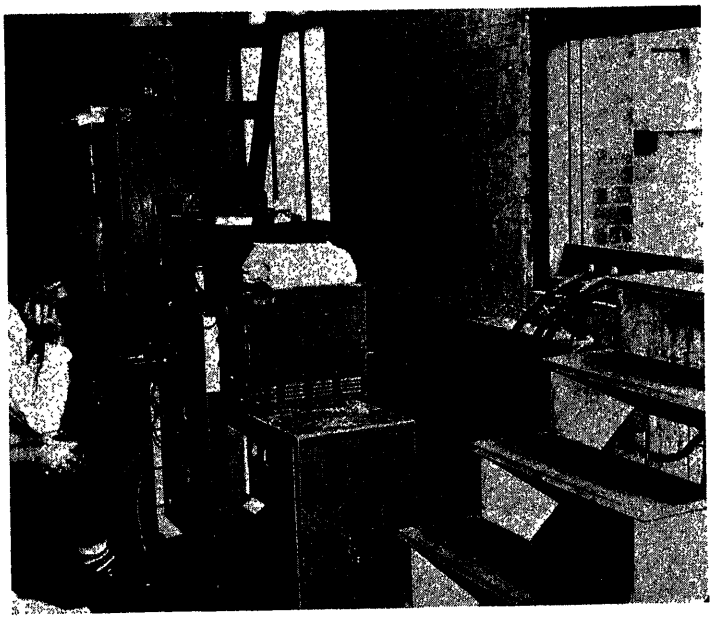

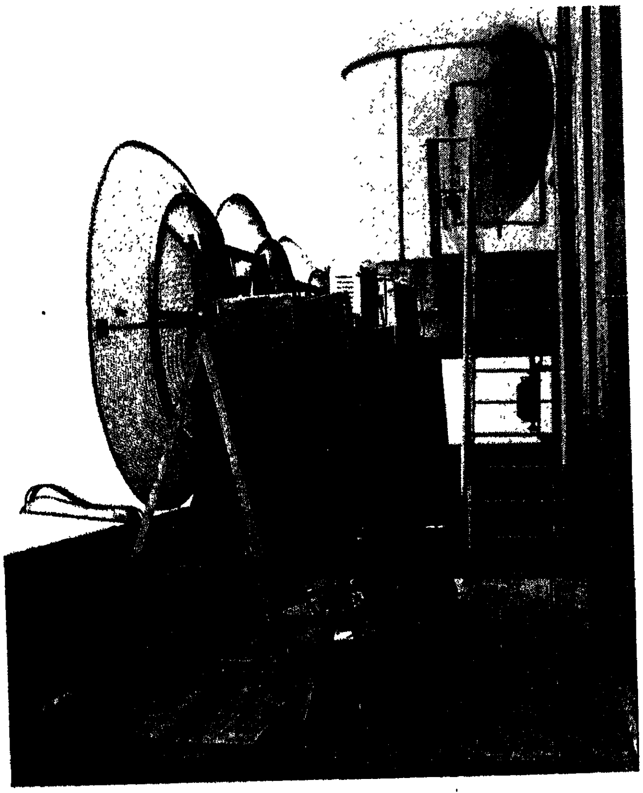

Figure 21 (left). TE microwave equipment located on 44th floor parapet at the Civic Opera Building. Cupola at upper right contains WNBQ microwave equipment

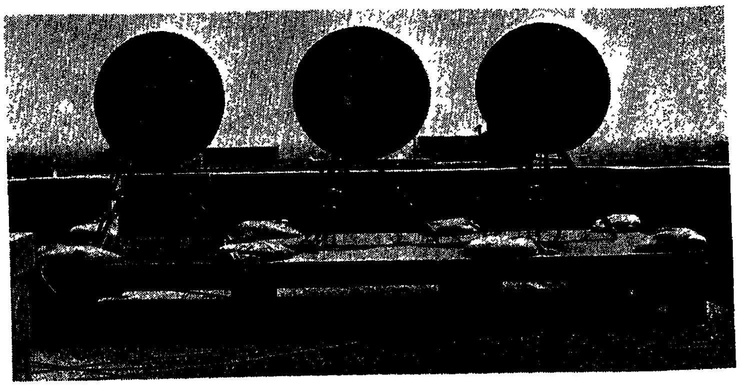

Figure 22 (above). RCA microwave equipment located on top of the Hilton Hotel. Control equipment is located underneath this roof

To provide amplification and equalization on the new wire lines extending south of the Loop area for the convention period, a new item of equipment was made available, the *A-2X* amplifier; see Figures 8 and 9. This had gain and equalization potentials in excess of the *A-2* amplifier, thus permitting adjacent amplifiers to be spaced $5^{1}/_{2}$ miles apart instead of 4 miles. The advantage of this item is readily apparent in view of the relatively inexpensive modifications of the *A-2* amplifiers necessary to convert it to an *A-2X* amplifier. Figure 10 shows the portion modified. The additional gain and equalization are obtained by adding an additional amplifier to the *A-2* system between the input and output amplifiers and providing additional space for equalizers on the equalizer panel. Thus the *A-2X* provides gain and equalization on circuits up to 85 decibels of 4-megacycle loss as compared to 65 decibels for the *A-2* system. Installations of these amplifiers were made at the Wabash Office in the Loop area and at Amplifier Station Number 1. This station was constructed at a location based upon the spacing which could be tolerated between adjacent *A-2X* amplifiers. The Wabash installation is shown in Figure 11.

Another item of equipment which was installed at a number of locations was the Receiving Line Amplifier, Figures 4 and 5. This item, which is compact, and most important, more economical than the *A-2* amplifier, was designed for use at the receiving terminal of relatively short channels. Since it provides both equalization and gain it obviates the need for the *A-2* amplifier on channels of 35 decibels of 4-megacycle loss or less. It is made up of a modified input amplifier from an *A-2* system, an equalizer panel, a special impedance conversion device, and a *1-B* clamper. The impedance conversion device is necessary to change the equalizer panel impedance to that of the *1-B* clamper.

Because of the critical need for *A-2* amplifiers during the convention period, installations of these Receiving Line Amplifiers were expedited at the Civic Opera Building, the Franklin Building, and Number 2 Toll Office. Several portable units were also ordered for use where necessary at miscellaneous locations.

Installations of *197* repeating coils and *1-B* clampers were made at the Hilton Hotel, International Amphitheatres, and other locations. Portable clampers were ordered for use at miscellaneous locations. See Figures 3 and 12.

Microwave

To provide the required number of microwave channels it was necessary to obtain microwave equipment from other operating companies to supplement our own supply. Accordingly, four telephone equipment (TE) type microwave equipments were rented from the Wisconsin Telephone Company and two Radio Corporation of America (RCA) units were rented from the New York Telephone Company. The TE-type equipment operates at 4,000 megacycles and the RCA operates at approximately 7,000 megacycles. Together with the equipment owned or ordered by our company, this provided a total of six TE and nine RCA type equipments. Eleven of these units were planned for use between the Amphitheatre and various Loop locations, while the remainder were to be utilized as maintenance spares and for the provision of regular and unforeseen requirements occurring during the convention period. Various test and maintenance equipment such as oscillators, signal generators, and measuring devices were also obtained for the operation of both wire and microwave channels.

Space

As explained previously, it is company policy to have most channels extended through the Franklin Building for control and monitoring purposes. As applied to a typical microwave pickup, this means that the microwave transmitter would be located at or near the pickup point while the receiver would be located at one of our tall central office buildings in the Loop area. From this point the signal would be transmitted to the broadcaster by a wire channel through the Franklin Building. This is done to enable us to operate the microwave equipment at our locations as much as possible. However, because of the unusual nature of the demand for channels during the convention, it was necessary to establish microwave circuits directly between the pickup point and the broadcaster's location since sufficient wire lines were not available. To implement this plan it was necessary to secure space and roof rights at many more locations than would normally be necessary. The following locations were involved:

1. The International Amphitheatre (all microwave and wire channels).

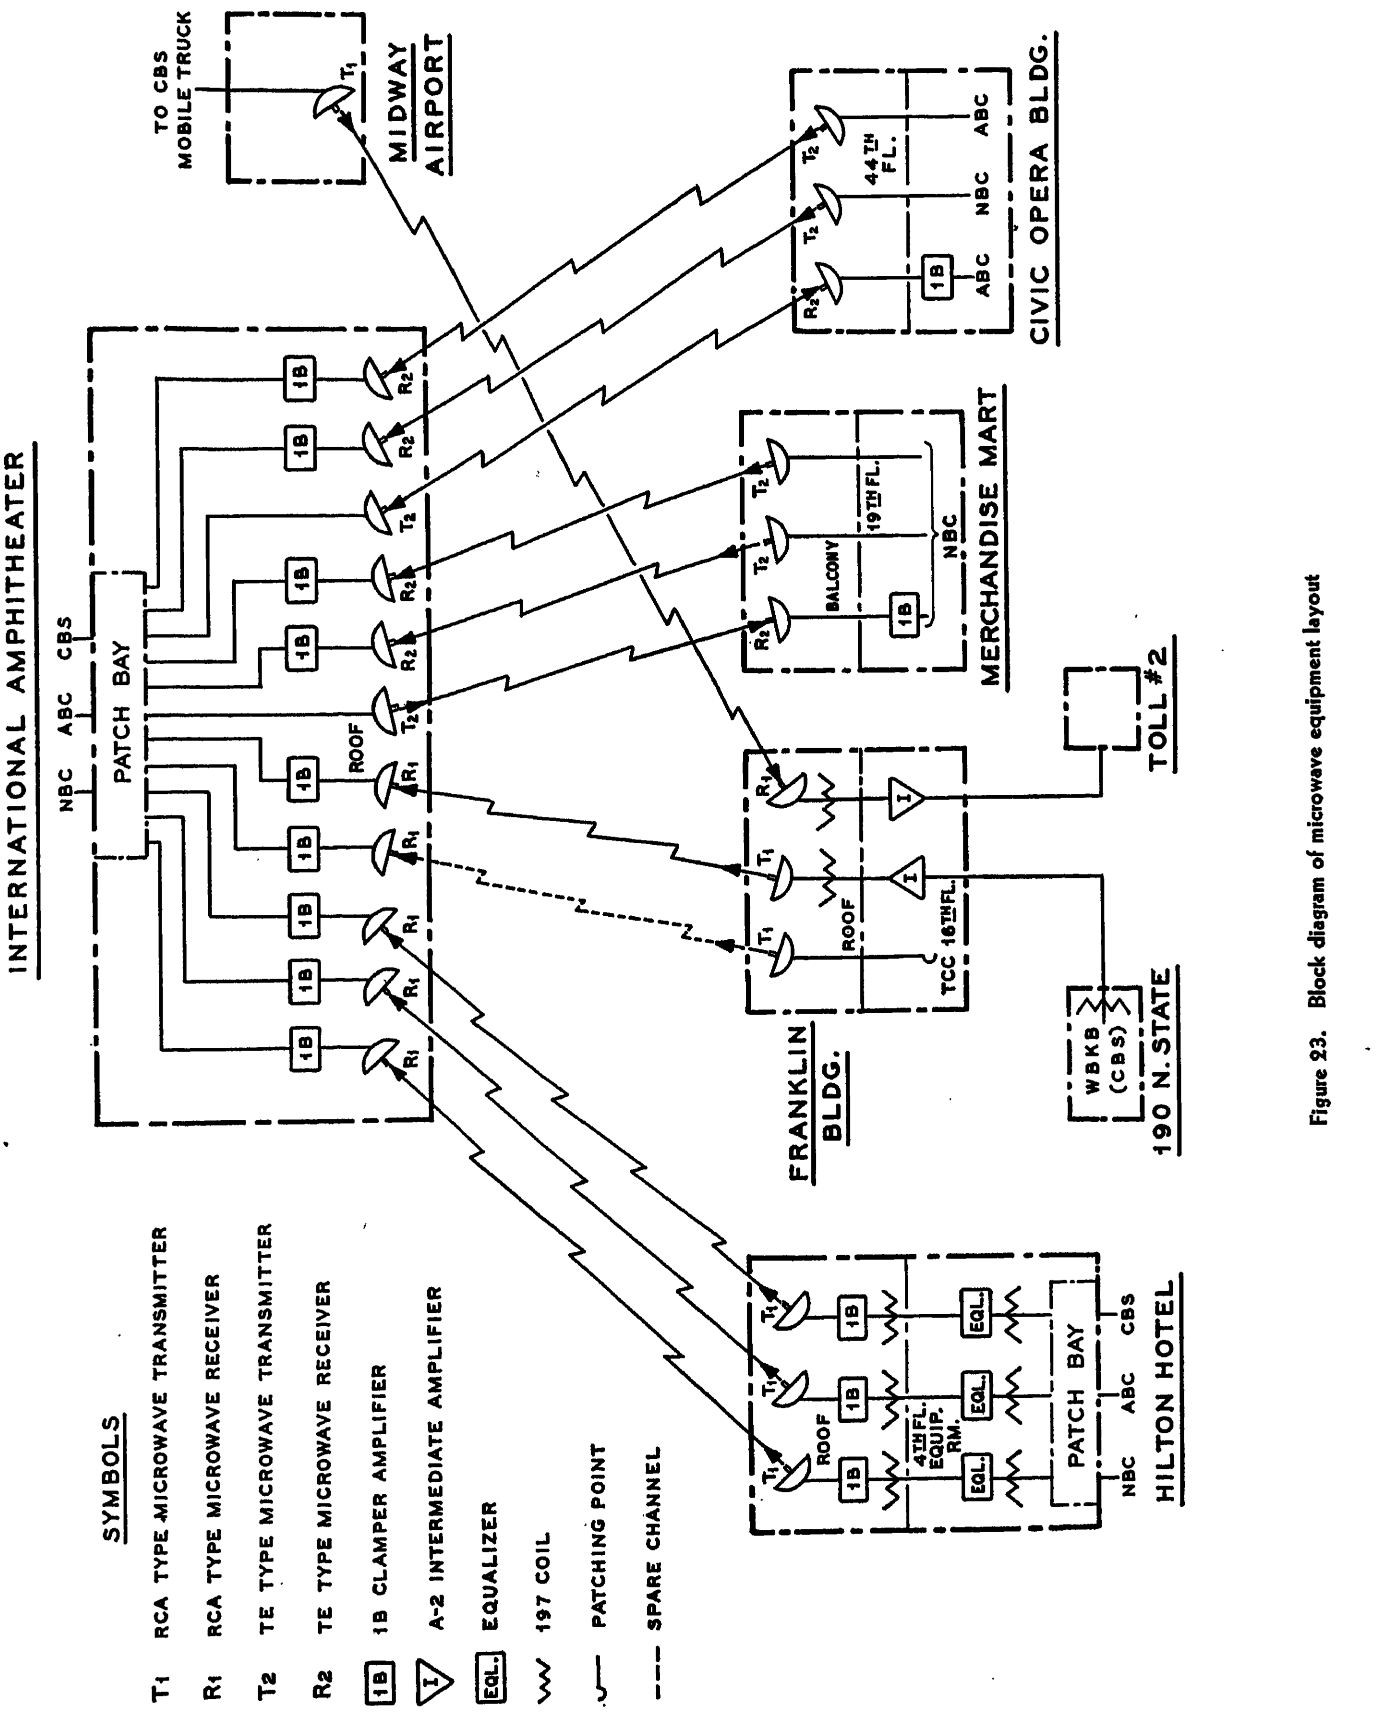

Figure 23. Block diagram of microwave equipment layout

2. The Civic Opera Building (ABC and NBC microwave channels).

3. Merchandise Mart (NBC microwave channels).

4. Hilton Hotel (microwave and wire channels).

The International Amphitheatre, where 11 microwave channels and eight wire channels would originate and terminate, imposed the most unusual requirements. Here it was necessary to secure space for 11 microwave equipments on the roof, space for associated control equipment within a distance of 200 feet of the roof, and finally space for amplifiers and other equipment for the wire channels. Surveys were conducted to determine what location on the Amphitheatre roof would provide line of sight coverage to each of the locations in the Loop area requiring a microwave channel. Based upon these surveys, which in some instances required microwave path clearance tests, the northwest penthouse roof of the Amphitheatre was selected. This afforded sufficient space for 11 equipments and provided the necessary clearance to each of the loop locations. Due to the fact that different types of equipment would be used, each requiring somewhat different mounting arrangements, a special platform was constructed for this roof location. See Figures 13, 14, and 15. Three TE equipments had mounting details for portable towers and hence required that a vertical frame be constructed. The other TE's and the RCA equipment were mounted both on the main platform level and a second level above this, providing clearance for the parabolas.

It will be noted that a special shack was constructed atop the platform. This was intended both for storage of test equipment and for installation of one of the TE microwave control and radio-frequency (r-f) units.

The earlier type TE transmitters were so constructed that the length of cable connecting the r-f to the control equipment was limited to 10 feet. Since one of these units was employed, it was necessary to place the control equipment in close proximity to the r-f equipment. However, because it was inconvenient to construct a shack close enough to the r-f equipment to permit use of such a short interconnection, the r-f equipment was separated from the antenna using transducers and coaxial cable, thus permitting an additional 30 feet of separation. See Figures 13 and 15.

The location for associated microwave control equipment also had to be satisfactory for locating the amplifying equipment for the eight wire channels. This then would permit one centralized location within the Amphitheatre where complete control could be obtained over the 19 video channels. The location selected was a large room immediately below the microwave roof location. Figure 16 shows a block diagram of the equipment layout in the room. The microwave equipment was divided so that the TE equipment was located on one side and the RCA on an adjacent side.

Each oscilloscope was associated with an RCA microwave receiver output, see Figure 17. Portable scopes not shown in the diagram were used for connection as required to the TE outputs. The *197* coils used for the wire circuits were mounted on a patch bay; see Figure 12. This patch bay was the central control point for all of our channels at the Amphitheatre. Electrically, it was located between the broadcasters' and our equipment and was designed primarily to permit a rapid switching of circuits or equipment in the event of trouble or changes in requirements. Twenty-five flexible coaxial leads were used to connect the various broadcasters' master control rooms on the second floor to this bay. The input and output of all equipment located in the room was connected to the patch bay with provision for monitoring at every point. This facilitated quick isolation of trouble.

At the Merchandise Mart, Figure 19, a special platform was constructed incorporating the same features for mounting the TE equipment as those used at the Amphitheatre. TE equipment was assigned inasmuch as the broadcaster used RCA equipment at this location which operated adjacent to our RCA band. It was felt that our use of RCA equipment might result in the introduction of mutual interference, especially during periods of tuning when high modulation levels were employed.

A power and ventilation room, Figure 20, immediately north of the platform was used to house the control equipment. From this location, coaxial cable was run to the *WNBQ* studios located on the floor below.

Three TE equipments were chosen for installation at the Civic Opera Building, Figure 21, for reasons outlined previously. Because of the substantial parapet height, a special raised platform was wedged between the 44th floor parapet wall and the building to provide equipment mounting space with sufficient clearance for the parabolas.

The control equipment was installed on the 45th floor just 150 feet north of this location. From this point connection was established to the studios of *WENR-TV* and the transmitter of *WNBQ* using short lengths of coaxial cable to the 44th floor and 42nd floor respectively.

The southernmost portion of the promenade roof on the 21st floor of the Hilton Hotel, Figure 22, was selected as a location for three RCA microwave equipments. A platform was erected to provide parapet clearance for the parabolas. A room just beneath the roof was selected to house the associated microwave control equipment. Since a substantial number of wire and radio channels originated and terminated here, the need for a control location was indicated. Therefore, the telephone equipment room on the 4th floor, Figure 3, was selected for installation of a patch bay. A balanced cable was employed between the equipment room and the roof location to provide a connection to the microwave equipment. Short lengths of coaxial cable were run from the patch bay to various broadcaster locations in the 4th floor and 5th floor.

PERSONNEL

The quantity of equipment planned for use during the political conventions required an increase in the number of personnel employed for television maintenance and installation. The normal force of 15 men was increased to 45 during this period with a proportionate increase in supervision. Because most of these new personnel had no previous television background it was necessary to establish a training course to include both theoretical and practical aspects of television installation and maintenance. This training period was begun some 2 months prior to the convention and was of approximately 4 weeks' duration. This permitted all personnel to have some practical training on the equipment before the convention started.

Design

The description given in the preceding paragraphs generally applied to preparatory work such as cable installation, equipment design, and so forth, based on estimates of circuit requirements received from the broadcasters. As actual orders for the channels were received, detailed circuit design was begun. Figures 1 and 23 depict the final layout for both microwave and wire channels. It should be emphasized that only channels ordered specifically for the convention are included in these layouts. Thus Figure 1 does not include, for purposes of simplicity, all of the channels available to each broadcaster which were in regular use during the convention period. This would include, for instance, in the case of *WNBQ*, six additional video channels from the Merchandise Mart used for regular network loops, remote studio pickups, and studio transmitter links, and in the case of other broadcasters a proportionate number of similar channels. Microwave facilities in normal use are also not included. As is evident, wire facilities extending to the Amphitheatre all employed equipment for transmission from this location. This was done to facilitate quick rearrangement of channels in the event of trouble and to simplify equalization and maintenance problems.

In addition, it was desired that each network feed from the Amphitheatre be provided with uniform facilities.

An extremely important consideration in establishing both wire and microwave channels was the provision of spare facilities. The quantity of channels which would be used during the convention was unprecedented in our previous experience and indicated that spare facilities should be available wherever possible. (These facilities were employed for our own use, however, and were not assigned to any particular broadcaster.) A study of Figures 1 and 23 will indicate that spare facilities were available in both directions between the Amphitheatre and Toll Number 2, between the Hilton Hotel and the Television Control Center in one direction, and between the Civic Opera Building (either ABC or NBC) and the Television Control Center in one direction. Additional facilities were available between the TCC and Toll Number 2 in both directions. Not included in the attached drawings are channels available from the TCC to each broadcaster for normal program use which could be used as additional paths during the convention period. Spare channels were equalized to each patch point so that many channel rearrangements were possible in the event of a failure of a particular section. To give an example, if one of the microwave circuits failed between the Hilton Hotel and the Amphitheatre, a spare wire channel between the Hilton Hotel and the TCC could be patched to a spare microwave channel between the TCC and the Amphitheatre to re-establish the circuit. This could be done in a matter of seconds in the event of a failure.

All channels, however, were not provided with spare facilities as is evident in Figures 1 and 23. The cost incurred in providing a complete spare system would be prohibitive and could not be justified on the basis of future usage.

MICROWAVE CHANNELS

Several problems were presented in the design of the microwave channels. In regard to the use of frequencies for operation of the RCA microwave units, our license permitted the use of only three frequencies for broadcast pickup purposes. Since five RCA units were planned for use on essentially parallel air paths to the Amphitheatre and others were in use on air paths likely to present interference problems, special temporary authority was obtained from the Federal Communications Commission to use frequencies licensed for closed channel operation (Theater TV). To reduce further the possibilities of mutual interference on adjacent channels operating over these parallel air paths, special twisted wave guide feeds were employed to rotate the polarization of the microwave energy by 90 degrees; see Figure 15, upper left. This virtually eliminated coupling with other units operating with normal polarization. These feeds were employed on equipment on the center frequency of the broadcast microwave band and on one of the low-band (Theater TV) frequencies. They were particularly useful during line-up periods when modulation levels were somewhat higher than normal.

Our TE equipment license permitted operation in the 3,700 to 4,200-megacycle band. This apparently large band available for selection of six channels of 20 megacycles width was limited by a number of factors. First of all, the transcontinental *TD2* microwave system extending east to New York and west to San Francisco employed frequencies in this range. The Loop buildings on which the TE microwave equipments were located were in proximity to the *TD2* antennas on the Toll Number 2 office. Since the orientation of the TE antennas was similar to that of the *TD* antennas, mutual cross-channel interference would result if common frequencies were employed. This limitation was further aggravated by the transmitter Klystrons used for the TE equipment. Only two of the six TE type equipments had transmitter Klystron tube mounts which permitted the use of a tube, recently made available, which would cover the entire 3,700 to 4,200-megacycle band. The old-type Klystron covered the range of 3,900 to 4,200 megacycles. Finally, only two of the microwave receivers contained wave guide filters which would suppress image frequencies. By the time we were able to squeeze a total of 120 useful megacycles out of this 500-megacycle band we felt very sympathetic to the Federal Communications Commission's problem in allocating frequencies.

It will be noticed in Figure 16 that a *1B* clamper amplifier was connected to the output of each microwave receiver at the Amphitheatre. Each unit performed two functions: first, to reinsert the d-c level before distributing the signal to the broadcaster; second, to permit an increase in level in the event of a decrease in the signal strength in some portion of the microwave circuit. The latter was necessary since even with optimum modulation the maximum output of the RCA or TE receiver into coaxial cable is approximately 1.5 volts peak to peak. The standard level used during the convention period in all broadcaster connections was 1.4 volts peak to peak resulting in what was thought to be a low gain margin.

WIRE CHANNELS

Little trouble was experienced in establishing wire line channels employing *A-2* amplifiers and other equipment which had been in use for some time. However, the new *A-2X* amplifier installations introduced many problems not encountered in preliminary development work. One involved the reduction of feedback between various points in the 85-decibel amplifier. This was solved by increased spacing between input and output leads, and by redesigning patch points and equipment bay wiring.

Another problem resulted from an attempt to equalize the six video wire channels extending from Wabash central office through Amplifier Station Number 1 to the Amphitheatre. To explain this problem additional *A-2* amplifier characteristics will be discussed. The *A-2* system originally was designed for a maximum equalization of 65 decibels due to the gain limitations of the associated amplifier equipment, that is, the equalizer inserts a frequency selective loss which makes the over-all loss of the cable plus equalizer uniform. This loss then must be made up by flat gain amplifying equipment to sustain the transmission level of a video signal. This 65-decibel limit postulates the use of a certain number of equalizers which are, within limits, not frequency selective below 10 kc. The cable attenuation loss, which increases with frequency when added to the reflection loss of the line which decreases with frequency, produces an approximately uniform response below 10 kc. Reflection loss arises from the fact that the source and terminating impedance of the *A-2* amplifier is 110 ohms, differing markedly from the characteristic impedance of the PSV cable below 10 kc. (As frequency increases the characteristic impedance of the cable starts from a large value with a highly reactive component and approaches a purely resistive value of 120 ohms.) The response, however, is not sufficiently uniform, requiring that each equalizer incorporate a slight correction. These corrections add to the proper value for 65 decibels or less but, with the large number of equalizers used in an 85-decibel line, an overcorrection results, producing a low frequency slope. All of the lines established through the repeater hut required the use of special equalizers to correct this low frequency slope loss.

Operation

Most troubles occurring during the period of both conventions were of an ordinary nature such as vacuum-tube failures, power failure, and the like. However, one particularly aggravating trouble involved equipment grounding at the Amphitheatre. This was evidenced as a 60-cycle signal superimposed upon the video signal and was objectionable only in so far as additional equipment was required. However, considerable apprehension was felt lest the interference become great enough to affect proper clamping. Without going into the many details of time-consuming efforts used to reduce this interference, it is sufficient to say that the trouble arose because of the differences in ground potentials between our location and the broadcasters' location. It does seem imperative in the future that installations of this kind should be planned in advance by the various organizations concerned and that methods of establishing a suitable ground system be agreed upon.

During the convention period a number of requests were received for channels to miscellaneous locations such as the Municipal Airport, hotels, depots, and so forth, with very little advance notice, requiring close co-ordination of commercial, engineering, and installation departments. In one instance, a request was received one evening for a circuit from the airport for the pickup of the arrival of President Truman's plane, the *Independence*. A circuit to this location had been established previously on several occasions using microwave equipment. However, recent construction work on a new hanger on the airport grounds had blocked the normal microwave path to the Loop area. Therefore, a new route had to be cleared quickly. The mobile television truck was maneuvered to a point on the field where a line of sight path was available and the microwave equipment was placed on the top of the truck. Transmission was good but was subject to interruptions by planes taxiing across the path. A conference with ground crew officials at the airport assured us that the path would be kept clear even though it meant some last-minute changes in their plans for "spotting" the *Independence*.

During the conventions, all responsible groups were organized to take instant action to minimize service outages which would naturally eventuate from the use of so much electronic equipment. However, months of preparation, planning, and training permitted us to reduce these outages to an almost negligible value. Of approximately 400 channel hours of program time which were provided to telecasters, only $9^{3}/_{4}$ minutes were lost, a percentage of 0.04. Program time is defined in terms of intervals during which the channel intelligence is actually being telecast. This does not include lost channel time, another index used to gauge our performance, which included failures occurring during the period the channels are ordered by the customer for line-up or stand-by regardless of telecast. This amounted to some 10 hours of a 4,000-hour total. Nevertheless, judging by public reaction to the national conventions there were some viewers who might have preferred to see a less impressive record.

Capacitors in Power Systems with Rectifier Loads

A. SCHMIDT, JR.
FELLOW AIEE

STATIC capacitors have come into widespread use as an efficient and economical source of reactive power for a-c systems. Harmonic voltages are sometimes a problem when applying capacitors to a system.

Years ago the principal sources of system harmonics were rotating machines and transformers. More recently, the widespread application of apparatus taking nonsinusoidal current, particularly mercury-arc rectifiers, has introduced other sources of system harmonics. These harmonics often require consideration when rectifiers and capacitors are connected to the same system.

Equivalent Circuit

If the voltage of a generator has a harmonic content of appreciable magnitude and if a capacitor and parallel inductance are connected to the generator, having equal impedances at one of the harmonic frequencies, harmonic currents of considerable magnitude will appear in the capacitor. Now consider the case of a harmonic-free generator connected to devices which take nonsinusoidal current from the generator. Such devices include rectifiers, transformers (whose magnetizing current is nonsinusoidal), certain types of electronic welding equipment, apparatus controlled by saturable reactors, and so forth.

Treatment of such circuits is facilitated by considering the devices as harmonic generators which deliver into the system the same harmonic currents which are normally taken from the system by the devices in question. This procedure will yield results in circuit problems which in many cases are only approximations, because the harmonic voltages resulting from the circuit action may react on the pseudoharmonic generator and modify its output.

Figure 1 shows how parallel resonance can occur when capacitors are connected to a system in parallel with a device taking nonsinusoidal currents from the system. Figure 1(A) shows a rectifier connected to a feeder fed by a step-down transformer from a large source. A power factor correcting capacitor is connected to the feeder near the rectifier. Figure 1(B) shows the equivalent diagram. The rectifier is replaced by a constant current harmonic generator having an internal resistance R_0, which is determined by the rating of the rectifier transformer. The feeder and step-down transformer are represented by an equivalent inductance in parallel with the capacitor. If the reactances of the capacitor and the

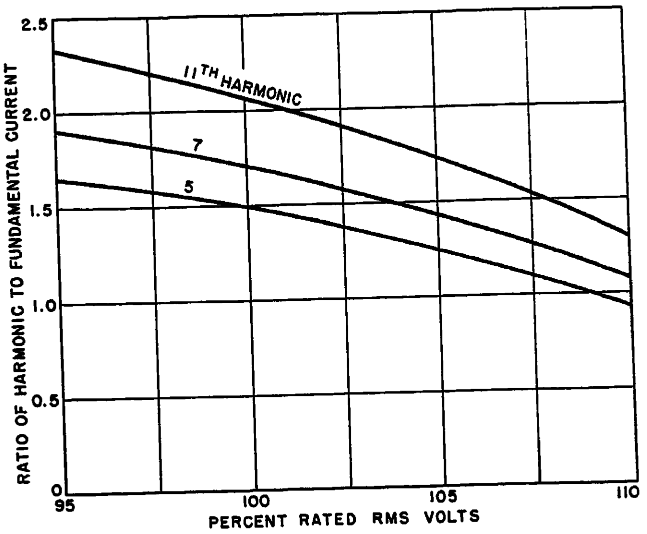

Figure 2. Harmonic current capabilities of capacitors with a single harmonic present

inductance are nearly equal at one of the frequencies of the harmonic generator, the currents in the capacitor and in the line will be substantially higher than the current delivered by the harmonic generator. The harmonic current may be high enough to damage the capacitor. There will be a high harmonic voltage on the feeder. This may cause local telephone interference. It may also increase heating of rotating machines on the system.

Rating of Capacitors

It is common practice to build power factor correcting capacitors with a kilovar capability which is 135 per cent of the name-plate rating with sinusoidal applied voltage. This permits a theoretical sustained overvoltage of 16 per cent without damage to the capacitor and constitutes a safety factor to provide for high line voltage and/or the presence of system harmonic voltages. Since harmonic voltages are present in any practical system, industry practice has been established which limits permissible maximum capacitor voltage to 110 per cent of rated voltage.

If the line voltage is maintained at rated value, the capacitor is able to handle harmonic currents of considerable magnitude. because the kilovolt-amperes due to harmonic current of a specified value are considerably less than the fundamental kilovars. For instance, a 7th harmonic current of 150 per cent of the rated fundamental current will result in a 7th harmonic voltage which is 21.4 per cent of the fundamental rating and 7th harmonic kilovolt-amperes of 32 per cent of the capacitor kilovolt-ampere rating. If there is no other harmonic present, the capacitor will be loaded to 132 per cent of its name-plate kilovolt-ampere rating even though the effective current is 180 per cent of the rated fundamental current.

Figure 2 shows the harmonic current capabilities of a capacitor which is loaded to 135 per cent of its kilovar rating, and shows how these capabilities are reduced when the fundamental voltage exceeds the rated value. If the total capacitor kilovolt-ampere due to the fundamental and harmonic current present in the capacitor exceed 135 per cent of the capacitor rating overheating and premature failure of the capacitor will result.

When capacitors are provided with protective devices, these devices normally respond to effective current. Thus, the capacitors may be removed from the circuit due to indication of overload, although actual overload may not be present.

A-C Harmonics in Rectifier Circuits

Figure 3 shows the form of the anode current in a 6-phase double-Y rectifier. The transformer primary current will consist of two such waves which have opposite polarity and are displaced 180 degrees. The latter current contains harmonics having orders of $6n \pm 1$, where n is any integer. If two or more 6-phase rectifiers are combined so that there are q phases, then the resulting harmonics in the a-c system have the orders of $qn \pm 1$.

Figure 4 shows the magnitude of the lower harmonics of a 6-phase rectifier as a function of the commutating angle u. The relation between commutating angle and commutating reactance is also shown. For a constant value of commutating angle, the magnitude of the harmonic is independent of the amount of phase control for values of over about 5 per cent.

The curves in Figure 4 are derived by rectifier circuit analysis, using standard conditions.[1] When capacitors which produce resonant conditions are introduced into the circuit, rigorous analysis is no longer practicable. Since it is convenient to use the concept of a harmonic generator in place of the rectifier, early investigators[2] working on interference problems employed a fictitious resistor in series with the pseudoharmonic current generator and then hypothesized a harmonic voltage generator having voltages which would deliver the currents in Figure 4 into the fictitious resistor. An empirically determined value for R_0 of $R_0 = \frac{1}{9} \frac{\text{transformer kilovolt-amperes}}{(\text{line amperes})^2}$ was found to give good agreement between observed data and calculations made according to this procedure when complex a-c networks were dealt with.

Remedial Measures

Because of the low amplitude of the higher order rectifier harmonics, capacitor overloading due to parallel resonance is unlikely if the kilovars of installed capacitors are less than about 1/2 of 1 per cent of the system short-circuit kilovolt-ampere at the point of installation. The possibility of telephone interference is present in this and smaller installations, and a survey is advisable when capacitors and rectifiers both having large kilovolt-ampere ratings are to be located in proximity to each other. If parallel resonance

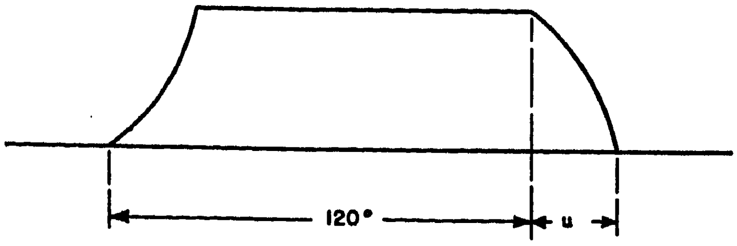

Figure 3 (above). Anode current of 6-phase double-Y rectifier

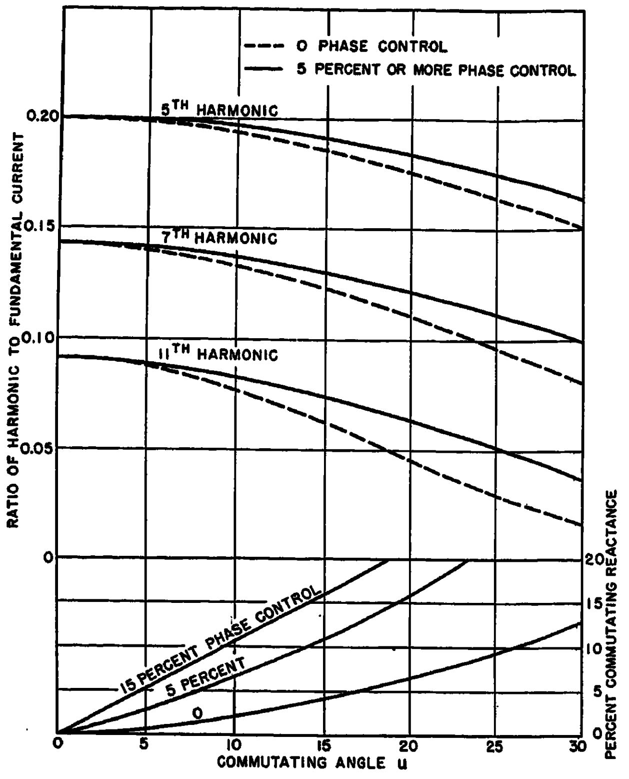

Figure 4 (right). Low order harmonic currents in 6-phase rectifier

is present, one of the following remedial measures may be employed:

1. If trouble is confined to a single frequency, all or a portion of the capacitors may be tuned with series inductance so that they constitute a low impedance shunt across the system at the frequency in question. This shunt will then accept practically all the harmonic current due to the rectifier at the resonant frequency, with a resulting system harmonic voltage determined by the impedance of the tuned shunt, which is low compared with the impedance of the capacitors. This is similar to the practice of using tuned shunts across a-c systems when rectifiers produce telephone interference due to the action between the harmonic currents generated by the rectifiers and the inductive impedance of the supply system. In such cases, shunts tuned to a number of the troublesome frequencies are connected across each phase of the supply system.

When a tuned shunt is employed, the harmonic current in the capacitor will be less than in the case of parallel resonance. Even so, it is possible to overload the capacitors in a tuned shunt, particularly when there are other sources of harmonic current present which add to the rectifier harmonic current. Thus care is needed in designing tuned shunts to assure sufficient capability on the part of the capacitors for all the available harmonic current at the resonant frequency.

If more than one harmonic frequency is present, a single tuned shunt may not eliminate harmonic troubles. The impedance of the tuned shunt will be inductive at frequencies higher than that for which the shunt is tuned. If all the capacitors are not used for this shunt, the remainder of the capacitors will be in resonance with a new value of inductive impedance at some higher frequency and difficulty may continue.

2. If series reactors are connected to all the capacitors to resonate at a frequency lower than any harmonic due to the rectifiers, then the series combination will be inductive at all frequencies due to the rectifiers and no resonant condition can exist between the capacitors and the system.

Any tuning arrangement will increase the fundamental voltage across the capacitors. For instance, in applying the foregoing scheme, if the lowest harmonic frequency in the system is the 5th, and the capacitors are tuned to the 4th harmonic, the resulting fundamental voltage across the capacitors will be increased from 100 per cent to 106.3 per cent of the line voltage. There will also be some 5th harmonic current since the tuned capacitors and the system will divide the 5th harmonic current in inverse proportion to their impedances at this frequency. The use of any tuning scheme therefore requires examination of the increase in capacitor loading.

In occasional applications, the need for series reactors with the capacitors may be anticipated. In such cases the capacitor designer can provide the higher voltage rating which is needed.

3. Sometimes resonance conditions occur under circumstances where no interference results and where the capacitors are not overloaded, but the capacitor fuses or other protective devices open the capacitor circuit because of the high effective current. In such cases, the level of current protection may be raised if it can be established that the total kilovolt-amperes permitted in the capacitors are within their rating.

In the majority of cases, capacitor protection is provided by fuses. These perform two functions: overload protection, and fault protection. In cases of a capacitor fault, the fuse should open before the capacitor case bursts. Co-ordination of fuse opening time and capacitor bursting time under fault conditions will establish the maximum fuse rating that may be used.

Case Histories

1. A 300-kw 6-phase rectifier was connected to a high-voltage system through a step-down transformer and a 4,000-volt overhead line approximately 4 miles in length. To correct the power factor of the load at the rectifier location, a 135-kilovar power factor correcting capacitor bank was connected to the 4,000-volt line near the rectifier.

During operation of the rectifier, there was frequent blowing of the fuses connected in series with the capacitors. Serious telephone interference was experienced. Analysis of the system indicated that the reactance of the step-down transformer and overhead line was approximately equal to the reactance of the capacitors at the 6th harmonic. The capacitors were sectionalized and inductances were connected in series with them to form 5th and 7th harmonic traps. Telephone interference and the blowing of fuses ceased.

2. Power factor correcting capacitors totaling 2,340 kilovars were located near an electrochemical installation having 4,300 kva of 6-phase rectifiers. Very serious telephone interference was experienced, centering about the 11th harmonic. Analysis of system impedance

indicated parallel resonance between the capacitors and the system in the neighborhood of the 11th harmonic. When the capacitors were disconnected, the harmonic voltages resulting from rectifier action became normal.

The capacitors were split into two sections. One was tuned to the 12th harmonic with a series reactor and the other to the 18th harmonic. The resulting combination provided low impedance shunts across the system to the 11th, 13th, 17th, and 19th harmonics, and reduced telephone noise to an acceptable value.

3. A 5,000 kw 12-phase rectifier installation was operated with a 1,125-kilovar capacitor installation in the vicinity. Serious telephone interference was experienced. The capacitors were fused at 1.8 times their rating and the fuses were often blown.

Investigation showed that the capacitors were in resonance with the system at a frequency slightly below the 11th harmonic. The 11th harmonic current in the capacitors was found to be substantially greater than the fundamental current and many times the 11th harmonic current in the rectifier supply, showing the effect of parallel resonance. Operation of the system with the rectifiers disconnected demonstrated that the rectifiers were the source of the 11th harmonic. Thus, tuning of the capacitors to the 11th harmonic could be depended on to reduce telephone interference to an acceptable level and to prevent blowing of capacitor fuses due to parallel resonance between the capacitors and the system.

4. Instances have arisen in large electrochemical installations with power factor correcting capacitors where unbalance is present between rectifiers. Such installations are generally arranged for 36 to 72-phase operation and no low frequency harmonics are present in the line current to the rectifiers if all the rectifiers share load equally. However, some 5th or 7th harmonic voltage is usually present because of action between transformer magnetizing current and system impedance. The presence of capacitors is likely to increase the system impedance and thus accentuate this action.

Thirty-six-phase operation of a large rectifier installation is obtained by connecting some of the rectifier transformers to the system through phase-shifting autotransformers. This causes the harmonic voltages to have a different phase relation to the fundamental in each rectifier. The output voltage of a rectifier is determined by the average voltage of an anode during its conducting period. If a harmonic voltage of the nth order is present, it will affect the average anode voltage unless the conducting period is an exact multiple of $360/n$ degrees, which is normally not the case. Furthermore, the phase angle of the harmonic voltage will influence the commutating angle, which in turn will affect the output voltage.

Thus, the presence of harmonic voltage will cause unbalanced load among the rectifiers. This in turn will increase the low frequency harmonic currents in the system so that a cumulative effect is produced with large resultant unbalance in load. This can be overcome by the use of phase retard on some of the rectifiers. This is objectionable because of increased commutating duty on these rectifiers. Tuning of the capacitors to a suitable frequency would limit the harmonic voltage and reduce unbalance.

Conclusions

Parallel-type resonance between capacitors and system reactance in the presence of harmonic sources such as power rectifiers may cause:

1. Overloading of capacitors, particularly if installed kilovars are much in excess of 1/2 of 1 per cent of system short-circuit kilovolt-amperes.
2. Operation of capacitor overcurrent protective devices.
3. Telephone interference.

These conditions can be remedied by the connection of suitable reactors in series with the capacitors when the voltage rating of the capacitors is not exceeded by so doing.

A Subscriber Toll Dialing Tape Reader

W. H. BLASHFIELD
MEMBER AIEE

Synopsis: Low cost machine scans punched tape produced by customer-dialed long-distance calls and prints a ticket or punches a card for each call. Process includes automatic rate selection and charge computation.

TO IMPROVE service and avoid the unprofitable manual handling of short-haul toll calls, systems have been developed which enable the telephone user to dial numbers in nearby towns. In one such system, intended for small independent offices and described in an earlier paper,[1] the call record is a punched tape as illustrated in Figure 1. Because the tape is not easy to read by eye, an automatic "reader" is needed to present the information in a form more suitable for the telephone company's billing department.

Several factors are involved in choosing the type of presentation. For the small company, simple and inexpensive equipment is the first consideration. For larger companies, a record permitting efficient handling of a large volume of business is important. In any company, the presence of operator-written toll tickets makes it desirable that the tape-reader record be capable of being handled in the same manner as the written tickets.

The availability of an inexpensive printer resulted in the development of a reader producing printed tickets. The tickets are the same size as standard toll

---

Paper 53-112, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted November 5, 1952; made available for printing December 5, 1952.

W. H. BLASHFIELD is with the North Electric Manufacturing Company, Galion, Ohio.

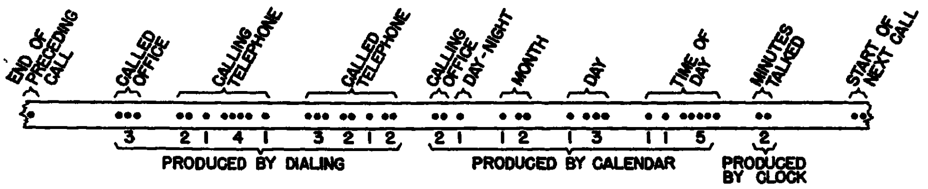

Figure 1. Punched tape. Called office and day-night entries are sometimes omitted

tickets, permitting them to be sorted and handled together with operator-written tickets. Furthermore, the electrical operation of the printer is similar to that of business-machine card punches, so that a standard card punch can be substituted for the printer if a company's volume of business is sufficient to warrant punched-card accounting.

The reader is shown in Figure 2, and a printed ticket in Figure 3. The punched black paper tape is received from the recording equipment on 8-millimeter movie reels, and is run through the reader backwards to avoid rereeling. A motor drives the tape past a phototube scanning unit which operates relay circuits that analyze the information and actuate the printer. Approximately 45 minutes are required to print tickets for one reel of tape carrying about 300 telephone calls.

The reader not only prints the information found on the tape but also computes and prints the charge for each call. If toll dialing is provided between two towns only, all calls take the same rate and computation is relatively simple. If a number of towns are involved in a dialing network, however, calls among several offices may appear on the same tape, requiring the reader to recognize the offices, choose the appropriate rate, and compute the charge based on that rate.

Because of the differences in scope of computation, two types of readers are made, one for the simple single-rate situation, and the other arranged for automatic rate selection. The simpler type contains about 10 tubes and 50 relays, the more elaborate version requires twice as many relays. The latter type will be described here.

Tape Information

To place an interexchange call, the subscriber dials an office code for the town he wishes to reach, then dials his own telephone number, and then dials the desired telephone in the distant office.

Office codes may be one or two digits, depending on the number of offices and arrangement of trunks in the network. With a 2-digit code, the first digit selects a tape recorder, and the second digit selects the desired office and also is punched on the tape to record the identity of that office. For example, if the subscriber dials office code *83*, the *3* is the first information on the tape, as illustrated in Figure 1.

The tape recorder consists of a punch magnet driven directly by dial impulses and a step magnet to step the tape each time it is punched. The step magnet can also be operated independently to provide separation between digits and numbers.

After the office code, the dialing of the subscriber's own number is recorded, followed by the dialing of the called number. (The customer is requested to dial his own number in order to avoid the complex and costly equipment that would be required to locate and record that number automatically. A simple circuit compares the number dialed with the calling line to insure that the calling number is dialed correctly.)

When the call is answered, the recorder engages a calendar, which punched a digit identifying the originating office, followed by a day-night digit indicating weekday or night-Sunday-holiday. Then comes the month, day, and time of day. (Time of day is in hour and tenth; thus *115* is 11:30 A.M.) Following the calendar information, a clock punches the tape once a minute to record the duration of conversation.

The day-night digit (*2* for weekday, *1* for night-Sunday-holiday) tells the reader whether day or night rates apply, night rates in telephone parlance being effective every night and also all day on Sundays and holidays. The calendar can supply day-night information to the tape rather easily, whereas it would be difficult for the reader to recognize Sundays and holidays from the date alone, although such readers have been built (Figure 2 is an example). As differentials between day and night rates usually exist only for distances greater than 40 or 50 miles, the day-night digit is omitted in many installations.

The called office digit also is absent in systems using single-digit office codes. This does not produce an ambiguous record, for in a single-digit system the recorders will be located in trunks directly connecting two offices, so that the calling office code punched by the calender is sufficient to identify both offices.

Ticket Information

The ticket of Figure 3 corresponds to the tape of Figure 1. Ticket information differs from the tape in that

1. the charge is computed and printed;
2. an *8* (or other appropriate digit) preceeds the calling and called office digits to produce the complete office codes;

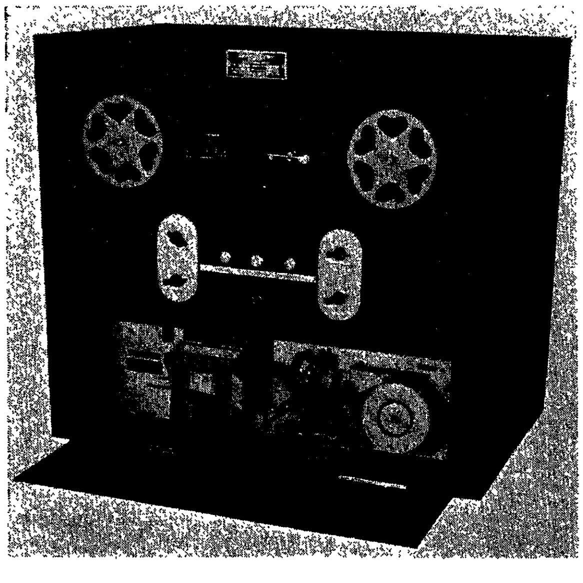

Figure 2 (left). Front view of tape reader with hinged bottom panel open to show printer

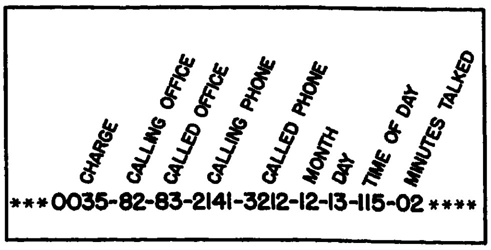
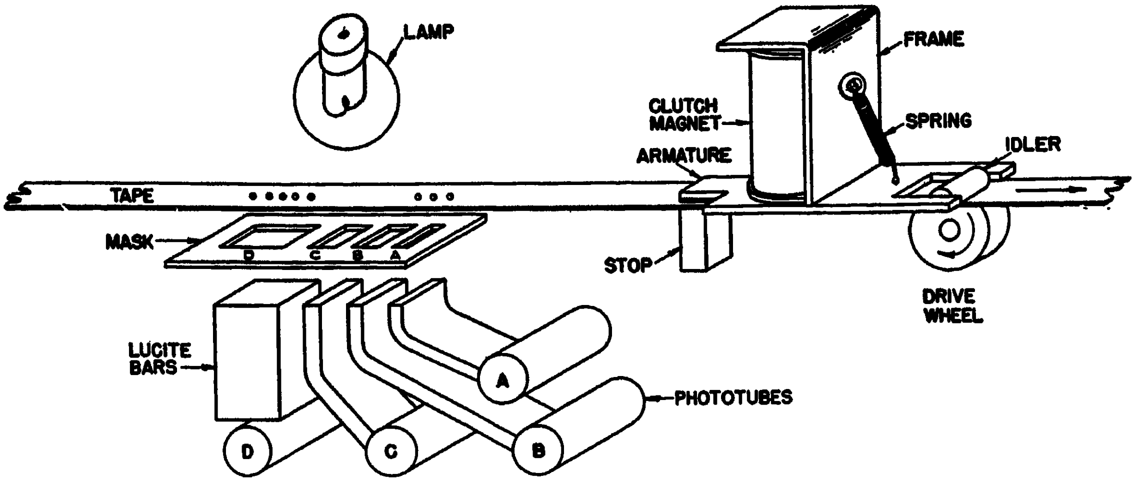


0035-82-83-2141-3212-12-13-115-02*

Figure 3 (right). Printed ticket

Figure 4. Scanner and tape drive principles



3. the calling office code is shifted to a position near the beginning of the ticket; and
4. the day-night digit is not printed.

The position of the calling office code is changed simply to make the ticket easier to read. The day-night digit is not printed because it only supplies information to the reader and would serve no useful purpose on the ticket. The charge appears at the beginning of the ticket because that is actually the end of the printed information with the tape and printer running backwards.

Ticket Printer

The printer is a *JP-2* Message Ticketer manufactured by the Teletype Corporation of Chicago, Ill.[2] A type wheel carrying the ten digits and dash and star is rotated continuously by a motor and friction clutch. On the same shaft is a pair of brushes rotating over a stationary commutator on which each segment corresponds to a character on the type wheel. If voltage is applied to a segment, a print magnet is energized when the brush reaches that segment, forcing the paper against the character on the type wheel. When the print magnet is released by deenergizing the commutator segment, a ratchet mechanism steps the paper ahead. The paper is on a continuous roll, and is cut into tickets by a magnetically operated knife.

Because the paper can be stepped only by operating the print magnet, dashes are printed to separate different numbers, and stars are printed to build out the ticket to standard toll-ticket length.

Printer operation consists of energizing a lead (commutator segment) corresponding to the digit to be printed; standard card punches are actuated in the same manner. For that reason, circuits designed to control the printer can also be used to produce punched cards.

Tape Scanner

Reader operation consists basically of counting each series of holes on the tape and then energizing the printer lead corresponding to the digit counted. Series of holes are recognized by the spaces between them.

Three widths of spaces are used: (1) narrow between digits, (2) medium between numbers, (3) wide between calls. Any space signals the reader to print the digit counted: a medium space indicates that a dash is to be printed in addition to the digit, a wide space indicates the end of the call information.

The scanner and tape drive mechanism are illustrated in Figure 4. The tape rides over a mask containing four slots, lettered *A*, *B*, *C*, and *D*. Lucite bars guide the light from each slot to a corresponding phototube. Narrow slot *A* is used for hole counting, impulses from phototube *A* driving a relay counting chain. Slots *B*, *C*, and *D* are for space recognition, slot *B* being covered by a narrow space, *B* and *C* by a medium space, and slots *B*, *C*, and *D* by a wide space.

A clutch controls the tape drive. When the clutch magnet is energized, the left-hand end of the armature is lifted away from the stop against which it has been holding the tape, and the idler at the opposite end is forced against the continuously rotating drive wheel to drive the tape. After each series of holes scanned, the space covering slot *B* releases the clutch and closes a circuit to print the digit that has been counted. After printing, the counting circuit is reset and the clutch re-energized to start the tape for the next digit.

As mentioned earlier, the tape is scanned backwards to avoid the need for rereeling. Backward operation has the further advantage that incomplete calls can be recognized and ignored.

From the tape of Figure 1, it will be seen that the first information scanned is the minutes of conversation, followed by a medium space. If, however, the called number had been busy or had not answered, no calendar or clock information would have been punched in the tape; then the first thing scanned would have been the last digit of the called number, followed by a narrow space. If the reader sees a narrow space after the first digit scanned, it prints nothing, but simply lets the tape run until the next call is reached.

Block Diagram

Referring to Figure 5, the tape scanner drives the hole counting chain which furnishes information both to the printer

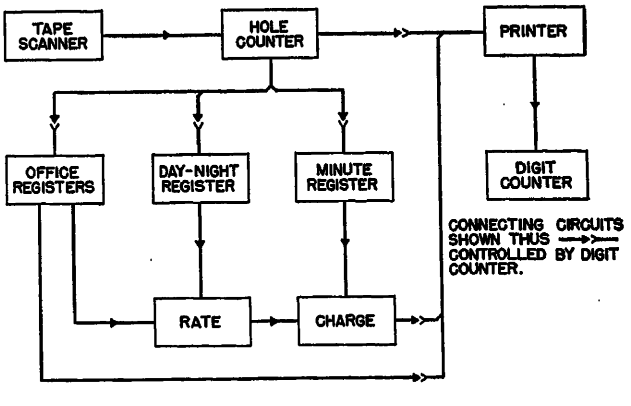


Figure 5. Block diagram of reader

and to the registers which store the figures necessary for charge computation.

The digit counting chain counts each character printed, keeping track of the location of information on the tape and ticket. This chain is driven by contacts on the print magnet and controls the connection of the various registers and printer to the hole counter, determines the number of stars to be printed to reach a standard ticket length, and controls the cut magnet that cuts off the ticket.

As a call starts through the reader, the minutes of conversation are scanned and counted first, and the digit counter energizes both the printer and the minute register. Although the minutes consist of a single series of holes, the counting circuit breaks the information into tens and units digits.

Next the time of day, day, and month are scanned and printed, but not registered. Then the day-night digit and the calling office digit are scanned and registered, but not printed. The digit counter controls the connection of the registers and printer at the proper points. When digits are registered without printing, the registers step the digit counter.

The called and calling telephone numbers are printed, and last comes the called office digit, followed by the wide space marking the end of the call. When that digit has been printed, the reader automatically prefixes an *8* to complete the office code. Then the printer is connected to the office register to print the calling exchange digit which had been stored earlier without printing. Here, again, an *8* or other appropriate digit is automatically prefixed.

At this point the printer is switched to the computer circuit, which delivers the charge for the call. Finally stars are printed until 40 characters are reached to give a standard length ticket.

Computing

As indicated by the block diagram, the combination of offices and the day-night indication determine the rate; then the rate and minutes of conversation are combined to give the charge.

A typical toll rate is "35 cents for 3 minutes, 10 cents each additional minute." Four factors are involved: (1) initial charge, (2) initial period, (3) overtime rate, and (4) overtime period. Another example, differing in all four factors, is "20 cents for 5 minutes, 5 cents each additional 2 minutes."

Charge computation based on such rates involves addition, subtraction, multiplication, and division. Circuits to perform all four arithmetical operations in a universal manner would be quite elaborate, but the amount of equipment can be reduced drastically by taking advantages of limitations in the rate structure.

For example, all rates are multiples of 5 cents. An overtime rate of 20 cents per minute usually applies to distances of about 100 miles, and distances greater than 100 miles are rarely encountered in independent telephone companies. For all practical purposes, therefore, overtime rates can be considered to be 5, 10, 15, and 20 cents. Then overtime charge computation consists of multiplying one of only four numbers (rates) by a 2-digit number (minutes or pairs of minutes). When limited to this extent, multiplication requires relatively little equipment.

Rates are set in the reader by strapping between terminals. Each office combination is represented by a set of four terminals. Another group of terminals represents rates and periods. Each of the four office-combination terminals is strapped to an appropriate rate or period terminal to give the initial period, initial charge, overtime rate, and period for that office combination.

If there is a differential between day and night rates, sets of day-night terminals are interposed in the strapping between the office-combination terminals and the rate-and-period terminals to give different rates for day and night.

The strapped terminals are on a multiconductor plug which fits a permanently wired jack in the back of the reader. Different plugs can be strapped for different rates and office codes; then if a large company has several separate groups of offices, the corresponding rate plug can be inserted in the jack when running tapes from a given group of offices.

Circuit Design

Reliability, simplicity, economy, flexibility, and speed were factors governing the reader circuit design. The importance of reliability and accuracy in a machine producing information for thousands of telephone bills is obvious. Various types of self-checking circuit principles have been employed, and choice of components and circuit values has been very conservative.

After each digit scanned, the tape is stopped until the printer prints; any print failure will leave the machine permanently stopped. Only make contacts appear on register, rate selection, and computing relays, so that failure of any relay will result in an open circuit, breaking the chain of information to the printer and thereby stopping the machine.

Besides open circuits, it is possible that short circuits, crosses, or grounds might occur accidentally. These usually result in the simultaneous energization of two or more print leads. For example, a short circuit or spurious relay operation in the minute register would look like more than one number of minutes, resulting in an attempt to compute two charges and to print two things at once. A trap circuit monitors the printer and stops the reader if two print leads are energized simultaneously.

The positions of the digit counter are compared with the medium spaces on the tape, giving a check both on correct digit counting and on proper number of digits per number on the tape.

Because the spaces on the tape are measured by physical distance (slots *B*, *C* and *D* in Figure 4) rather than by any method involving time, tape speed is unimportant. There is no lower limit on speed, for all tube circuits are direct-coupled and no slow relays are used. At the other extreme, readers are tested for satisfactory operation at 100 holes per second, or twice the normal tape speed.

Electron tubes are long life types operated conservatively, and the number of tubes and tube types has been held to a minimum. The light source is provided with efficient reflector and lens to produce intense illumination at the scanning mask, resulting in more than adequate output from the phototubes without the use of undesirably high load resistors. The black paper cuts off the light completely when spaces in the tape cover the slots.

Relays are standard telephone types of proved reliability in circuits which avoid marginal operations or close timing. Forced-sequence principles are used extensively, each step in the circuit operation depending on, and being initiated by, the completion of a preceding step. This provides maximum reliability, because a failure at any point stops the entire operation; it also gives maximum speed, because operations follow each other at their own inherent speeds rather than being assigned definite times in which to occur.

Simplicity is of great importance in equipment intended for small independent telephone companies, for such companies rarely have skilled men capable of understanding and maintaining complex equipment. Unfortunately, a machine which performs all the functions of the tape reader cannot avoid a certain amount of complexity, but circuits have been kept as straightforward and understandable as possible, and the design has adhered to types of circuits and apparatus which

most apt to be familiar to the average
hone man.

he printer is rugged and quite simple
hanically, permitting adjustment or
ir by a person with no unusual
hanical skill or training. The only
r mechanical parts in the reader are
tape drive motor and clutch.

elays have been used in preference to
tron tubes wherever possible, because
small company telephone man usually
ws nothing about electronics but has
east a speaking acquaintance with re-
circuits as the result of the extensive
of relays in dial switchboards.

bservation and testing are facilitated
test keys. The reader can be made to
1 one digit and stop, print that digit
stop again, and so on, each successive
ration being initiated by the manual
nipulation of a key. This slow-motion
ciple is augmented by a switch to
n off the tape drive motor, permitting
tape to be fed very slowly by hand so
t tube voltages and relay operations
be observed for each hole in the tape.
th these facilities, a case of trouble can
isolated rather quickly and easily.

ow cost is facilitated in both models of
ders by the use of a simple and inex-
sive printer. Furthermore, the single-
e model avoids much of the relay equip-
nt found in the automatic rate-selec-
n model, bringing the cost in range
the smallest telephone companies.

n the single rate reader, the registers
l rate and charge circuits of Figure 5
eliminated, leaving only the tape
nner, printer, and hole and digit
nters. With a single rate, the charge
entirely a function of the number of
nutes talked; consequently the hole
nting relays have contacts wired in
h a manner that when minutes are
nted, the corresponding charge is printed instead of the number of minutes. On the remainder of the ticket, the information is printed in exactly the same form as it is found on the tape. This elimination of all storage and separate computing circuits results in a reader with simple circuits and a minimum of equipment.

The single-rate model is not limited to systems containing only two offices, but rather to systems in which all calls on a given tape take the same rate. For example, a network might contain several towns but have the trunks and recorders arranged in such a manner that a given tape recorder handles calls between only two towns. When running tapes from that recorder, the hole counter in the reader will be wired for the corresponding rate; when running tapes from a different recorder, the hole counter wiring can be changed to a different rate by a multicontact switch or by removing and inserting different multicontact strapped plugs.

High speed of operation is desirable in readers used by larger telephone companies. This is primarily an economic factor, of course; if doubling the speed of the reader more than doubles the cost, it is cheaper to use two slow readers than one fast reader.

Rate of ticket production is determined primarily by the speed of the printer and the speed of counting holes in the tape. The optimum counting rate is about 50 to 75 holes per second; at any lower rate the printer has to wait for the counting, whereas higher counting speed does not appreciably increase ticket production because the printer is unable to go any faster.

For reliable counting at, say, 50 holes per second, the counting circuit should be capable of following 100 holes per second. This is rather fast for conventional relay circuits, yet it was desired to use relays instead of electronic countres for the sake of circuit simplicity and flexibility. If we follow the obvious procedure of operating a relay from phototube A, that relay operating and releasing from every hole in the tape and driving a relay counting chain, we are confronted not only by a problem of speed but by the problem of mechanical wear and contact erosion on the rapidly operating driving relay.

These problems were solved by eliminating the driving relay and developing a relay counting chain driven directly by an electronic circuit. This circuit is essentially a gas tube "flip-flop" controlled by phototube A, with the relay chain advanced one step by each reversal of the flip-flop. This scheme, besides eliminating the speed and wear problems of a driving relay, inherently doubles the speed at which the chain can count and actually increases the speed still further by eliminating problems of pulse ratio, thereby permitting counting at a speed of 100 per second with conventional telephone relays.

The reader normally drives the tape at 50 holes per second, at which speed 350 to 400 tickets per hour are printed, or about 3,000 tickets per 8-hour day. This is adequate for the toll traffic of small- and medium-sized independent telephone companies, and the low cost of the machine permits using two or more readers in companies with larger volumes of business.

Nuclear Power Plant Control Considerations

M. A. SCHULTZ
MEMBER AIEE

THE development procedure for designing the control system for a nuclear power plant is basically the same procedure as for any other type of power plant. The presence of a nuclear reactor as a component in the system imposes many unusual design problems. The purpose of this article is to review general plant considerations affecting control system design, giving special emphasis to the features of reactor control.

The basic method of approach to control system design consists first of studying the plant operational requirements and the plant control requirements. Following this review a preliminary block diagram of a control system to fulfill these requirements may be attempted. However, after a study of this diagram, it often becomes apparent that the inherent dynamics of the plant and the characteristics and limitations of some of its components are of utmost importance. Modifications are then made to the proposed block diagram. Once the desired operation of the control system is fully understood, the problem of synthesizing the control system can begin.

At the present state of the art the problems introduced by the reactor necessitate more study than do the conventional ones. Some literature has been written about reactor control,$^{1-4}$ but very little is available on the control of power plants employing a reactor. An outline of the considerations required before a plant control design can be completed is given here.

Plant Operational Requirements

Certain information must be known concerning the operation and output of the plant. These operational requirements are usually given in the basic plant specification.

For the sake of illustration an elementary block diagram of a possible nuclear power plant is shown in Figure 1. Here the reactor is considered merely as a source of heat energy. When this heat is extracted by passing a coolant through the reactor, the heat energy is then transferred via a heat exchanger to a turbine system, and the output shaft of the turbine can be made to drive many types of working apparatus. The primary coolant considerations are basic for control design, and it may be mentioned in passing that gas, water, and liquid metals have been proposed as reactor coolants.

The ultimate usage of the system of course determines the specified output requirements. A useful principle of control design is to attempt to place the primary operating controller near the output of the system. Consequently, the characteristics of the output loading as a function of turbine horsepower output is of first interest. In the case of an aircraft power plant this information might be specified in terms of aircraft speed as a function of turbine output. For a shipboard plant the information might be supplied in the form of propeller rpm versus turbine output. In any case, an understanding of the relationship between the turbine and the load output is necessary to plant control.

Another factor affecting the type of control system is the operational transitions required. These transitions determine the range of control and the output level variations required. Minor consideration is given to whether the final output is to be continuously variable, variable in steps, or some combination of the two.

Start-up and shut-down requirements affect the control system. Here the nuclear reactor plays a prominent part in determining plant performance, for nuclear reactors cannot be started up too fast and never can be really shut down. In considering the output of the nuclear reactor there is no such thing as zero power involved. Even in a brand-new, cold, clean reactor which has been shut down as much as possible an inherent source of neutrons exists which causes a certain amount of nuclear fission to occur. This fission produces minute amounts of power and in the process more neutrons are released. This effect requires that the reactor neutron output be monitored continually to see that the neutron level is kept under control. In practical cases this monitoring means that instrumentation for measuring neutrons must be capable of operating over ranges as wide as 6 to 10 decades and control provisions must be provided over a similar range. Starting up a reactor from a cold condition means that the reactor can operate over a neutron range of many decades before any appreciable useful power begins to occur at the output. Some arbitrary number of neutron fissions has to be taken as zero power. For example, 1 per cent of full-load out-put might be considered to be the equivalent of zero power. Transitions between 1 per cent full power and 100 per cent full power can be made relatively rapidly, but because of the safety aspects involved transitions from a cold start-up must be made quite slowly.

A reactor which has been operating at a high power level is turned off neutron-wise by manipulating the reactor control rods to reduce the reactivity of the reactor. However, many secondary radiations, particularly gamma rays, exist from the formed fission products. The amount of power from these secondary radiations is in some instances very substantial. Consequently, although the reactor has been turned off to the best of the ability of the operator, serious amounts of power still may be given off for a considerable length of time. Control-wise, this condition means auxiliary devices may be necessary to dump this spare power into a useless load. It can be seen, therefore, that the start-up and shut-down of a nuclear power plant is dependent upon the reactor characteristics and differs from conventional plant techniques.

The transient output requirements of the plant are also of some importance. From an operational point of view certain peak demands will be made on the system. These demands are similar to those made on a conventional plant whereby above rating performance can be obtained for short intervals of time. The operational probability of such demands and the operational probability of any preferential power level of operation must be analyzed. For example, in a central station plant where a relatively fixed load can be made to exist it might be desirable to operate the nuclear powered generator at 100-per-cent capacity during most of its lifetime.

Paper 53-31, recommended bythe AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted October 16, 1952; made available for printing November 14, 1952.

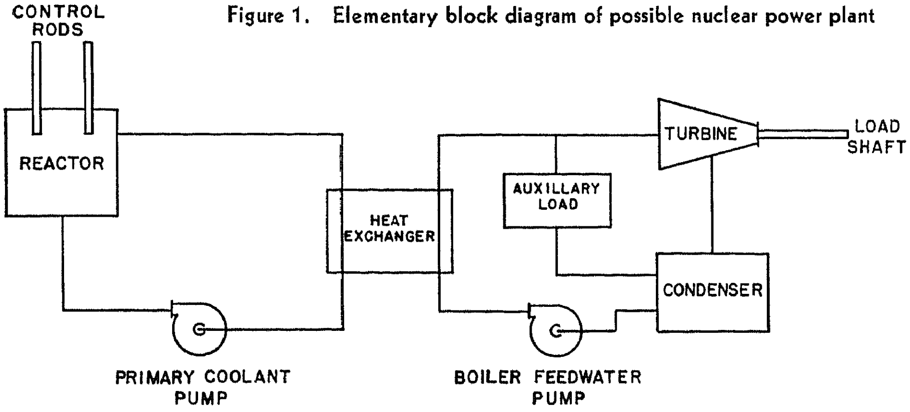

Figure 1. Elementary block diagram of possible nuclear power plant

If this were the case the plant control system might be optimized at this load value.

The design of the reactor with respect to poison overide is another important operational control consideration. When some types of reactors are shut down, nuclear poisons are known to build up and reduce the over-all reactivity of the reactor. In time these poisons die away. A certain amount of additional reactivity can be designed into a reactor to overide this poisoning effect. The amount of the poisoning overide which is built into the reactor becomes an operational factor because, with only a small amount of overide reactivity in the system, the poisons can build up in a given amount of time to an amount capable of making the reactor inoperative. Before this time is reached the reactor might be turned back on and the poisons effectively burned out. If, however, the reactor poisons have built up to such a level that the plant cannot be turned on, it then becomes necessary to wait until the poisons die down to where the reactor can again be made critical. To build enough reactivity into a reactor to always overide the poisons may require a large amount of fissionable material. If the service to which the power plant is put is such that the plant must be shut down frequently for critical periods then some other means must be found for supplying auxiliary power during the dead off time of the reactor.

Another of the factors which is involved in the design of control components is the reactor and plant lifetime. Contrary to popular opinion, reactors do not have an indefinite life. The uranium atoms which are involved in the fission process become used up and although a tremendous amount of energy is available each time a uranium atom is fissioned, ultimately enough fissions occur so that the reactor becomes depleted in uranium and will no longer maintain a chain reaction. Other factors, such as radiation damage to the structural material of the reactor or the corrosion of any portion of the mechanisms, may cause the end of life of the reactor. If the design of the plant can be made such that all components have an effective indefinite lifetime compared with the lifetime of the reactor, it may then be feasible to employ some means of changing the fuel or of possibly even changing reactors.

Plant Control Requirements

Once the over-all characteristics required of the plant have been specified, certain of the details of these characteristics pertaining directly to the control system can be examined. Detailed control information that is needed is the steady-state output error that can be tolerated. That is, how important is it that the plant give out a fixed number of kilowatts or a given propeller rpm and hold this output regardless of operational transients. The steady-state output error directly specifies the tolerable steady-state plant instrument errors. Frequently, control systems are devised whereby the errors of many instruments in many loops add up to produce a higher probable error than the over-all specifications permit. On the other hand, it is possible in the design of certain loops to integrate out instrument errors in such a manner that they do not show up in the final output. From the over-all error permitted the designer can work backwards through each loop, figuring the steady-state error that conventional control components will impose upon the system.

Similarly, certain plant and reactor transient errors may be permitted for some of the instruments. For example, if two thermometers are used in the system and one thermometer has a much larger time constant than the other, it is obvious that in a transient change both of these thermometers will not read identically. If these instruments are used in control loops the output of a particular loop may temporarily permit an error to exist in the plant output.

One control requirement which is peculiar to the nuclear power plant is the instrumentation setup for alarm, cutback, and scramming circuits. Alarm circuits are common in the power industry, but the peculiar notion of "scram" is one limited to the reactor field. A scram in reactor parlance consists of an attempt to insert as much negative reactivity as possible into the reactor in as short a time as possible. Practically, a scram usually means injecting safety rods into the reactor with some violence. The safety requirements of the reactor are such that it is usually necessary to employ scramming devices. However, from a practical power point of view it is obvious that the plant must be kept in an operable state as continuously as possible. The plant must not be shut off every time some minor control in a secondary loop malfunctions. Therefore the control designer's problem is to limit the number of controls which can cause a scram to an absolute minimum.

For all accidents other than the type requiring a scram, it is possible to cut back the reactor power level or to merely ring an alarm and have an operator manually make the necessary adjustment or shutdown.

Plant Dynamics

The heart of the control system problem is the primary coolant system operating cycle. There are many patterns into which the temperature and the flow of the coolant coming in and out of the reactor may be manipulated to produce the desired output power. The system operating cycle may be determined by many items such as auxiliary requirements, corrosion, or peak temperatures permitted. However, in a control system designed about a reactor one should attempt to follow this basic premise: If the reactor has a negative temperature coefficient the reactor system would prefer having the average coolant temperature constant. A word of definition is necessary concerning the reactor temperature coefficient. To say that a reactor possesses a negative temperature coefficient means that as the reactor average temperature increases its over-all reactivity decreases. That is, the chain reaction will slow down with increasing temperature. This condition is obviously desirable.

Let us examine the simple plant shown in Figure 2 in the light of this premise. This figure shows a primary coolant being circulated at constant flow through a re-

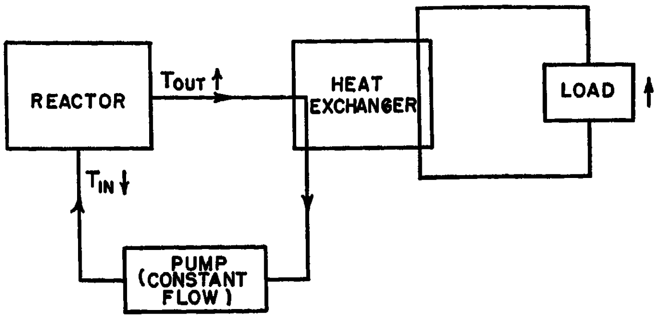

Figure 2. Simplified power plant block diagram with reactor having negative temperature coefficient

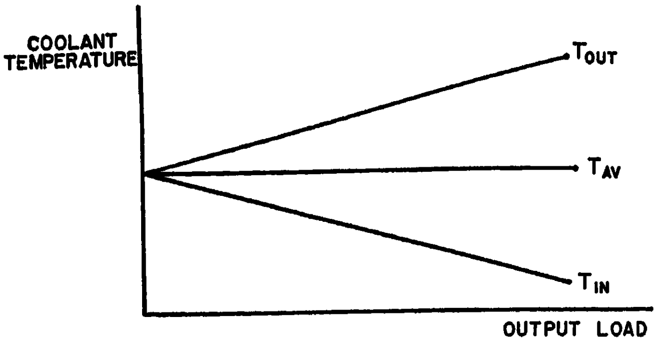

Figure 3. Steady-state temperature pattern

actor having a negative temperature coefficient. A steady output is being produced; now suppose that more output is required by the load. This greater loading causes more heat to be extracted from the heat exchanger and for a short period of time the heat capacity of the heat exchanger can usually supply this load. However, the additional energy extracted from the system requires that the temperature of the coolant into the reactor must drop. If the reactor has a negative temperature coefficient as defined here, the dropping of the coolant temperature inserts more reactivity into the reactor. If the reactor was initially in a critical state it now temporarily becomes supercritical. More energy is then available from the reactor, and consequently the output temperature of the coolant rises, and in the steady state the reactor returns to its critical condition with the average coolant temperature the same as it was initially. These steady-state temperature conditions are shown in Figure 3. It will be noted that without any control mechanism whatever the reactor system has stabilized itself about a given average temperature and automatically supplied any reasonable demand put upon it. This is the case only where the program of primary coolant operation is such that the average coolant temperature remains constant.

Let us assume now that for some reason other than the reactor control system it is desirable to establish a different pattern of coolant temperatures. A reasonable pattern might be that shown in Figure 5. This figure shows a simple system which might be called for by some structural condition desiring to keep the outlet temperature fixed at a given maximum level. Figure 4 shows a block diagram of how this condition might be achieved. Again if more load were required the inlet temperature to the reactor would drop. More reactivity would be inserted in the reactor because of the negative temperature coefficient. The outlet coolant temperature would tend to rise, but now a control has been inserted on the outlet temperature which measures the temperature and then varies the coolant pump speed in such a manner as to reduce this outlet temperature. In this manner it is very feasible to hold the outlet temperature constant as a function of load, as seen in Figure 5. However, it will be noted that the average coolant temperature drops with load, meaning that the reactor, because of its negative temperature coefficient, would tend to operate in a supercritical condition. Consequently another control loop, usually rod control, must be added to the system to extract the reactivity put in by the change in coolant temperature.

The system of Figure 4, from a control point of view, compares unfavorably with the previous system. Here the external control systems which have been added cause the reactor system to operate in a manner contrary to its own inherent stability. Consequently, the system is not quite as safe and requires considerably more control equipment. Neither of the simple systems described is completely practical for an actual plant, but many derivatives and variations can be derived which will fulfill the required specifications in a compromise manner.

Once the primary system operating program has been determined it would be very desirable to have the transfer functions of all of the major system components available. Unfortunately, in the present state of the art the control designer must be satisfied with far less. Usually a simplified approximation to the transfer function of a given component is made analytically, and the simplification is usually so great that the resulting equations can be handled easily in multiloop analogue networks.

Still more information is needed, however, before the designer can attempt to synthesize a complete control system. The transport times of the various coolants and the various loops must be known. Plants can be laid out with many feet of pipe between major components, and the time delay in these pipes is an important part of the control system. Of particular need is the total coolant circulating time, the time the primary coolant is in the reactor, the time the primary coolant is in the heat exchanger, and the time the primary coolant is in the pipes.

Miscellaneous Plant Information

There are many miscellaneous bits of information which also must be considered before the control system can be synthesized. Some of these factors depend upon the type of main coolant system used. For example, in systems employing water or gas as the coolant, it will usually be found necessary to pressurize the main coolant system in order to obtain reasonable plant efficiency.. Operating a

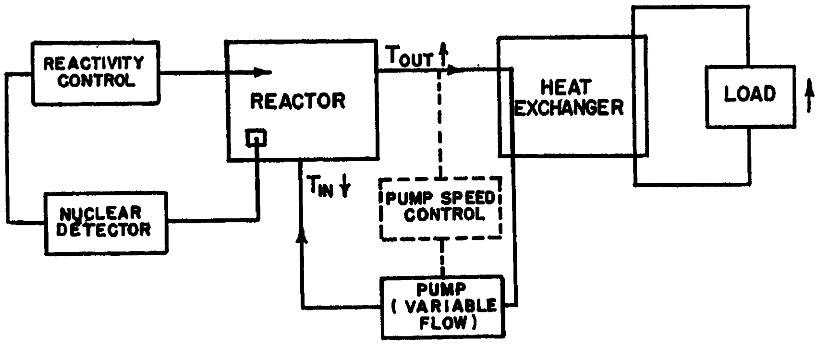

Figure 4. Block diagram of system maintaining primary coolant outlet temperature constant

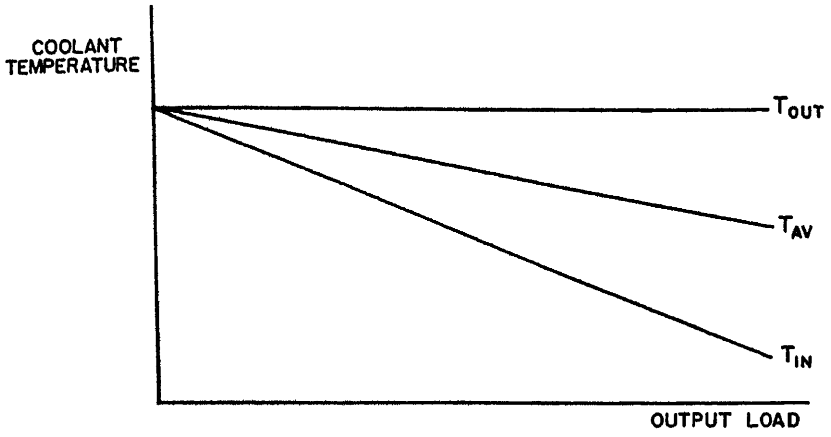

Figure 5. Steady-state temperature pattern

op under pressure calls for a complete ressurizing system including heaters and ontrols. These controls of necessity tie with the controls of the main coolant ystem.

Another auxiliary system which directly ffects the main system is provision of evices to take care of emergency electric ower failures. It may be desirable in ome plants to provide auxiliary means of umping power or employing elaborate ail safe mechanisms.

A third item which affects the design is he type of coolant control permitted. If umps or blowers are used to circulate the rimary coolant, multiple unit operation nay be considered. Multispeed units, ariable speed units, or the switching of units on or off the line are methods where-y coolant control may be achieved. ne scheme may have a considerable dvantage over another in a particular lant design.

Another factor is the auxiliary load hich the plant must supply in addition o its primary output. In a nuclear ower plant for a vessel, for example, a onsiderable hotel load exists separate rom the prime task of driving propellers. It may also be desirable that most of the irect auxiliaries, such as pumps, be tied n to the nuclear powered system. This statement implies that a certain percent-ge of the auxiliary load must be furnished from a source other than the nuclear power plant. Just as the battery on an automobile is required to run certain of the automobile's auxiliaries, a given amount of non-nuclear power is usually necessary to start the plant and keep it in operation. To start the plant and its auxiliaries and maintain them under given operating conditions usually will require a large amount of detailed electric switchgear. This apparatus, though complicated in its own right, is conventional in nature and is usually capable of supplying the control system designer exactly what he wants.

When all of these factors have been considered, the control system designer can then synthesize the entire system. The problems of the designer now involve problems of components, particularly the limitations of the various components. These limitations usually lead to the separate protection circuits for each of the major components.

Component Characteristics and Limitations

Components such as the turbine, the heat exchanger, the reactor vessel, the pumps, and the reactor itself require the most study. As each plant will contain a different group of components with different limitations, only a few of the more obvious conventional characteristics and limitations of the plant will be mentioned in order that more emphasis may be placed on the reactor characteristics.

Of interest to the control designer are the heat exchanger temperature limitations. The structural limitations of the heat exchanger will probably permit only certain rates of change of temperature during both start-up and shut-down operations. In other words, a heat exchanger may have a limitation stress-wise such that the temperature of the coolant flowing through it may be permitted to change only by so many degrees per minute. A completely different rating, however, may be given the boiler for very short time transients. The same condition exists with respect to the reactor container. This container will have stress limitations also which will prevent any attempt to change coolant temperatures faster than a given rate.

Minor component limitations exist in the piping and the specific instrumentation of each component. Consideration of these limitations usually lead to the settings on the relief valves.

Reactor Nuclear Characteristics

It is now necessary to examine roughly the various factors contained within the reactor itself which affect the over-all plant control. It has been shown[2] for control purposes that the reactor can be considered as a nonlinear device having an approximate transfer function of the form

$$K_rG_r(s)=\frac{K_rN_0}{s+a} \qquad (1)$$

where

K_r and a are constants
s is the Laplace transform operator
N_0 is the neutron level at which the reactor is operating

The problem of controlling a loop containing this component whose gain depends upon the level at which it operates has been given extensive study.[2,3] The ultimate objective of this study was to be able to specify components of a control system which would manipulate the nuclear control rods. In practice, the nuclear characteristics of the reactor are also involved in the detailed rod moving mechanism design.

To the component designer the problem of rod mechanism design is a simple one of merely asking how far a given control rod must move and how fast. These questions can be answered by the reactor designer who must determine first the total number of control rods required and where they are placed in the reactor. These answers are derived from heat transfer considerations. He must then consider the problem of the effectiveness of these rods in changing the over-all reactivity of the reactor. He must also consider how this effectiveness changes during the lifetime of the reactor. The variation of these constants with time brings up for consideration again the kinetic relationships of the various poison build-ups and burn-outs in the reactor. Reactor fuel depletion must be considered again and the total amount of reactivity to be built into the reactor determined.

The next reactor consideration is that of the magnitudes of the various coefficients of reactivity. The temperature coefficient of reactivity has been mentioned previously and its absolute magnitude is necessary to enable the determination of the degree of stability of the primary loop. Another coefficient of reactivity may be determined for some reactors and this is a pressure coefficient. This term is defined in a manner similar to the temperature coefficient and consists of the amount the reactivity of the reactor changes, and in what direction, as the pressure of the coolant in the reactor changes.

Another nuclear constant of importance to the control designer is the so-called "mean neutron lifetime." This is the average time taken by a neutron in starting out at birth in fission and dying by creating another fission or being absorbed or lost in some other portion of the reactor. The importance of the mean neutron lifetime control-wise comes about in that it affects the constant *a* of equation 1.

Start-up and shut-down reactor considerations call for knowing the amount of non-neutron power produced immediately after shutdown and the neutron level to which the reactor will ultimately drop to after a prolonged shutdown. This information, plus the information concerning the artificial source of neutrons placed in the reactor, is necessary for proper nuclear instrument design. The nuclear instrument design considers these facts, the known instrument sensitivities, the neutron and gamma flux levels about the reactor, and the type of instrumentation philosophy required. This information is then filtered into the control system and the placement of the instruments and their operation in the control system determined.

Conclusion

Many of the factors involved in the control of a nuclear power plant have been mentioned and it is apparent that the operational requirements of the plant determine the control system in the same manner as in a conventional plant. It has been noted that the fact that a reactor is present in the system does not alter any of the conventional requirements. Rather it appears as though a given performance can be specified for the nuclear plant and the the reactor and all of its appurtenances can be tailored to fit the required output.

No Discussion

Transmitting Terminal Apparatus for NTSC Color Television

PAGE BURR
NONMEMBER AIEE

DURING the last few years several laboratories in the United States have been carrying on investigations directed toward supplementing the present monochrome television service with transmissions in color. In most cases these investigations of color television systems have been confined to proposals which were expected to receive the wide public acceptance which has characterized monochrome television. The probable commercial success of a color television system may be estimated by noting the degree to which it satisfies certain important criteria. One of these resides in the fact that the system should be "compatible." That is, it is desirable, that television broadcasts in color should be reproduced in monochrome by the 20,000,000 odd black-and-white receivers now in the hands of the public without the necessity of modifying these receivers in any way. Second, in addition to providing full color to a color receiver, the system should provide as high a degree of pictorial definition to both monochrome and color receivers as is now realized in the monochrome service. Third, as a purely technical matter, the radio-frequency spectrum space allocated to the television service should be utilized as efficiently as possible. The color television system which is now being field-tested by the National Television System Committee (NTSC)[1,2] represents the results of these investigations. This system satisfies these criteria in large measure.

At the present writing the details of the NTSC standards are receiving intensive study and test, and it is possible that some alterations of the November 1951 field-test specifications may be adopted. The techniques described in the present paper are necessarily based on the existing field-test specifications. It is believed that the principles and methods used will in general be of continuing interest, although some particulars of the standards may later be different, requiring corresponding modifications of the equipment.

Color Specification in the NTSC System

The NTSC system specifies color values in television images by the use of several concepts which, although common in the science of colorimetry, may not be familiar to workers concerned with other uses of additive or subtractive color systems. It is common knowledge that any color may be specified in terms of the intensities of three primary lights which, when added together, achieve the subjective effect of a "match" with the sample. An important restriction upon the character of these primaries is that they must be independent, that is, no combination of two of them may be capable of matching the third. In practice these lights are usually red, green, and blue.[3-6] As a result, initial investigations in the field of color television were confined to systems wherein the color values of the scene in terms of red, green, and blue were sequentially or simultaneously transmitted to the remote receiver by means of one or

more separate television channels.[7,8] This practice is strictly analogous to the process of making color separations in color photography, as, for example, in the use of the so-called "1-shot" color camera.[9,10]

As work on various color television systems progressed it became apparent that several alternative methods of color specification were more attractive for color television transmission. One of these alternate methods describes a colored area by means of three quantities proportional to subjective brightness, hue, and saturation. Brightness is closely connected with intensity and is an idea with which we are generally familiar. The concept of hue relates to the nearest shade among the pure spectrum colors or among the purples (that is, mixtures of spectral red and blue) which most closely matches the sample. Saturation is a measure of the degree to which the particular color is pure in the sense of being free of dilution with white or gray light. As an example, pastel or tinted shades are usually characterized by low saturation. In color television terminology the brightness attribute of a colored area is termed its *luminance*. The qualities of the sample relating to colored characteristics, that is, hue and saturation, are termed *chrominance*. In more specific terms chrominance represents the colorimetric difference between any color and a reference gray or white of equal luminance. For the NTSC transmission this reference shade corresponds to average daylight, and is known as Standard Source C of the Commission Internationale d'Eclairage.[11]

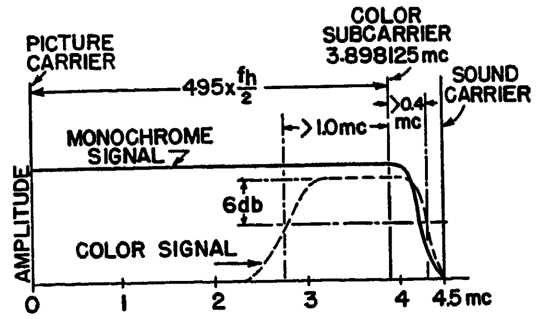
A series of experiments fundamental to the development of the NTSC transmission has established that the ability of the eye to resolve fine details of contrasting luminance in a picture is approximately 60 per cent greater than the corresponding ability to resolve fine details which contrast only in chrominance.[12] Consequently, it became apparent at an early stage that the preservation of high definition in the transmission of color television images was very largely controlled by the provisions made for handling the luminance detail.

Relationship to Present Monochrome Signal

The significance of the NTSC color specifications will become apparent when it is noted that present-day monochrome transmissions provide the receiver with information which is approximately representative of the luminance of the scene. As a result, the major problem to be resolved during the development of the NTSC transmission scheme has been to devise a method for incorporating chrominance data into the monochrome service without degrading the performance of existing black-and-white receivers. These receivers would therefore continue to be useful and would serve to reproduce in monochrome the programs transmitted in color.

The method by which this incorporation has been contrived is most easily understood through the application of Fourier series analysis to the video signal wave form of a monochrome transmission. The spectral distribution revealed by this analysis extends to a frequency of approximately 4 megacycles. However, examination of the spectrum indicates that the energy is not continuously distributed, but rather is present only in discrete bundles centered around specific frequencies[13] which are harmonics of the line repetition rate of the television scanning process. A considerable portion of the spectrum of a present-day monochrome transmission is, therefore, in a quite literal sense, not utilized. This statement may be easily verified by the owner of a reasonably selective high-frequency communications receiver. Further, it may be shown that if a signal component (as for example a continuous carrier wave) is introduced into one of these unused "gaps" in the spectrum, then the result would not be perceptible upon an ideal television display. In practical receivers, however, nonlinear phenomena, together with certain properties of the eye, compromise this ideal "invisibility" to a point where the visibility of the signal component is low, rather than zero.

Considerable experimental evidence has accumulated to substantiate the conclusion that these gaps in the television transmission spectrum will accommodate additional signal components without seriously degrading the quality of the received images. It is immediately apparent, therefore, that these unused portions of the spectrum provide a suitable con-



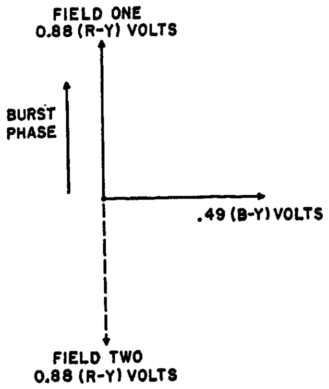


Figure 2 (left). Complete spectrum

Figure 4 (right). Phase relations of NTSC chrominance subcarrier efficient and consists of the amount the reactivity of the reactor changes, and in what direction, as the pressure of the coolant in the reactor changes.

Another nuclear constant of importance to the control designer is the so-called "mean neutron lifetime." This is the average time taken by a neutron in starting out at birth in fission and dying by creating another fission or being absorbed or lost in some other portion of the reactor. The importance of the mean neutron lifetime control-wise comes about in that it affects the constant a of equation 1.

Start-up and shut-down reactor considerations call for knowing the amount of non-neutron power produced immediately after shutdown and the neutron level to which the reactor will ultimately drop to after a prolonged shutdown. This information, plus the information concerning the artificial source of neutrons placed in the reactor, is necessary for proper nuclear instrument design. The nuclear instrument design considers these facts, the known instrument sensitivities, the neutron and gamma flux levels about the reactor, and the type of instrumentation philosophy required. This information is then filtered into the control system and the placement of the instruments and their operation in the control system determined.

Conclusion

Many of the factors involved in the control of a nuclear power plant have been mentioned and it is apparent that the operational requirements of the plant determine the control system in the same manner as in a conventional plant. It has been noted that the fact that a reactor is present in the system does not alter any of the conventional requirements. Rather it appears as though a given performance can be specified for the nuclear plant and the the reactor and all of its appurtenances can be tailored to fit the required output.

Transmitting Terminal Apparatus for NTSC Color Television

PAGE BURR
NONMEMBER AIEE

DURING the last few years several laboratories in the United States have been carrying on investigations directed toward supplementing the present monochrome television service with transmissions in color. In most cases these investigations of color television systems have been confined to proposals which were expected to receive the wide public acceptance which has characterized monochrome television. The probable commercial success of a color television system may be estimated by noting the degree to which it satisfies certain important criteria. One of these resides in the fact that the system should be "compatible." That is, it is desirable, that television broadcasts in color should be reproduced in monochrome by the 20,000,000 odd black-and-white receivers now in the hands of the public without the necessity of modifying these receivers in any way. Second, in addition to providing full color to a color receiver, the system should provide as high a degree of pictorial definition to both monochrome and color receivers as is now realized in the monochrome service. Third, as a purely technical matter, the radio-frequency spectrum space allocated to the television service should be utilized as efficiently as possible. The color television system which is now being field-tested by the National Television System Committee (NTSC)[1,2] represents the results of these investigations. This system satisfies these criteria in large measure.

At the present writing the details of the NTSC standards are receiving intensive study and test, and it is possible that some alterations of the November 1951 field-test specifications may be adopted. The techniques described in the present paper are necessarily based on the existing field-test specifications. It is believed that the principles and methods used will in general be of continuing interest, although some particulars of the standards may later be different, requiring corresponding modifications of the equipment.

Color Specification in the NTSC System

The NTSC system specifies color values in television images by the use of several concepts which, although common in the science of colorimetry, may not be familiar to workers concerned with other uses of additive or subtractive color systems. It is common knowledge that any color may be specified in terms of the intensities of three primary lights which, when added together, achieve the subjective effect of a "match" with the sample. An important restriction upon the character of these primaries is that they must be independent, that is, no combination of two of them may be capable of matching the third. more separate television channels.[7,8] This practice is strictly analogous to the process of making color separations in color photography, as, for example, in the use of the so-called "1-shot" color camera.[9,10]

As work on various color television systems progressed it became apparent that several alternative methods of color specification were more attractive for color television transmission. One of these alternate methods describes a colored area by means of three quantities proportional to subjective brightness, hue, and saturation. Brightness is closely connected with intensity and is an idea with which we are generally familiar. The concept of hue relates to the nearest shade among the pure spectrum colors or among the purples (that is, mixtures of spectral red and blue) which most closely matches the sample. Saturation is a measure of the degree to which the particular color is pure in the sense of being free of dilution with white or gray light. As an example, pastel or tinted shades are usually characterized by low saturation. In color television terminology the brightness attribute of a colored area is termed its *luminance*. The qualities of the sample relating to colored characteristics, that is, hue and saturation, are termed *chrominance*. In more specific terms chrominance represents the colorimetric difference between any color and a reference gray or white of equal luminance. For the NTSC transmission this reference shade corresponds to average daylight, and is known as Standard Source C of the Commission Internationale d'Eclairage.[11]

A series of experiments fundamental to the development of the NTSC transmission has established that the ability of the eye to resolve fine details of contrasting luminance in a picture is approximately 60 per cent greater than the corresponding ability to resolve fine details which contrast only in chrominance.[12] Consequently, it became apparent at an early stage that the preservation of high definition in the transmission of color television images was very largely controlled by the provisions made for handling the luminance detail.

Relationship to Present Monochrome Signal

The significance of the NTSC color specifications will become apparent when it is noted that present-day monochrome transmissions provide the receiver with information which is approximately representative of the luminance of the scene. As a result, the major problem to be resolved during the development of the NTSC transmission scheme has been to devise a method for incorporating chrominance data into the monochrome service without degrading the performance of existing black-and-white receivers. These receivers would therefore continue to be useful and would serve to reproduce in monochrome the programs transmitted in color.

The method by which this incorporation has been contrived is most easily understood through the application of Fourier series analysis to the video signal wave form of a monochrome transmission. The spectral distribution revealed by this analysis extends to a frequency of approximately 4 megacycles. However, examination of the spectrum indicates that the energy is not continuously distributed, but rather is present only in discrete bundles centered around specific frequencies[13] which are harmonics of the line repetition rate of the television scanning process. A considerable portion of the spectrum of a present-day monochrome transmission is, therefore, in a quite literal sense, not utilized. This statement may be easily verified by the owner of a reasonably selective high-frequency communications receiver. Further, it may be shown that if a signal component (as for example a continuous carrier wave) is introduced into one of these unused "gaps" in the spectrum, then the result would not be perceptible upon an ideal television display. In practical receivers, however, nonlinear phenomena, together with certain properties of the eye, compromise this ideal "invisibility" to a point where the visibility of the signal component is low, rather than zero.

Considerable experimental evidence has accumulated to substantiate the conclusion that these gaps in the television transmission spectrum will accommodate additional signal components without seriously degrading the quality of the received images. It is immediately apparent, therefore, that these unused portions of the spectrum provide a suitable con-

veyance for the chrominance information which we desire to add to the already present luminance transmission.[14] This is illustrated in Figure 1, which provides a pictorial representation of a section of the spectrum, showing the regions which may be used for the chrominance transmission. Figure 2 shows the complete television signal spectrum including that section which is also devoted to the transmission of chrominance information. In the NTSC transmission the chrominance information is inserted as suppressed-carrier modulation[15–18] of a frequency in the vicinity of 3.89 megacycles. This subcarrier frequency is chosen in such a way that both the subcarrier and its side bands fall in the gaps of the luminance signal spectrum. It will be noted that the chrominance information is shown as occupying an effective band of approximately 1.6 megacycles on a vestigial-sideband basis. This frequency range is sufficient in view of the comparatively low definition required of chrominance information.

Electrical Representation of Luminance and Chrominance

Before proceeding to a general discussion of transmitting terminal apparatus, it will prove advantageous to describe the electrical nature of the luminance and chrominance signals.

As a matter of practical expediency it must be assumed for the present that the pickup device functions in a manner analogous to that of the 1-shot photographic camera referred to previously. That is, the color camera in the television studio will provide the signal-processing apparatus with three video signals which are representative of the green, red, and blue values of the scene. The output signals from such a camera are therefore not directly suited for transmission by a system of the type described here, and must be converted, by a simple co-ordinate transformation, into data of the desired form.

The luminance signal may be obtained by properly weighting the green, red, and blue camera outputs according to their luminance contributions to the reproduced image and then adding them. That is

$$Y=0.59G+0.30R+0.11B \qquad (1)$$

where Y represents the luminance signal voltage, and R, G, and B denote the camera output signal voltages. The three numerical coefficients are determined by the relative luminosities of the three particular reproducing primaries employed at the receiver and by known properties

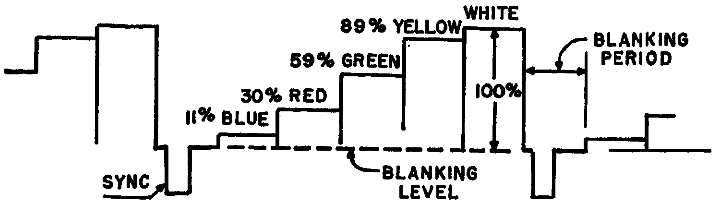

Figure 6. Luminance signal resulting from color bars

of the average human eye.

A method of performing this synthesis of the luminance signal is shown in Figure 3. In this diagram the green, red, and blue signal sources are presumed to be adjusted so that, when the camera is scanning a portion of a scene which is white or gray (no color), the values of the three output voltages are equal. The network of three resistors connected to a common output junction establishes that the summation voltage on this junction will be in proportion to the coefficients of equation 1.

As previously stated, chrominance describes all those attributes of the scene which are not embraced by the luminance information. Also, chrominance requires two quantities for its specification. These two "dimensions" may be obtained electrically by forming the "difference signals,"

$$\begin{array}{l} R-Y \\ B-Y \\ G-Y \end{array} \qquad (2)$$

Any two of these three voltages completely specify the chrominance signal. That is, the quantity $G-Y$ is not independent of $R-Y$ and $B-Y$, but may be expressed in terms of these two chrominance components by substituting equation 1 into equations 2 as follows

$$(G-Y)=a(R-Y)+b(B-Y) \qquad (3)$$

or

$$0.41G-0.30R-0.11B=a(0.70R-0.59G-0.11B)+b(0.89B-0.59G-0.30R) \qquad (4)$$

Hence, since G, R, and B are independent of each other, we have upon equating coefficients for R and B respectively

$$\begin{array}{l} 0.70a-0.30b=-0.30 \\ -0.11a+0.89b=-0.11 \end{array} \qquad (5)$$

Therefore

$$a=-0.51,\ b=-0.19$$

and

$$(G-Y)=-0.51(R-Y)-0.19(B-Y) \qquad (6)$$

It is of interest to note that the original red, green, and blue camera signals can be reconstituted by a proper combination of any two of the chrominance components with the luminance signal.

Modulation of Color Subcarrier by Chrominance Signal

The modulation of this 2-dimensional signal upon the single color subcarrier wave at approximately 3.89 megacycles may be accomplished by a number of means. Fortunately, as is well known, there are two parameters describing a sinusoidal current which may be varied independently. The first of these represents the amplitude of the wave while the second denotes its phase with respect to some reference standard. The chrominance information is modulated upon the subcarrier by means of a technique of this type. It might be said that the amplitude of the modulated subcarrier is a function of the saturation of a colored area while the phase is indicative of the hue.

Although the end result of the modulation process may be rigorously regarded in this light, it will be considerably more convenient to consider that the modulated subcarrier wave is actually composed of two orthogonal sinusoidal components which are independently modulated in amplitude. In particular, Figure 4 provides an illustration of the modulated chrominance subcarrier components. Inasmuch as the vector field represented by the chrominance signal is 2-dimensional, there are a number of axes upon which orthogonal projections of the signal characteristics could be taken. In the example shown the vectors are **R-Y** and **B-Y**. The coefficients of the respective signals indicate their normalized magnitude relative to a luminance signal of unit value. It has been implied previously that for any portion of the televised scene which is white or gray, the values of R, B, and Y are all equal. It is of interest to note that under these conditions the chrominance components vanish.

The paper so far has shown that the transmitting terminal apparatus may be resolved into two separate and distinct functions. The first of these is the generation and processing of the luminance signal and is closely related to present-day transmission practice. The second involves the generation and modulation of the chrominance information and the insertion of the modulated subcarrier into the luminance transmission channel.

The Luminance Channel

Figure 5 is a schematic of the complete luminance channel. The resistive matrix for generating Y from the color-separation signals will be found at the upper left of the drawing. This signal is subsequently applied to a luminance amplifier and delivered to a standard television transmission line, which presumably terminates in the radio-frequency transmitter. In addition an amplifier is provided to insert the conventional synchronizing information for controlling the scanning process in the remote receiver. The luminance signal output from this apparatus is indistinguishable from a conventional black-and-white television video signal as it might exist at various points in the studio facilities of a broadcaster.

Figure 6 shows an example of the video signal which would be generated if the color camera were directed at a geometrical pattern of vertically disposed colored bars. The order of the bars horizontally across the picture is shown as blue, red, green, yellow, and white. The wave form indicates that the luminance contribution of the primary color bars is in direct proportion to the coefficients of equation 1. The luminance contribution from the yellow bar is that due to the sum of red and green. The white bar, being composed of all three primaries, displays a value of 1.0 in luminance. The synchronizing signal and the blanking period are also shown by the diagram. It is perhaps of interest to note that the luminance signal in a color television transmission represents the so-called orthochromatic representation of color values in black and white which is familiar to workers in photography.

The Chrominance Channel

At first sight the apparatus for generating the chrominance information and modulating the subcarrier with this information may appear complex. It will shortly become apparent, however, that it is in general a straightforward equipment embodying circuitry which has long been standard in various branches of the communication art.

Figure 7 is a block diagram of the chrominance channel. The corresponding schematic diagram is shown in Figure 8. The input to the apparatus is derived from signal lines carrying the original color-separation signal information. These color signals are applied to a matrix of the type previously described in order to obtain the luminance component Y. The luminance signal together with

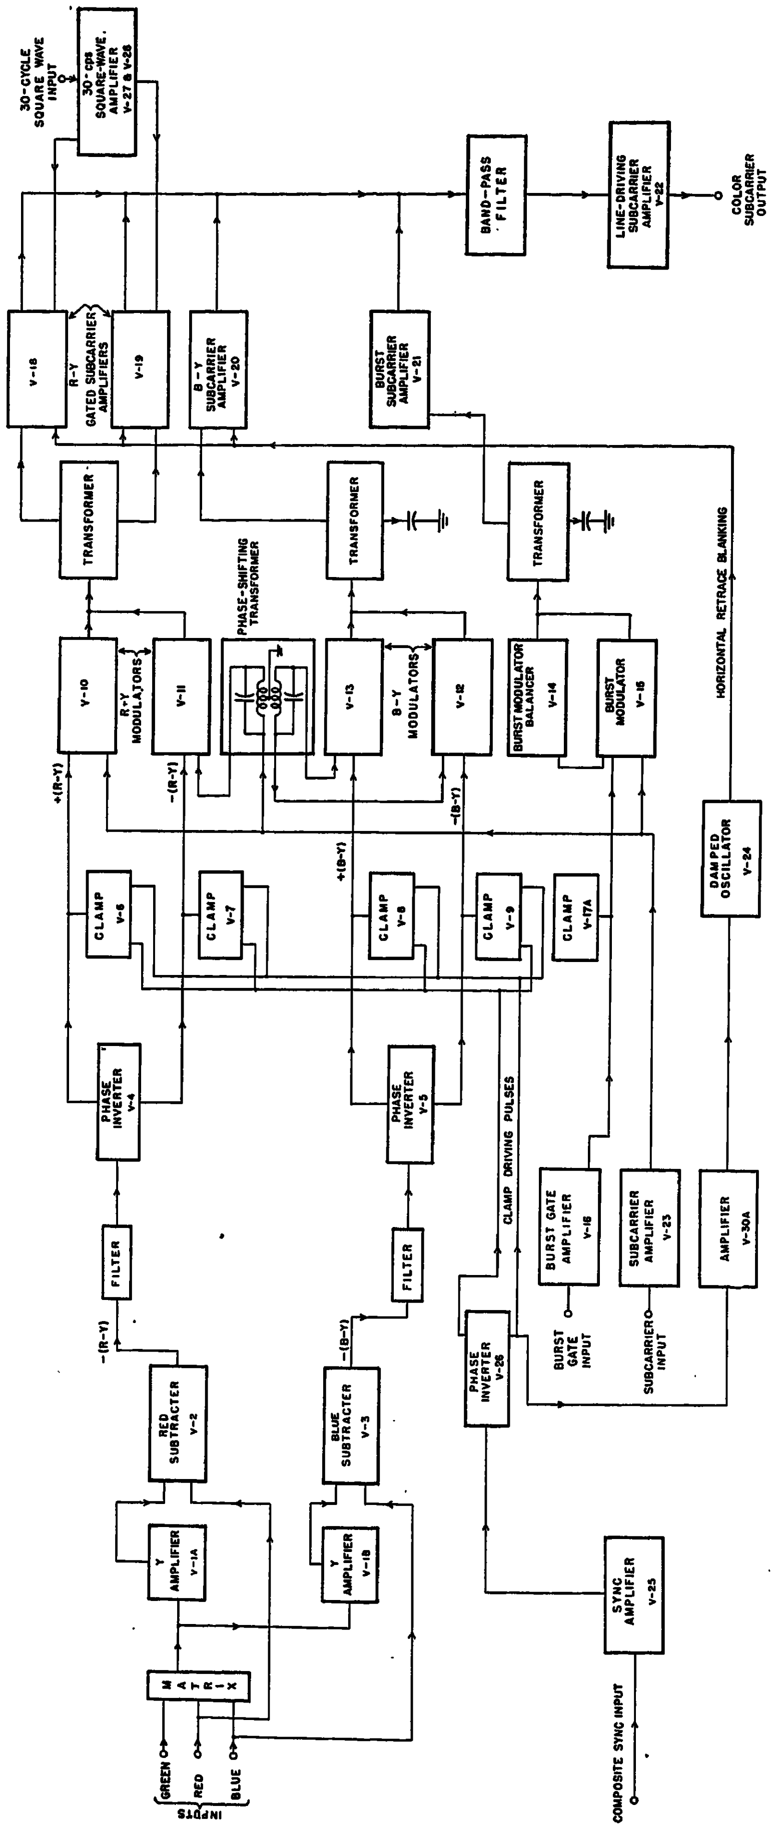

Figure 7. Block diagram of chrominance channel

the red and blue color-separation signals are then applied to a pair of subtracting amplifiers. Figure 9 shows a simplified schematic of such a subtracter. The output from these subtracters constitutes the required *R-Y* and *B-Y* chrominance components. The signals are then passed through low-pass filters which limit the chrominance information to a spectrum extending from zero to approximately 2 megacycles. The filter networks are followed by a pair of phase inverters in order to make the chrominance components available in opposing polarities or "push-pull." Conventional video clamping circuits are then employed to establish the potential of black in the signal at a specified value. The video circuit manipulations of the signal are completed at this point.

The next step involves the actual modulation process. To this end two sets of doubly balanced modulators are employed. This arrangement has been extensively used in carrier telephone practice on wire and radio circuits. Both the modulating signal and the local subcarrier source are injected in phase opposition so that the output of the modulator contains neither carrier nor modulation signals but only the modulation side bands. The necessary orthogonal relationship of the chrominance signal vectors is obtained by exciting the *B-Y* modulator with a subcarrier source differing in phase by 90 degrees from that applied to the *R-Y* modulator.

It has been considered desirable up to the present time to reverse the phase sequence of the radiated chrominance subcarrier on alternate fields of the television signal. This practice ameliorates certain difficulties which are inherently characteristic of vestigial-side-band operation. The necessary phase sequence reversal is accomplished by alternately inverting the polarity of the modulated *R-Y* chrominance signal component. This operation is illustrated in the vector diagram, Figure 4. During field 1 of the television transmission the vector diagram is as shown by the solid line, while for field 2 the R-Y vector occupies the position indicated by the dotted line. Phase reversal of the *R-Y* component is obtained by alternately selecting one of two outputs from the phase-inverting transformer following the *R-Y* modulators as shown in the block diagram. This selection is performed by a pair of gated amplifiers *V-18* and *V-19*, which are alternately switched into conduction by a 30-cycle square wave which is related to the field being transmitted and which is generated within the system synchronizing apparatus. The output of

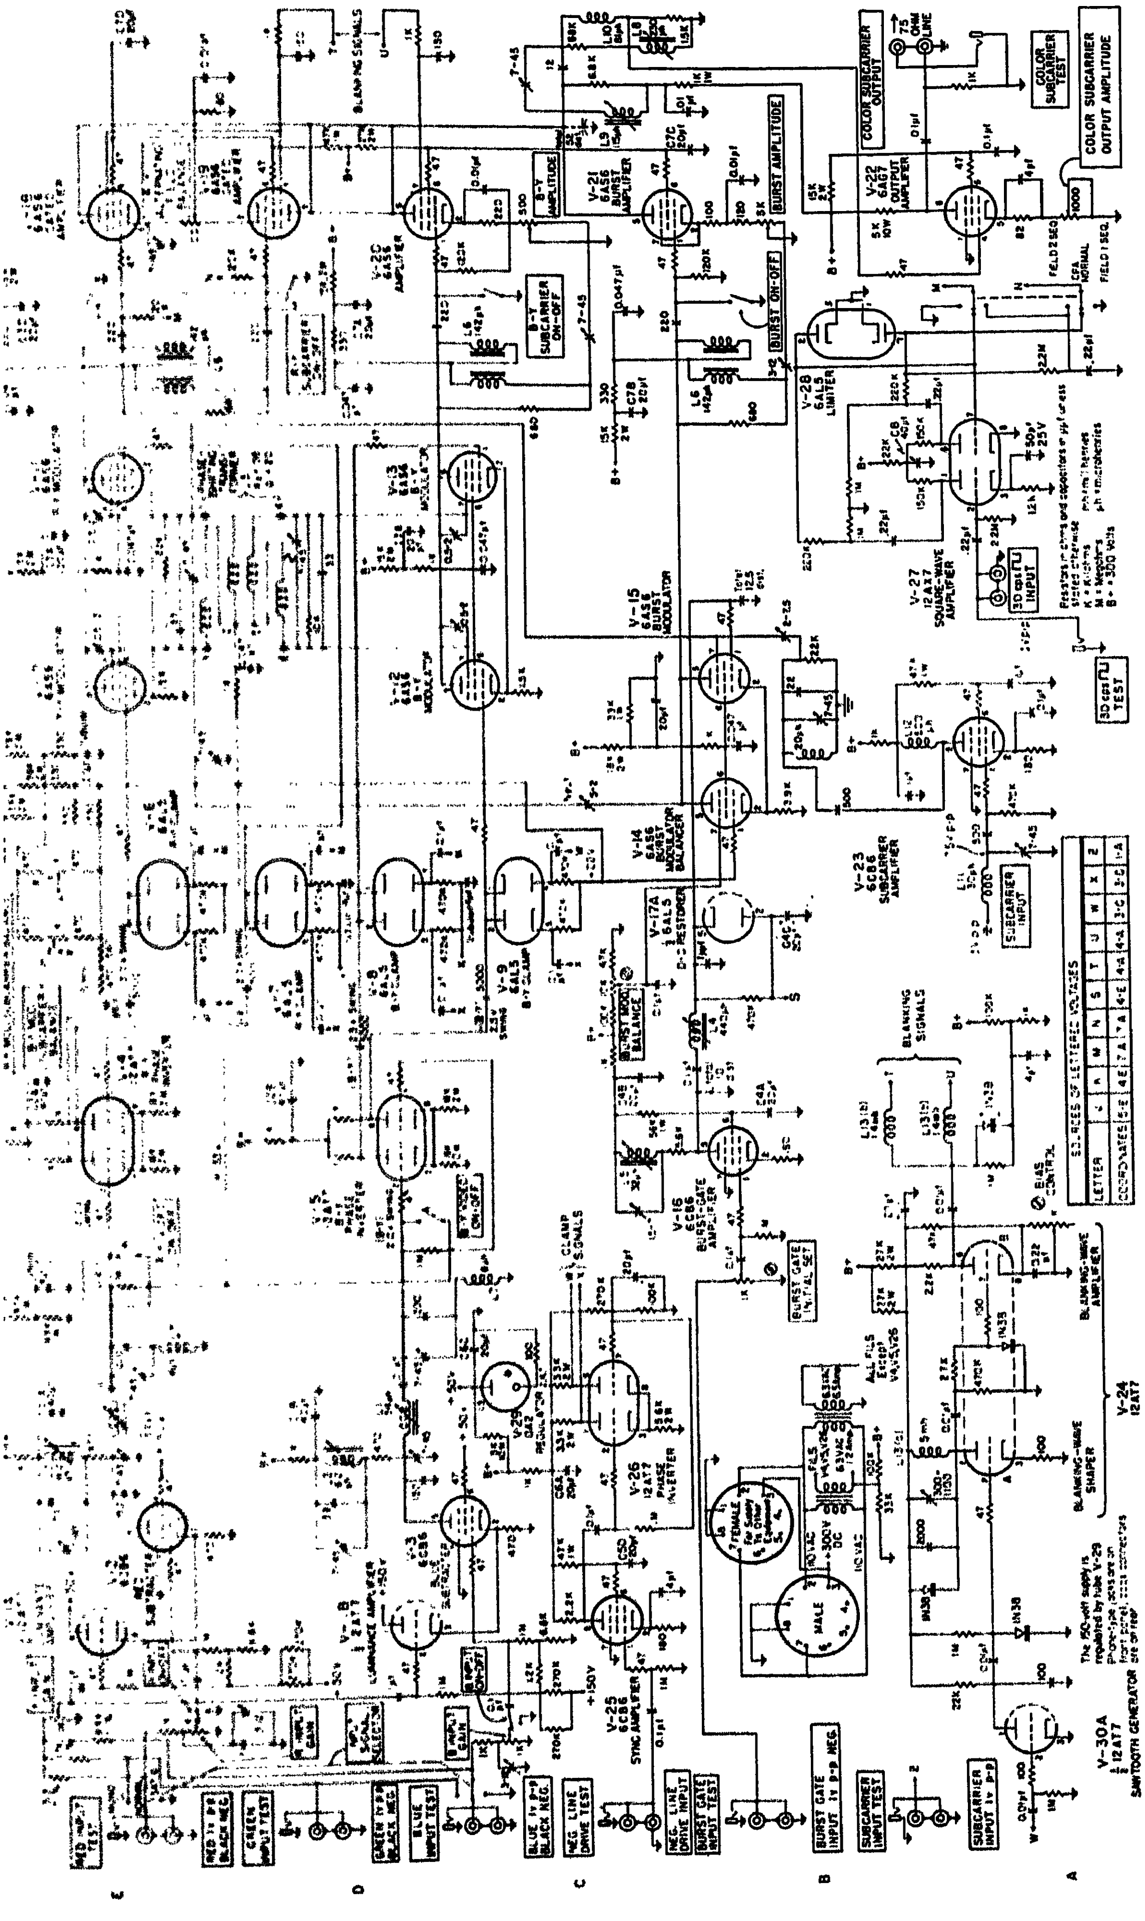

Figure 8. Schematic of chrominance channel of encoder

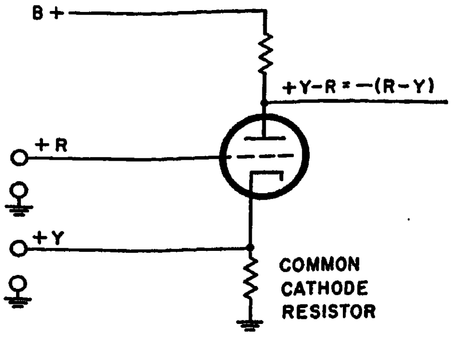

Figure 9 (left). Subtraction of two signals

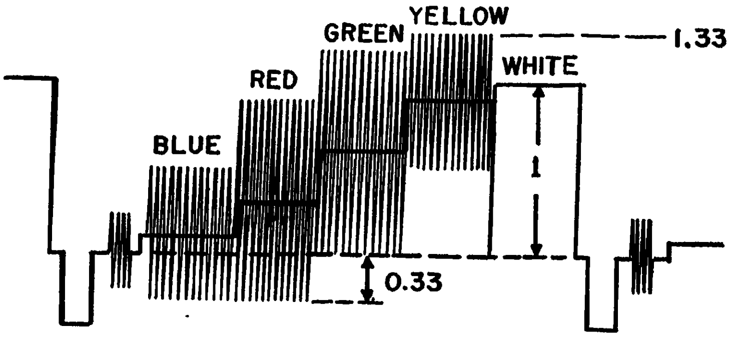

Figure 11 (right). Complete color television signal

these gated amplifiers is then combined with the *B-Y* modulated subcarrier component. These two signals together comprise the chrominance subcarrier. If the studio camera is televising a scene composed of the colored bars described previously, the output from the chrominance channel would have the appearance shown in Figure 10. That is, corresponding to each color bar there is a particular amplitude and phase of chrominance signal. The diagram illustrates the character of the signal which is added to the luminance signal output to form the complete NTSC color transmission. The result of this addition (which may be accomplished simply by connecting the two cables together) is shown in Figure 11.

It is worth while to repeat that the conventional monochrome receivers which are now in the hands of the public are responsive only to that component of the signal shown in Figure 6. The additional chrominance information as detected by a monochrome receiver will in general be low in reproduced amplitude and will cause little degradation to the picture because of the inherent low-visibility properties which have been discussed previously. On the other hand, in a color receiver designed to operate with this transmission, special circuits will be provided whose function is solely to utilize the added chrominance information. The magnitudes of the component vectors composing the chrominance signal will be detected in the receiver through a process of synchronous demodulation which is essentially the reverse of the modulation process taking place at the transmitter. The luminance information is readily obtained at the second detector of the color receiver in the conventional manner. Consequently the addition of the chrominance components to the luminance information in proper proportion through the use of simple resistive mixing arrangements will allow the recovery of the original red, green, and blue color signals for the operation of the tricolor picture tube of the receiver.

Color Synchronizing Signal

A general description of the transmitting terminal apparatus would not be complete without reference to the synchronizing signal provisions which must be included for the remote color receiver. Inasmuch as synchronous demodulation of the chrominance signal is required, it is apparent that the color receiver must provide a local source of continuous color-subcarrier voltage having the correct phase with respect to that employed at the transmitter. In order to accomplish this objective, the NTSC transmission includes a "burst" of subcarrier information during each horizontal retrace period of the television system. The form and location of this burst are shown in Figure 12. The burst signal consists of 9 or 10 cycles of reference-phase subcarrier following the synchronizing pulse used by the receiver deflection circuits. This reference phase of the burst is shown as the burst phase in the vector diagram, Figure 4, and coincides with that of the *R-Y* subcarrier component transmitted during field 1 of the television signal. Inasmuch as the burst comprises information which is for the use of the chrominance circuits in the receiver, it appears logical to generate it in the chrominance signal channel at the transmitting terminal. The tubes labelled *V-14*, *V-15*, and *V-21* on the schematic and the block diagram perform this function. In the particular apparatus shown the burst modulator is so connected that the burst phase is inherently coincident with that of the *R-Y* signal. The burst will also be noted on the diagram of the complete signal shown in Figure 11.

Service Experience

Extended laboratory trials of color television transmission apparatus of the type described have shown it to perform satisfactorily in service. There is ample evidence to support the expectation that both transmitting and receiving apparatus for the NTSC transmission system will be simple in fundamental concepts, straightforward in execution, and stable in performance.

Synopsis: The steady increase in the severity of operating conditions for capacitors and the need for more diverse characteristics has spurred the search for new and better capacitor dielectrics. The synthetic plastics industry, which is the source of a number of useful dielectric materials, has recently produced a new and promising dielectric in film form known as polyethylene terephthalate or "Mylar." This material is unusually strong, has a high softening point, and is available in very thin films which makes it especially suitable for capacitor insulation. The electrical characteristics of capacitors wound with Mylar film are likewise promising. As compared to mineral-oil-impregnated paper capacitors, unimpregnated Mylar capacitors exhibit higher dielectric strength, higher insulation resistance, and can be operated at higher ambient temperatures. Their loss characteristics are comparable with those of impregnated paper and the capacitance stability over the usual range of ambient temperatures approaches that of mica capacitors. Mylar is relatively nonhygroscopic and tests indicate that for moderate atmospheric conditions capacitors made from it do not require additional moisture protection. The film can be metallized readily by current techniques and, when used in metallized capacitors, appears to possess advantages over metallized paper in several respects.

The Need for New Dielectrics

THE diversity of requirements for electrical insulating materials is seemingly ever increasing and the urge to meet these demands is great. This has caused a continual scanning of new materials with the hope of finding some with better properties or a more advantageous combination of properties than those now in use. It is to be expected that the chance of finding such a material is small because the insulating materials now in use have been selected with great care and many improvements have been made in them. For example, paper has been used as insulation in wound capacitors for many years. It is an excellent material for this purpose and difficult to surpass. Nevertheless, it does have some inherent shortcomings. Paper decomposes at elevated temperatures and the trend in recent years toward higher operating temperatures for electric equipment has emphasized this restriction on its use. Also paper is hygroscopic and this necessitates thorough protection against atmospheric moisture which adds greatly to the cost and size of capacitors. In addition, the quality of paper is rather difficult to control because the raw material, wood, or other cellulosic plant fiber, from which paper is made is variable in composition; and too, the paper-making process is quite complex. Thus, one sees that there is ample incentive to replace or supplement even so firmly entrenched a material as paper.

General Properties

One of the more fruitful fields in the search for better materials is the synthetic plastics industry. A number of insulating materials for a variety of purposes have come from this field and recently a very promising one, polyethylene terephthalate, has been added to the list. This material, variously known as Terylene, *V-200* film, or Mylar film, promises to be outstanding for capacitor insulation and may also be adaptable to coil interleaving. Terylene is the name used by Imperial Chemicals, Ltd., of Great Britain, while the DuPont Company which developed manufacture of the material in this country called it *V-200* film during the early stages of development but have now adopted the trade name, Mylar, for the film.

Mylar is a polyester of ethylene glycol and terephthalic acid. It is a colorless transparent material with a specific gravity of about 1.4. It is exceptionally tough, having a high tensile strength and much better tear resistance than most plastic films. For this reason it is feasible to make very thin films which is a decided advantage for capacitor insulation. The softening point of the film

Table I. Dielectric Properties of Mylar

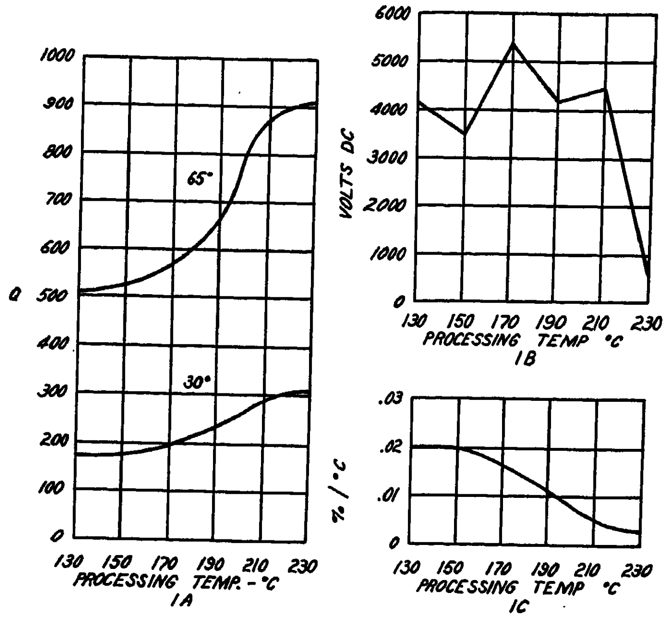

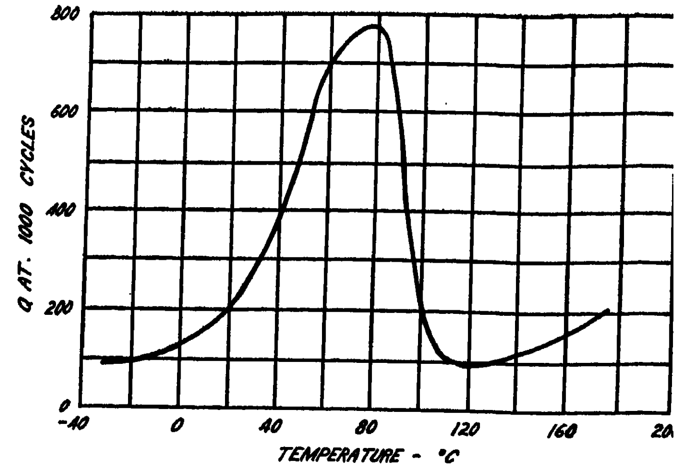

Figure 1 (left). The effects of capacitor unit processing temperature o (A) Q at 1,000 cycles, (B) ultimate dielectric strength, and (C) temperature coefficient of capacitance in per cent per degree centigrad

Figure 2 (above). The effect of temperature on Q at 1,000 cycles o a Mylar capacitor

is about 240 degrees centigrade. However, under proper conditions it can be fused at somewhat lower temperatures. Mylar film is quite stable chemically. It is highly resistant to moisture penetration and also to decomposition by hydrolysis. Since chemical and physical properties such as these are admirably suited to electrical insulation, the dielectric properties of the material were investigated. The results of preliminary work are shown in Table I. The dielectric breakdown strength of the film is found to be approximately 50 per cent greater than that of impregnated paper. At room temperature the d-c resistivity of Mylar is very high, its power factor is about the same as that of impregnated paper, and its dielectric constant is intermediate between paper and the hydrocarbon polymers, polysytrene, or polyethylene.

Characteristics of Mylar Capacitors

These properties of Mylar film, particularly its high dielectric strength and mechanical strength, high temperature stability and low d-c conductivity, make it especially attractive to the capacitor design engineer. In addition, some of its electrical properties can be improved by suitable heat treatment. This is illustrated in Figure 1 which shows the effect of heat treatment at temperatures up to the softening point of the film. A temperature of approximately 200 degrees centigrade for 2 hours is sufficient to produce the greater part of the benefits of such a treatment but the period of heating is not critical and longer times can be used to obtain some additional improvement. However heating for very much longer time or at much higher temperatures may produce a degradation, especially in breakdown voltage, as illustrated by the last point of the dielectric strength curve in Figure 1. Excessive heating leads to rapid crystallization of the film and the reduction in breakdown voltage of the units is believed to be due to the resulting embrittlement and mechanical damage to the film although there may be a change in its inherent dielectric strength.

DIELECTRIC STRENGTH

The data in Figure 1 were obtained with 0.2-microfarad capacitors having a single layer of Mylar approximately 0.0009 inch thick between electrodes. From the breakdown voltage data it can be seen that an ultimate dielectric strength of 4,000 to 6,000 volts per mil is realized. Tests with thinner single sheets between electrodes have given results averaging as low as 2,000 volts per mil, but it should be emphasized here that these are average results on a number of capacitors each having a total dielectric area of the order of 2 square feet. The usual dielectric strength test using electrodes of small area normally gives values much in excess of those obtained in capacitor units and it would therefore be expected that such tests would give values higher than the maximum given here.

CAPACITANCE STABILITY

Capacitor units which have been heat-treated at temperatures of approximately 200 degrees centigrade have the layers of film fused together and to a considerable degree the film adheres to the foil so that the winding becomes a solid mass. Consequently, such units show a high degree of capacitance stability even when subjected repeatedly to temperatures as high as 150 degrees centigrade.

DIELECTRIC LOSSES

The Q of Mylar (where $Q=(2\pi fC)/G\approx$ 1/power factor) at 1,000 cycles exhibits a maximum at about 80 degrees centigrade as illustrated in Figure 2. At lower frequency the peak is reduced and tends to shift slightly toward lower temperatures while at much higher frequency the curve is relatively flat. The variation in Q at 1,000 cycles with temperature makes direct comparison with other dielectrics difficult but in general it may be said that the Q of Mylar is at least equivalent to that of mineral-oil-impregnated paper over the temperature range of −40 to 100 degrees centigrade. It is inferior at room temperature and below to some impregnated paper capacitors which are designed especially to have low a-c losses. These and the other data reported herein are based on relatively few lots of the film and are not necessarily representative of what may be expected in large scale use of the material. However, there is relatively good agreement between data reported herein and that published by Reddish.[1]

TEMPERATURE COEFFICIENT OF CAPACITANCE

The capacitance-temperature characteristic of Mylar capacitors is shown in Figure 3. Large variations in capacitance are noted but mainly outside the usual range of temperatures. Within the operating range usually encountered, the temperature coefficient of capacitance of suitably processed units is lower than for any of the commonly used dielectric materials excepting mica. Frequency affects the shape of the capacitance temperature curve, and at frequencies higher than the 1,000 cycles for which Figure 3 is plotted the slope of the curve becomes somewhat greater over its central portion.

Insulation Resistance

Another of the outstanding properties of Mylar is its high resistivity over a very wide temperature range. Of the commonly used capacitor dielectrics only polystyrene exhibits a higher resistivity, and its use has been limited by a relatively low softening point, high cost of thin films, and other factors. While Mylar does not have the extremely high resistivity of polystyrene, its resistivity is much higher than that of other commercially used dielectrics as illustrated in Figure 4 which also shows for comparison the leakage resistance characteristic of a mineral-oil-impregnated paper capacitor. It may be noted that the Mylar capacitor has approximately 50 times the insulation resistance of the paper capacitor over the whole temperature range.

Life on Alternating Voltage

When operated with appreciable amounts of internal a-c corona Mylar film capacitors fail within hours or days, indicating only moderate corona resistance. Unimpregnated Mylar capacitors exhibit corona at 300 to 400 volts rms a-c and impregnation with oil or other suitable material is necessary if alternating potentials greater than these are involved. It is encouraging to note, however, that capacitors do not fail immediately on exposure to severe corona so that premature failure is not likely to result from infrequent short periods of overvoltage.

Life on Direct Voltage

The stability of Mylar under high electrical stress and at high temperature is likely to prove one of the most important of its advantages over other capacitor dielectrics. Impregnated paper capacitors are generally limited to operation at temperatures of 100 degrees centigrade or less but preliminary tests indicate that Mylar film capacitors may be used at temperatures at least as high as 150 degrees centigrade. Life tests in which capacitors are operated at a stress of approximately 700 volts per mil at 85 degrees centigrade are usually expected to produce capacitor failures within a period of 1,000 hours or less. In a test with Mylar capacitors at a dielectric stress of approximately 600 volts per mil there have been no failures after 5,000 hours at 130 degrees centigrade plus more than 4,000 hours at 150 degrees centigrade. Much more study will be required before temperature and voltage ratings can be firmly established but these preliminary results are most promising, particularly in the light of experience with other organic dielectric materials.

Moisture Resistance

All of the results discussed so far have been obtained with conventionally wound capacitors containing one or two layers of film between aluminum foils and heat-treated after being wound. The use of an impregnant may be necessary under conditions such as previously noted for high alternating voltages but in general it is felt that impregnation is unnecessary or even undesirable. Especially for those applications where the ultimate in insulation resistance or minimum a-c losses are required, the use of dry, heat-sealed Mylar appears to be most suitable. On the other hand, where the highest electrical characteristics are not required but where cost is a primary consideration, Mylar also appears to fill the need. Mylar capacitors are much more inert to the harmful effects of atmospheric moisture than impregnated paper types so that for applications involving moderate humidity conditions we believe that it is possible to use heat-treated Mylar units without additional protection.

An experimental capacitor intended for such application is shown in Figure 5. The terminals of this capacitor are headed wires embedded in the ends of the unit during heat treatment so that they are securely anchored. Heat-treated units of Mylar have withstood continuous

Figure 3 (below). The capacitance-temperature characteristic of a Mylar capacitor at 1,000 cycles

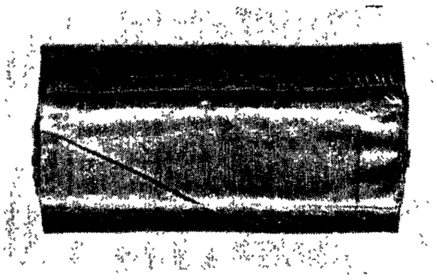
Figure 7 (right). A metallized Mylar capacitor unit



exposure to atmospheric conditions of 90-per-cent relative humidity at 85 degrees Fahrenheit for 7 months with no significant change in insulation resistance. In some instances, microscopic holes along terminals or at other points destroy the effectiveness of the Mylar seal, but vacuum impregnation of the heat-treated capacitor with wax seals those which might otherwise permit moisture to enter. Life tests on continuous voltage of unencased Mylar capacitors such as described also indicate that so long as humidity and temperature conditions are not extreme the life is not significantly affected by exposure to atmospheric conditions.

Film Structure

In heat-sealing capacitors made with films of several different thicknesses, it was found that all except one sealed satisfactorily. Units made with 0.25-mil film did not seal well; that is, in these units the dielectric extending beyond the metal foil electrodes did not fuse together to form a solid transparent mass like the other films. Investigation of this odd behavior led to an interesting correlation between certain physical characteristics of the sheets and heat-sealing properties and also dielectric properties. Despite the fact that wound capacitor units did not seal satisfactorily, sheets of the 0.25-mil grade fused together as well as the other grades when firmly pressed together and heated to the temperature employed to seal the units. This suggested a physical difference in the make-up of the various grades and hence the degree of orientation of polymer chains in the plane of the films was measured.

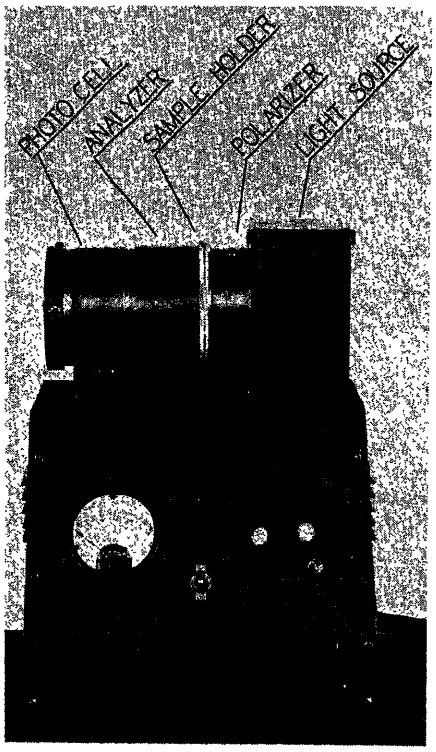


Figure 6. Polarimeter used to measure molecular orientation in Mylar and other films

These measurements were made in the apparatus shown in Figure 6. This is a polarimeter designed to measure orientation in sheets of anisotropic materials. A sample of the film is placed in a rotatable holder between polarizers whose planes of polarization are at right angles to each other. If the film is optically anisotropic, it will twist the plane of the beam from the polarizer so that it may pass through the analyzer. The light falling on the photoelectric cell on the other side of the analyzer will register on the microammeter shown on the panel. If the polymer chains are aligned or oriented with respect to some axis in the plane of the film, it is found by rotating the sample that at four different angular positions 90 degrees apart the transmitted light will reach a maximum and between these points it will reduce to a minimum. The ratio of the maximum to the minimum is a measure of the degree of orientation with respect to a given axis in the plane of the film. This, together with the level of light transmission, serves to indicate the sort of orientation existent in the film. If during rotation of sample the amount of light transmitted changes from very high to very low, uniaxial orientation is indicated. If the level is high for all angular positions of the film, this indicates a planar orientation which might be obtained by simultaneously drawing the film in two directions at right angles to each other. If, however, the light transmission is low at all angular positions, this indicates the absence of orientation at least in the plane of the film. The data in Table II indicate that the 1.0-mil and 0.5-mil films are highly oriented uniaxially, while the comparatively high transmission of 0.35-mil film in all positions indicates some sort of planar or biaxial orientation. The 0.25-mil film, however, shows very little orientation in the plane of the film. Heating the films to temperatures of the order of 400 degrees Fahrenheit results in a considerable amount of deorientation in the films which were highly oriented originally but causes little change in the 0.25-mil film.

Table II. Orientation of *V-200* Film

Sample, Mils	Light Transmission, Microamperes Max.	Light Transmission, Microamperes Min.	Uniaxial Orientation Factor
Original Samples			
1.0	25.1	1.5	17
0.5	23.3	0.8	29
0.35	9.0	8.0	1.1
0.25	1.6	0.4	4
Heated Samples			
1.0 —heated 2 hours at 400 deg. Fahr.	16.8	2.9	6
0.5 —from heat-sealed unit	3.0	1.6	2
0.25—from heat-sealed unit	2.5	1.0	2.5

These data were interpreted as follows. Extrusion and drawing of the film produces strains which are accompanied by orientation of polymer chains, the latter being a manifestation of the former. Subsequent heat treatment permits relaxation of the strains and deorientation. At the same time dimensional changes in the sheet also occur. The length and/or width of a highly oriented sheet will decrease and its thickness increase. Thus, when a unit wound with highly oriented film is heated, these changes would cause the layers of dielectric to come together firmly and bond securely. Inasmuch as the 0.25-mil film is not well oriented, pressure from this source is lacking, and a unit made with this film will not seal unless sufficient external pressure is applied. Besides this correlation between heat-sealing of wound units and orientation of film there appears to be some relation between dielectric properties and polymer orientation. It will be recalled that Figure 1 shows a progressive improvement in most properties with increasing temperature of heat treatment. The film used in these tests was highly oriented originally, and it has been shown that heat treatment causes deorientation. This may indicate that the dielectric properties of highly oriented film are inferior to those of film having a low degree of orientation but it is probable that changes in other properties, such as crystallinity, also take place on heating and these may also affect the electrical characteristics of the film. Nevertheless, the data at hand indicate that from the heat-sealing standpoint alone highly oriented film is to be preferred because of the ease with which it may be heat-sealed.

Metallized Mylar

The high mechanical strength and tear resistance as well as the high softening temperature of Mylar film makes it particularly adaptable to current metallizing techniques wherein the metallic film is deposited on the dielectric by condensation of the metal vapor under vacuum.[2,3] Metallized Mylar capacitors such as illustrated in Figure 7 have all the advantages of metallized paper types such as small size and self-healing characteristics and they have the further advantage over paper in that the Mylar film does not need to be lacquered before it is metallized.

Results with metallized Mylar are as yet rather scattered but there is reason to expect that for equivalent performance capacitors made with metallized Mylar will be smaller than those made with metallized paper.

It now appears that Mylar film may become the chief contender for the place of paper as the dielectric in electrical capacitors and further that Mylar capacitors will be superior in several respects, including insulation resistance, temperature coefficient of capacitance, and operating temperature range.

Digital-to-Analogue Shaft-Position Transducers

S. J. O'NEIL
ASSOCIATE MEMBER AIEE

IN THE design of digital computers the input and output data are often fed in or taken out in analogue form. These analogue forms may be voltages, pressures, meter readings, graphs, and so forth. At some point the output signals usually have to be converted from electronic form to mechanical motions or to indications of some nature.

For some applications it may be necessary to convert the output from digital form to an analogue output in the form of a shaft position. Where the output is displayed visually on a dial, this is the case. If the output must be fed into some analogue device, the analogue input is often a shaft position.

Since the rotation of a shaft is a relatively slow process limited by the moment of inertia of the rotating member, the friction at the bearings or other points of sliding contact, and the torque available to produce the rotation, it is usually necessary to introduce a parallel digit storage register from which the proper analogue outputs are derived. The derivation of a shaft position from such a parallel digit storage register is the subject of this paper.

The Problem

The problem is illustrated by Figure 1 which shows a parallel bank of five switches feeding the input terminals of a 5-digit shaft-position transducer. This parallel bank of switches actually may be a set of relay contacts opened or closed by driving-amplifier stages to correspond with the state of a parallel bank of high-speed flip-flop tubes. The flip-flop register in turn would probably be but one of many such high-speed output registers. Table I shows the method of shaft-position coding assumed. Straight binary coding only is assumed.

A convenient formula for readily determining the angle associated with any binary number is

$$\theta_q = a\left(\frac{360}{2}\right) + b\left(\frac{360}{2^2}\right) + c\left(\frac{360}{2^3}\right) + \ldots$$

where θ_q is the angle associated with the binary number

$a\ b\ c \ldots$

where

$a = 0$ or 1 is the most significant digit.
$b = 0$ or 1 is the second most significant digit.
$c = 0$ or 1 is the third most significant digit, and so forth.

Principles of Operation

The devices described in this paper depend on the generation of a magnetic field by the stator windings of a synchro or resolver type of output member. The magnetic field can be either a direct or alternating field depending on whether direct voltages or single-phase alternating voltages are applied to the stator windings. The rotor winding can be energized with the corresponding type of voltage and the resulting magnetic field interaction will cause the rotor to turn through the minor arc until a stable relationship between rotor and stator magnetic fields exists. Alternatively, in the a-c case the rotor winding may be used as the secondary winding of a control

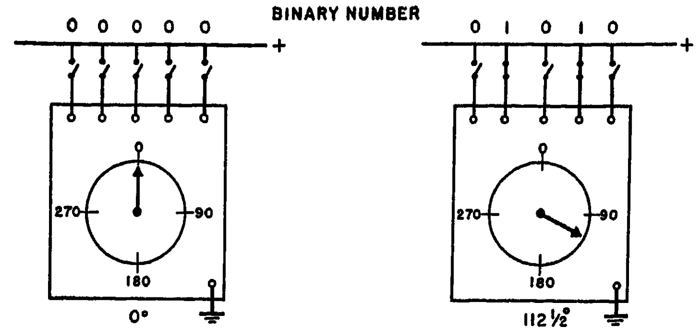
The author wishes to express his appreciation for the assistance of the members of the Air Force Cambridge Research Center Data-Link Utilization Unit who designed, built, and tested these shaft-position transducers and in particular to Second Lieutenant Robert P. Bigliano, United States Air Force, who invented the digital voltage divider network shown in Figure 6.



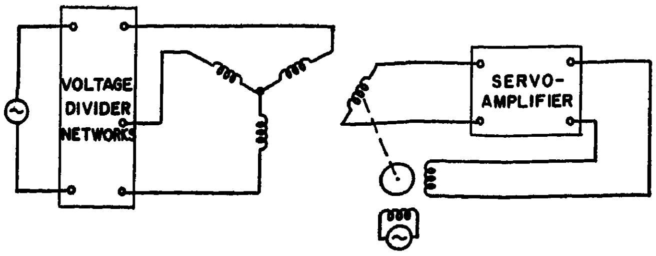


Figure 1 (left). The digital-to-analogue shaft position transducer

Figure 3 (above). Three-phase wound a-c control transformer

transformer which detects the amount and direction of angular rotation for a servomechanism follow-up system.

Figure 2 shows diagrammatically a 2-phase stator type of transducer which has two stator windings 90 degrees apart in space and a single rotor coil with a direct voltage applied to it.

Figure 3 shows a synchro-type transducer which is used as a control transformer to detect an error angle which is nulled by a servomechanism follow-up system.

Magnetic Field Generation

It is well known that the application of three alternating voltages 120 degrees apart in time phase to three windings symmetrically situated on a dynamo stator with their resultant coil axes 120 degrees apart in space phase will cause a rotating magnetic field to be generated in the stator, see Figure 4.

The direction of the instantaneous resultant magnetomotive force at time t_1 is given by the sum of three magnetomotive force vectors 120 degrees apart in space

$$F_r = F_1 + F_2 e^{j120°} + F_3 e^{-j120°}$$

where

F_r = the resultant magnetomotive force at time t_1

F_1 = the magnetomotive force in stator coil number 1 at time t_1

F_2 = the magnetomotive force in stator coil number 2 at time t_1

F_3 = the magnetomotive force in stator coil number 3 at time t_1

Neglecting saturation effects the direction of the resultant magnetomotive force may also be obtained by considering the instantaneous voltages in the stator coils. Since the coil voltages can be related to the applied voltages by means of a well-known circle diagram, the direction of the resultant field can be obtained directly from the applied voltages. If the direction of the instantaneous resultant magnetomotive force is known as a function of the instantaneous values of the applied 3-phase voltages, the angular direction of this field can be substituted as abscissa in Figure 4 in place of time. Therefore, Figure 4 not only can be used to obtain the instantaneous direction of a rotating magnetomotive force at some time t_1 but also can be used to obtain the resultant direction of the magnetomotive force set up by the application of direct voltages of suitable magnitude and polarity to the stator terminals. In other words, three direct voltages related in magnitude and polarity as shown for some angle in Figure 4 and applied to the coils will produce a resultant magnetomotive force in the direction of this angle.

If three single-phase alternating voltages related in polarity and magnitude as shown in Figure 4 for some value of resultant field direction are applied to the stator terminals, a stationary alternating magnetomotive force will be induced in this direction. These are the types of voltages which are normally induced at the stator terminals of a synchro transmitter whose rotor is held at some arbitrary position. In the circuit of Figure 3, for example, the output of the voltage divider network will be the equivalent output of a synchro transmitter.

The same principle can be applied to a machine with two stator windings 90 degrees apart (in space quadrature). The figure corresponding to Figure 4 for this case is Figure 5.

In this case the resultant magnetomotive force is given by

$$F_r = F_1 + F_2 e^{j90°}$$

Since the applied voltages are the coil voltages in this case, the direction of the resultant stator magnetomotive force can be related by a similar equation to the applied voltages.

Linear Voltage Approximations

The sinusoidal voltage amplitude curves shown in Figures 4 and 5 can be followed exactly to generate a very precise angle for a given digital input. Practically, however, this results in the use of a great number of switching elements in the voltage divider networks shown in Figures 2 and 3.

The use of digital information results in a quantization of the angle. For instance, if eight digits of a binary system are used to represent 360 degrees, only $2^8 = 256$ actual angles can be represented. Each angle will, therefore, indicate a range of angles

$$\theta = \theta_q \pm \frac{1}{2}\left(\frac{360}{2^n}\right)$$

where

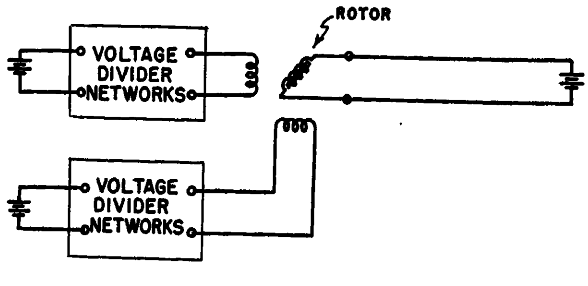

Figure 2. Two-phase wound d-c transducer

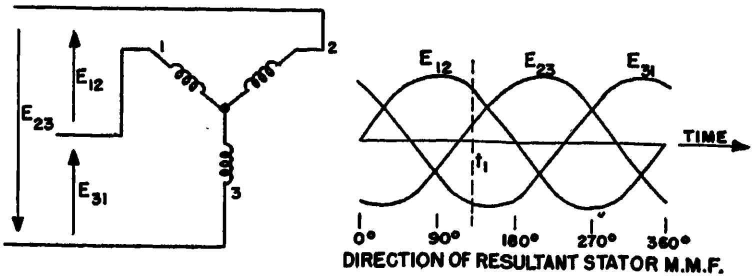

Figure 4. Instantaneous direction of resultant magnetomotive force in a 3-phase wound stator

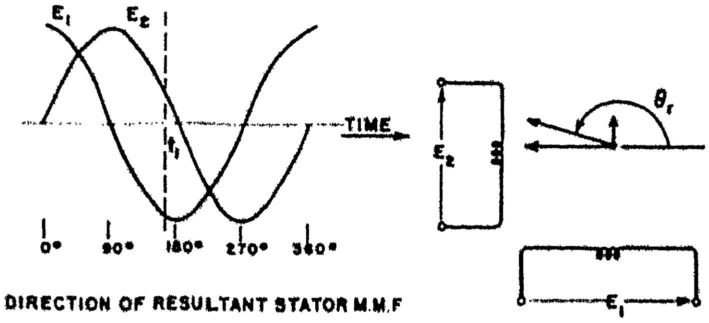

Figure 5 (above). Instantaneous direction of resultant magnetomotive force in a 2-phase-wound stator

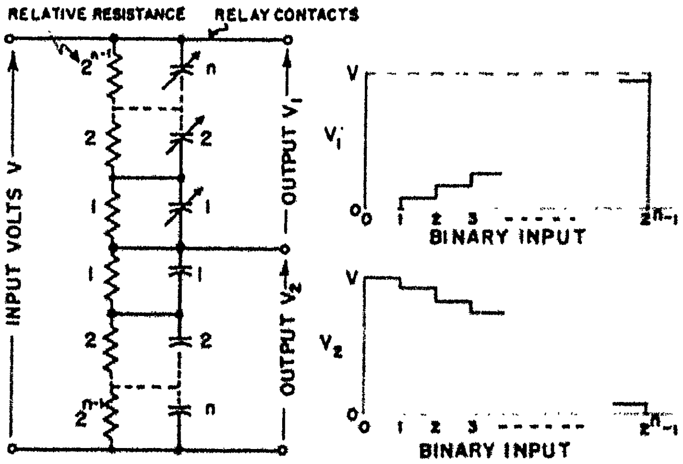

Figure 6 (right). Digital-to-analogue linear voltage divider

θ_q — the quantized angle derived from digital data

θ — the actual range of angles corresponding to θ_q.

n — the number of digits used to code the angle.

The degree of precision of any angle derived from digital data is $\pm 360/2^{n+1}$ degrees. Therefore, for an efficient over-all design the shaft position transducer need not yield an angle to an accuracy greater than $\pm 360/2^{n+1}$ degrees.

To minimize the number of switching components it is desirable to approximate the sinusoidal voltage amplitude distributions by straight line segments. A digital to analogue linear voltage divider involves fewer components than a sinusoidal voltage divider since linear voltages can be subdivided into binary form and added in combinations to produce any output. A circuit of this type is shown in Figure 6.

The circuit of Figure 6 produces two different discrete voltage outputs whose sum is equal to the input voltage V. The output voltage V_1 is a linearly increasing voltage proportional to the digital input. The output voltages may be expressed mathematically by the following

$$V_1 = \left(\frac{x}{2^n - 1}\right)V$$

$$V_2 = \left(1 - \frac{x}{2^n - 1}\right)V$$

where x = the decimal equivalent of the binary input represented by the energizing of the relays.

The accuracy of this circuit depends upon the precision of the resistors in the voltage divider network and the relative impedance of the connected load. If the load impedance is not high compared with the network resistance, a cathode follower stage may be introduced between the network and the load.

Design Problems

Two-Phase Wound Stators

The input voltage magnitudes to these windings may be approximated as shown in Figure 7 or 8.

The accuracy of the method of Figure 7 is ±1.1 degrees while that of Figure 8 is ±0.1 degree. The trapezoidal approximation of Figure 7 is therefore suitable for 5-digit or 6-digit coding where the degree of coding precision is ±5.6 degrees or ±2.8 degrees. Although the method of Figure 8 leads to a more complicated switching arrangement, its inherent accuracy makes it suitable for 8-digit or 9-digit coding where the degree of precision is ±0.7 degree or ±0.35 degree. It is apparent that for both of these methods some special switching must take place to select a given octant and that linear voltage dividers may be used inside the octant. The circuit diagram of a switching arrangement actually used for the multislope approximation of Figure 8 is given in Figure 9. This diagram shows the two stator coils

but does not show anything connected to the rotor coil. In practice the 2-phase output member has been used satisfactorily both as a transducer with a voltage applied to its rotor and also as a control transformer type of error detector for a servomechanism follow-up system. Greater accuracy can be obtained by using the torque amplification afforded by the servomechanism system. Devices which produce their own torque are limited by the angular displacement accuracy of the stator windings and the fact that the torque versus angular displacement curve is sinusoidal as in a synchro (see Figure 10) and coulomb friction produces some errors. In practice the application of pulsating direct voltages to the stator windings of transducers reduced the effects of coulomb friction and also resulted in a lower operat-

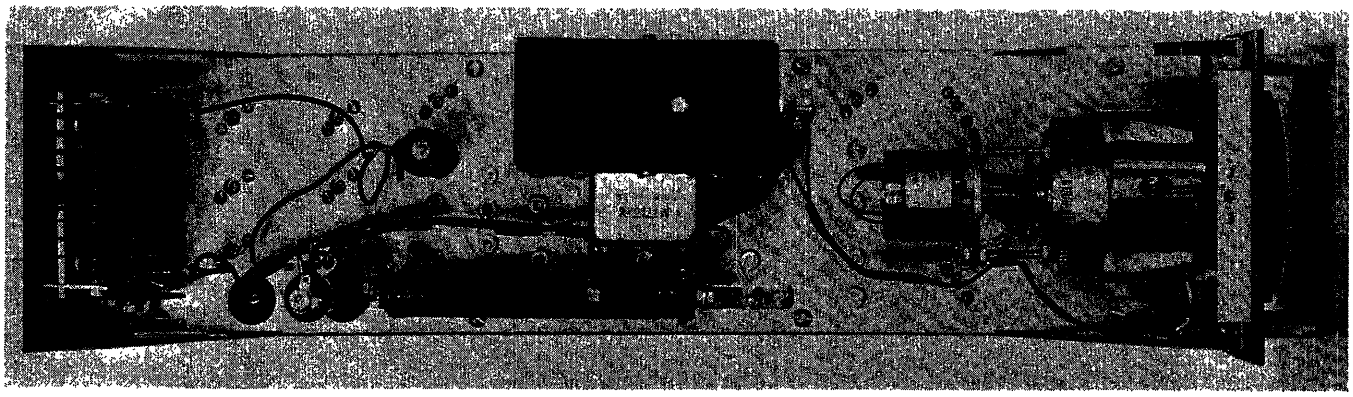

Figure 13. Top view of digital-to-analogue shaft position transducer

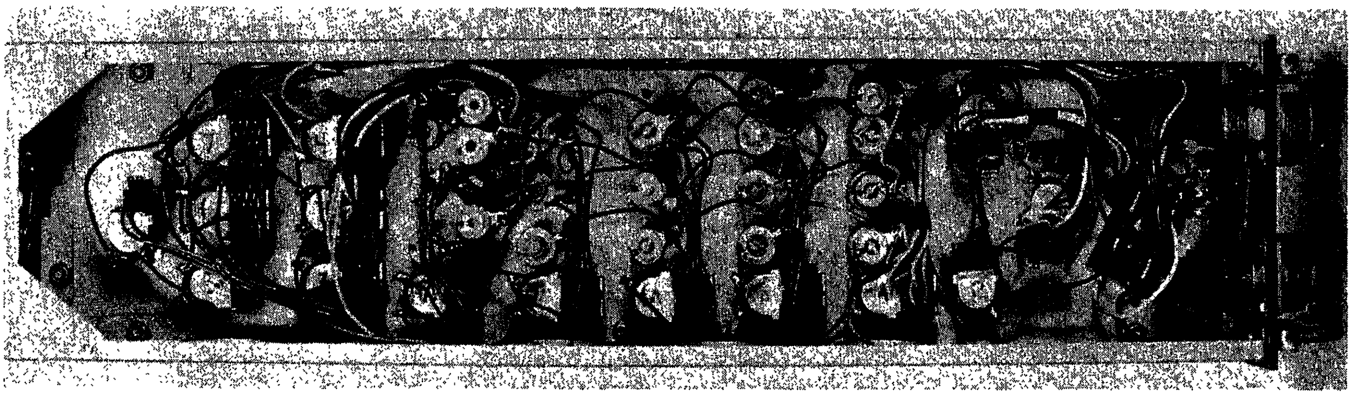

Figure 14. Bottom view of digital-to-analogue shaft position transducer

ing temperature.

The linear voltage approximations produce some unbalance between induced rotor voltages and the applied rotor voltages. These voltage differences set up circulating currents whose energy must be dissipated in the internal impedance of the voltage sources, the impedance of the transducer windings, and the voltage divider impedances. This internal dissipation of energy causes some heating, but this heating was not found to be excessive. The actual unbalanced rotor voltages are a function of the angular displacement of the transducer. A judicious choice of applied rotor voltage will limit this unbalance to equal maximum swings in either direction. For the trapezoidal case of Figure 7 this amounts to ±17 per cent of the applied voltage. For the multislope case of Figure 8 the maximum unbalanced voltage is ±3 per cent of the applied rotor voltage.

THREE-PHASE WOUND STATORS

The input voltage magnitudes to these windings may be approximated as shown in Figure 11.

The accuracy of this method is ±1.1 degrees which makes it suitable for 7-digit angle coding. A special form of coding is required since angular sextants, rather than octants, are used in this method. The first three digits may be used to select a sextant thereby wasting two out of eight possible combinations of the first three digits. If this device is used over an angle of 120 degrees or less, a straight binary system with no waste of digits is possible. The output of this device can be used to drive an ordinary synchro either as a synchro motor or as a control transformer error detector in a servomechanism follow-up system. If the output is used as a synchro motor to supply its own torque, the maximum unbalanced rotor voltage will be ±12 per cent of the applied rotor voltage.

Conclusions

This paper has presented for the first time the principles of operation of some minor-arc-sensing magnetic devices for converting from a digital parallel register output to a shaft position. The basic principles behind the generation of suitable alternating or direct voltages for application to standard 2-phase resolvers or 3-phase synchros have been developed.

Design approximations which can be used to minimize the amount of switching equipment were outlined, and criteria for arriving at suitable design approximations were shown.

These transducers can be used either to generate their own torque and turn to the proper position or they may be used as control transformers in conjunction with servomechanism follow-up systems.

The field of endeavor represented by the development of these digital-to-analogue transducers and their associated switching circuits will bridge the gap between the almost totally electronic functions of the digital computer and the mechanical or electromechanical functions of an analogue output.

No Discussion

Principles of Tape-to-Card Conversion in the AMA System

WILLARD B. GROTH
ASSOCIATE MEMBER AIEE

BILLING data for customer-dialed local and toll telephone messages are now recorded and processed by means of the automatic message accounting (AMA) system in the areas of seven principal cities in the Bell System network.

The AMA system records the information required for billing the customer in the form of perforations in paper tape in the central office. Recordings are made while the switching machinery is establishing connections between telephone lines and while the messages are in progress.

The perforated paper tapes are cut daily and forwarded to an accounting center where the information is processed through a series of machines each of which, with the exception of the last, produces new paper tapes. Individual message records are assembled and chargeable message units or chargeable time in the case of toll messages are determined. Individual message entries are sorted by calling line number, message units for a given billing period are added, and finally message unit summaries and individual customer toll slips are printed. The printed output of the AMA accounting center is used by clerical personnel in producing toll service statements and customer bills.

The AMA system in its first phase was completely described in an earlier paper.[1] It is the object of this paper to describe the latest development in the AMA system, namely the means and technique for converting at the most suitable stage in the process from the use of AMA paper tape to the use of standard business machine cards as a medium for handling message data. This development was carried on with the objective of making the accounting process more efficient by preparing toll service statements automatically and by providing the means for ultimately processing message unit data automatically. This process is known as tape-to-card conversion and will have a marked effect upon the routines followed in the accounting center. Tape-to-card conversion therefore is not merely an adjunct of the AMA system but a new process intended to supplement AMA in its present form. The system may then be more widely applied in an ever-increasing field.

Need for Improved Methods

Automatic message accounting, in its first phase, is not fully automatic in that the printed end products, message unit summary lists and toll slips, require manual processing. A message unit summary list for each central office indicates the summary of local message units for which each customer is to be billed. A portion of such a list with an interpretation of the numbers is shown in Figure 1. A toll slip shows for an individual customer a detailed record of all toll messages (nine per slip maximum) for a given billing period. A toll slip with the record for two toll messages is shown with an interpretation of the data in Figure 2.

A clerical force determines, from the message unit summary list, the charge including tax for each customer. They also compute the charge for each of the toll messages, the total of such charges, and the tax for all toll message business. A toll service statement giving details of all toll messages is furnished and a bill is prepared.

That message accounting on a fully automatic basis will eventually become imperative for efficient operation is indicated by the volume of traffic involved and the fact that an increasing proportion of toll messages, including the long-haul variety, will be customer-dialed in the not too distant future.

As an illustration of the tremendous volume of business involved, certain message rate statistics for the Bell System are shown in Table I. It might be expected that the numbers found in this table will increase through the coming years, and further, that the percentage of messages which are candidates for customer dialing will increase. This increased percentage might be anticipated since with a spread in the use of customer dialing and the decrease in times for establishing connections using the new switching systems, the tendency will be toward more frequent use of station-to-station service.

Modifying the System

The plan for making the system more fully automatic with the prospect o eventually making it completely automatic is to use standard punched card machines, products of the International Business Machines (IBM) Corporation. A system plan was devised to arrange a variety of card machines to process toll message information for the production of toll service statements. The toll service statement lists detailed information for each toll message including charge total toll message tax, and total charge plus tax for all toll messages for a billing period. This card machine system and its output are described in a companion paper.[2] Another system plan is to be made to use card machines for processing message unit message information.

The link required for bridging the gap between AMA and card machine systems is a machine which transfers message information from AMA tapes to business machine cards. The machine developed for converting from one recording medium to the other, for both local and toll messages, is the tape-to-card converter.

A brief review of the machine operations performed in AMA first phase will be given at this point so that the reader may gain a better understanding of the part played by the tape-to-card converter in the over-all system. The flow chart of

Figure 2. AMA toll slip and interpretation

Figure 3 indicates the first phase operations in sequence.

A central office AMA tape from a single recorder comes to the accounting center with a record of all messages, since the last tape cutting, that have passed over a group of a maximum of 100 trunk circuits. The record for each of the messages appears as several transverse lines of perforations in three distinct tape entries. Each of the entries is perforated at a definite stage in the progress of the call. The initial entry is made immediately after customer dialing and trunk seizure for the recording of calling line number and a 2-digit number designating the trunk. The called line number, called office, and area are also recorded if the message is to be detail-billed. The second entry is made when the called line is answered and records the start time of conversation and the number of the trunk. The third entry records the disconnect time and again the trunk number. Since many messages may be in progress at one time, the three piece records thereof may be interspersed on the common record tape.

The AMA assembler in the accounting center is used in a 2-stage process, sorting first by units and then tens digits of trunk number to perform the function of assembling the pieces of the individual message records on a new piece of AMA paper tape. Actually ten new tapes, numbered 0 to 9, are produced at each digital sort and they must be manually spliced together in numerical sequence to form a new continuous tape in preparation for the next stage in processing.

The AMA computer is then used to

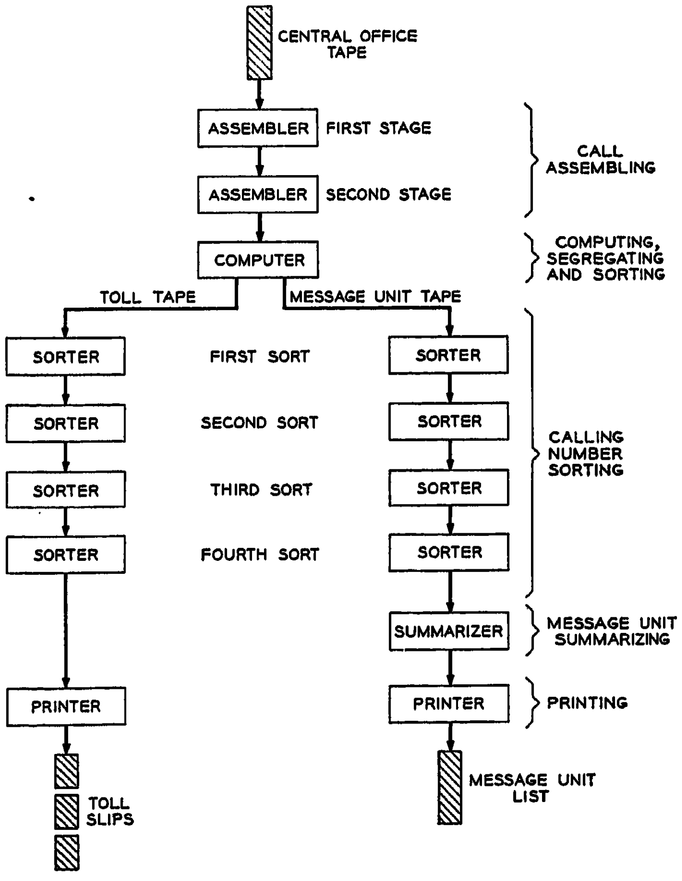

Figure 3. Flow chart of AMA accounting center processing (first phase)

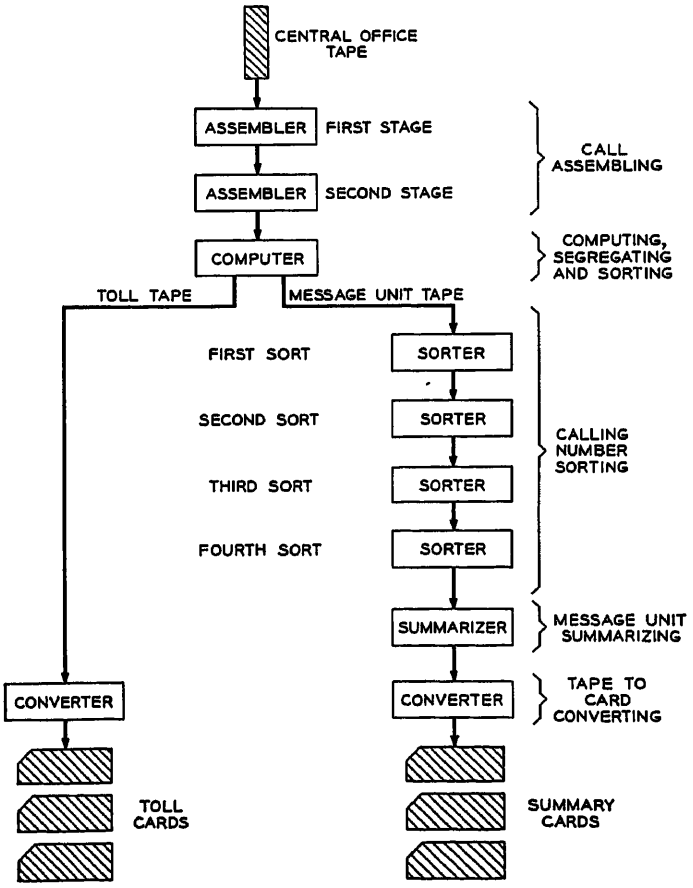

Figure 4. Flow chart of AMA accounting center processing (with conversion)

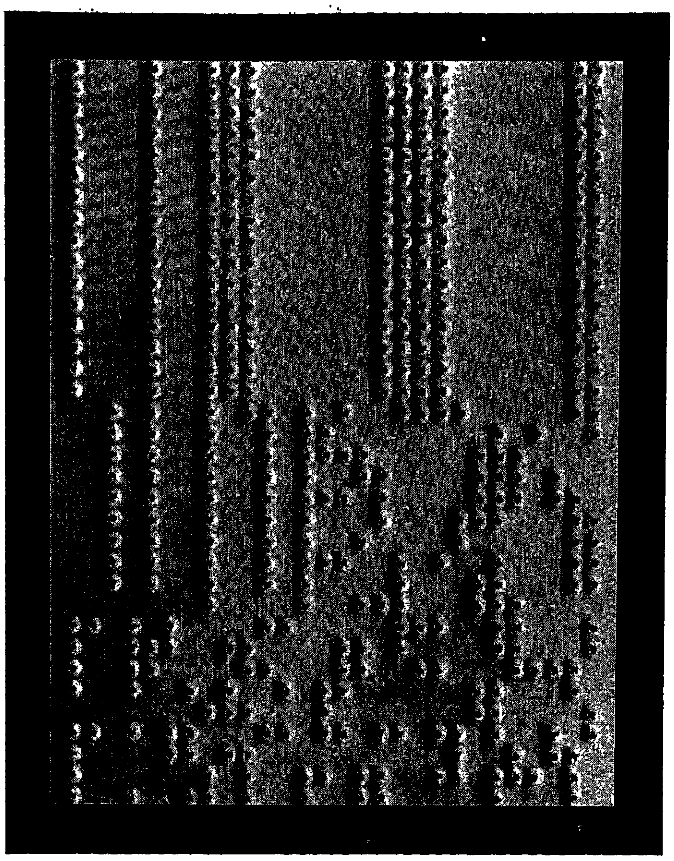

Figure 5 (left). Leading end of an AMA toll tape

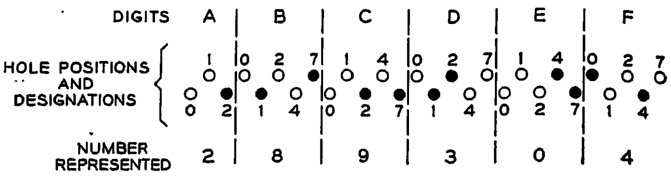

Figure 6 (above). Representation of an AMA tape line

perform the function of subtracting start time from disconnect time, for each message, for the determination of chargeable time in the case of toll messages or message units in the case of local messages. A distinction, not previously mentioned, exists between calls and messages. A message is defined as a completed call. Calls which are not completed, either because the called line is busy or because the call is not answered, will have no time entries perforated on the record tape. Approximately 30 per cent of all telephone calls fall in this category. Such calls are discarded by the computer. The computer performs another function, that of segregating messages by type, with the result that the recorded and calculated data for all local messages appear on a newly perforated set of tapes and the data for all toll messages on another new tape. Local message data may be perforated on a plurality of tapes when a sort by calling office is required or when a sort by one digit of calling line number will reduce by one the number of subsequent sorting stages.

The AMA sorter is then brought into play to sort the toll tape by calling line number in a 4-stage run. The final output of the sorter is a new tape with all the messages for one telephone line in sequence and these calling line records in numerical sequence. The sorter run is repeated for the local message output of the computer.

The AMA summarizer is used to process sorted local tape which results in the perforation of a new tape with one entry per calling line number with a summary of local message units.

Finally the AMA printer is put to work on summary tapes and sorted toll tapes for the production of the message unit summary lists and individual toll slips described here and shown in Figures 1 and 2.

The points at which the AMA local and toll streams are diverted for tape-to-card conversion were chosen for most efficient operation. The toll stream is diverted at the output of the computer where calculated data of chargeable time are available. Since the computer discards incompleted calls, the partial records thereof do not enter into the tape-to-card conversion process. AMA tape sorting is eliminated, since the punched card machine system is arranged in such a way that calling line number sorting must be done at a later state in the process. The sorting operation is then performed in card machines.

The stream of local AMA traffic is diverted at the output of the summarizer where the number of entries is reduced to a minimum. At this point there is only one entry per telephone line, if the summary is less than 1,000 message units, while at the output of the computer there is one entry per message. The sequences of operations for local and toll business thus determined are portrayed in the flow chart of Figure 4.

AMA Tapes and Business Machine Cards

A brief description of the physical appearance of an AMA tape and a discussion of the coding and tape reading techniques will serve to acquaint the reader with the input medium of the tape-to-card converter. The business machine card used for the output of the converter will also be described.

Figure 5 shows the leading end of a toll tape. AMA paper tape is 3 inches wide and when perforated with message information is covered with embossments which are a result of the method of perforation.

An information line on the AMA tape consists of 28 hole positions in a sawtooth line, so planned to allow sufficient clearance between mechanical parts of the perforators. A line is divided into six digits, *A* through *F*, as illustrated in Figure 6. The *A* digit comprises three hole positions (0, 1, 2). One of these positions will be perforated for the repre-

Table I. Bell System Estimated Annual Call Rate in Millions, December 1951

Type of Call	Customer-Dialed	Candidates for Customer Dialing	Remainder	Total
Multiunit				568
Short-haul toll		970*	112	1082
Multiunit plus short-haul toll†	405	1100	145	1650
Long-haul toll		300*	300	600
Multiunit plus all toll		1805*	445	2250

* Includes those already customer-dialed.

† 5 cents to 35 cents.

sentation of a number. For example, the black circle in the *A* digit in Figure 6 indicates a perforation representing the number 2. Each of the remaining digits, *B* through *F*, comprises five hole positions (0, 1, 2, 4, 7). Two of these hole positions will be perforated in each digit for the representation of a number. Since there are ten combinations of five things taken two at a time, any one of the ten digital values, 0 to 9, may be represented in any of the digit positions, *B* through *F*. The hole positions are designed to represent numbers on an additive basis. For example, 1 and 7 in the *B* digit represent the number 8; 2 and 7 in the *C* digit represent the number 9 and so on. The only exception to the additive rule is the combination, 4 and 7, which is used to represent 0.

Adjacent lines on an AMA tape are dovetailed together so that the spacing between hole positions in a line and between lines is uniform.

An AMA reader has 28 steel sensing pins which are brought against the paper tape for the reading of a line. Pins encountering paper will be restricted in their motion while those finding holes will travel farther causing contact closures. Eleven contact closures constitute the reading of a good line.

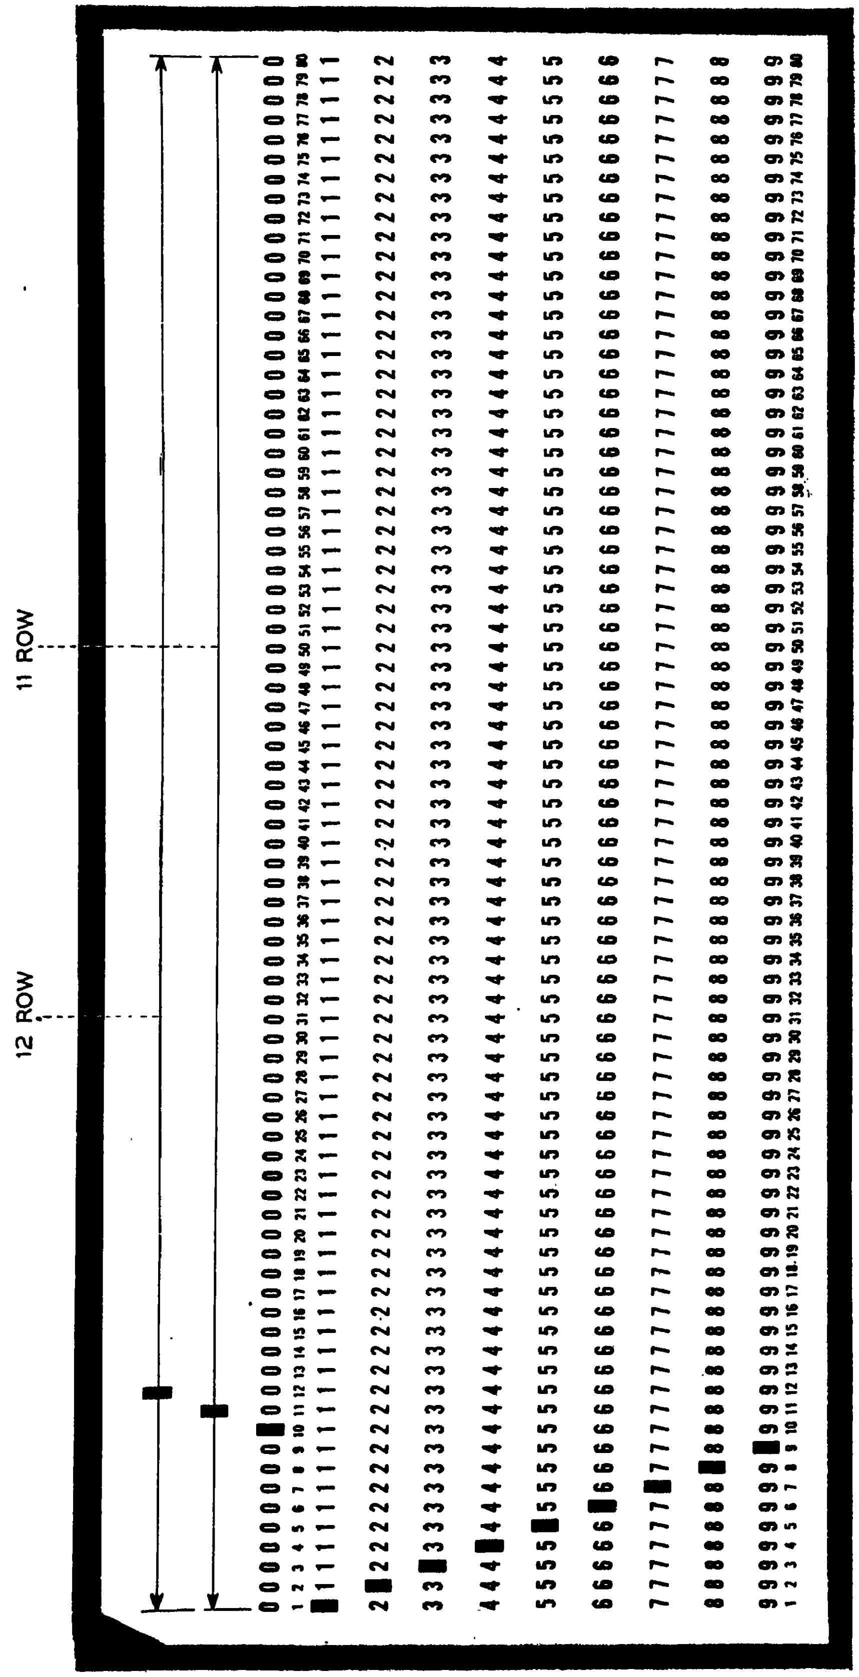

Figure 7. A numbered business machine card

A business machine card, representative of the output media of the tape-to-card converter, is made of stiff card stock $3\frac{1}{4}$ inches by $7\frac{3}{8}$ inches. Figure 7 shows a numbered card with several punched holes. The card is divided into a grid of 12 horizontal rows

12, 11, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9

and 80 vertical columns, each of which may be punched with one or more holes for the representation of information. The two uppermost positions, 12 and 11, are reserved for special punches; the remainder, 0 through 9, shown numbered in the illustration, are used for digital information.

The Tape-to-Card Converter—General

The machine used for conversion broadly resembles the other AMA accounting center machines. A standard AMA reader is used for electrically deciphering the information on the input tape. Relay circuits are used for the functions of memory, checking, and translating but here the similarity ends. The quantity and arrangement of the input information, the nature of the translations required, and the form of the output, as well as the manner in which the output mechanism operates, require the use of

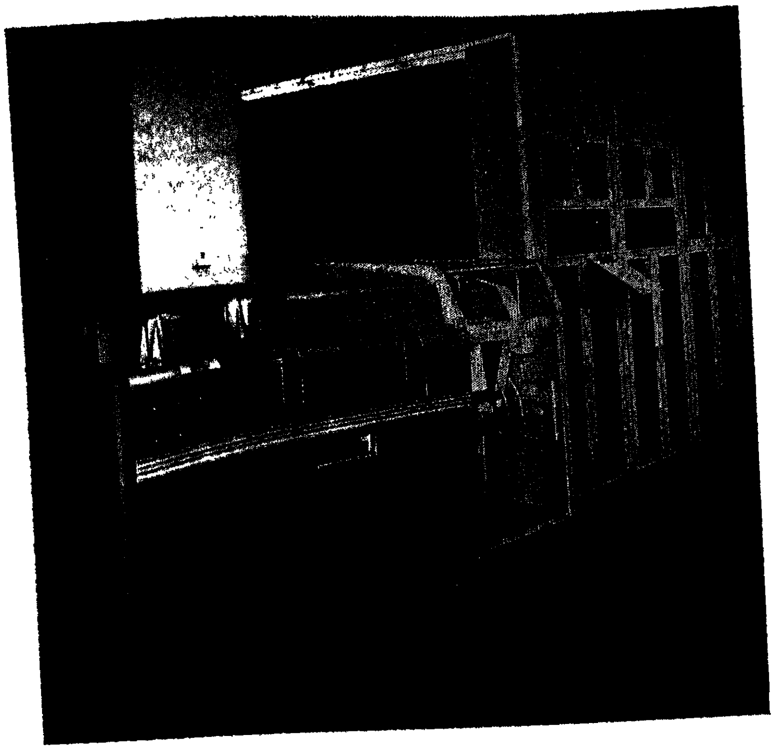

Figure 8 (left). The AMA tape-to-card converter

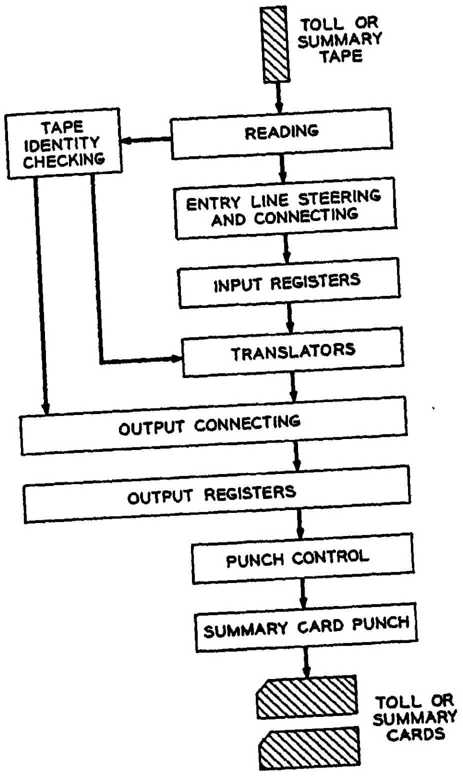

Figure 9 (right). Functional block diagram of AMA tape-to-card converter

unique circuitry throughout the machine.

The other AMA machines, with the exception of the printer, use perforators to produce output tapes of the same type as the input. The perforators are controlled by and synchronized with the reader, while the pattern of holes for a particular line is determined generally by information in relay storage registers. The converter, however, uses for its output a standard summary card punch. The card punch is controlled by relay circuits in the converter portion of the machine. The operation of these relay circuits in turn is controlled by and subject to the timing of the AMA reader. The control of the overall machine therefore is vested in the AMA reader, while the timing, to take full advantage of the speed of the output machine, is controlled by the fixed card cycle time of the punch. This problem of control and timing will be discussed in greater detail later.

Figure 8 shows the converter. Three relay cabinets, housing a total of approximately 700 relays and featuring operating and display panels, are shown with the reader cabinet and the associated IBM 519 Summary Punch.

Figure 9 is a functional block diagram of the converter. A tape to be processed for card conversion is fed into the reader of the tape-to-card converter. The job of the converter is to read and memorize the consecutive lines of a tape entry, perform certain translations, and control the card punch machine to punch memorized and translated information on a card.

The numbers are memorized exactly as found in the tape entry. Certain of these numbers, such as those representing calling line number, are to be punched in the output card, while others, such as a single digit representing the 3-digit calling office code, must be translated into a more suitable form before they are made available for punching. The necessary translations are performed during the reading and registering interval.

When the input tape entry has been completely read and satisfactorily registered, a signal to the card punch indicates that information will be available shortly for punching a card, thus setting the card feed mechanism into motion. At the same time, the registered and translated items of information required for punching are transferred to a set of output storage registers. When this second set of relay registers is completely filled, the connection between them and the input

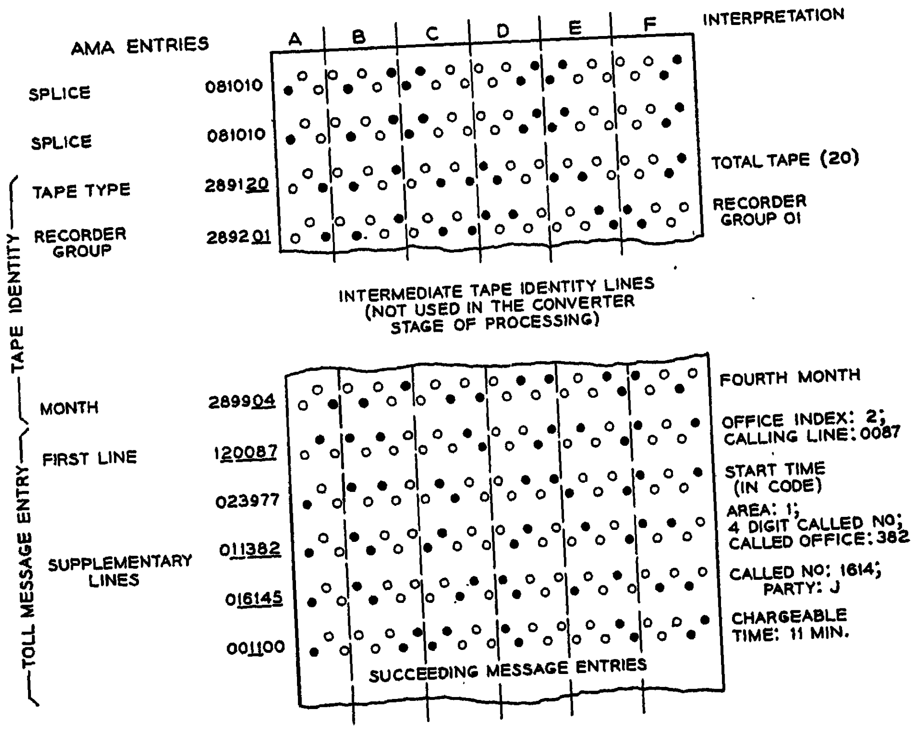

Figure 10. Representation of leading end of typical AMA toll tape

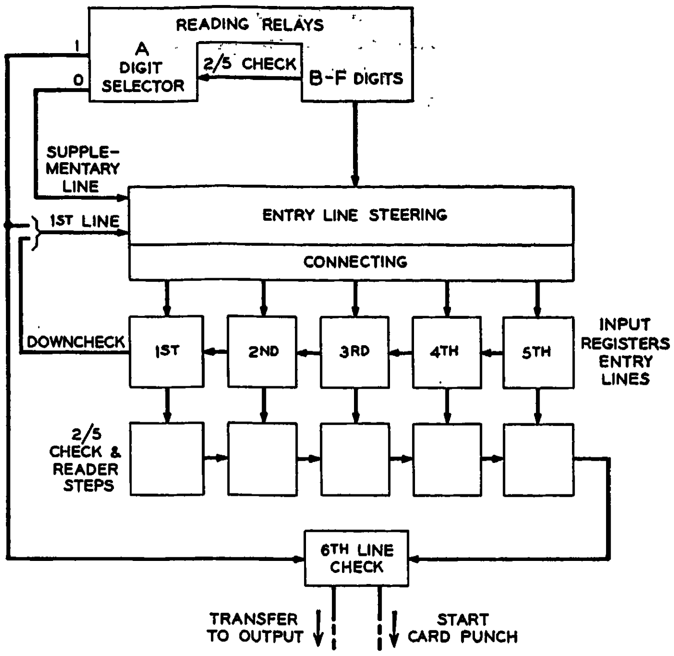

Figure 11 (above). Functional block diagram of reading and registering a toll tape entry

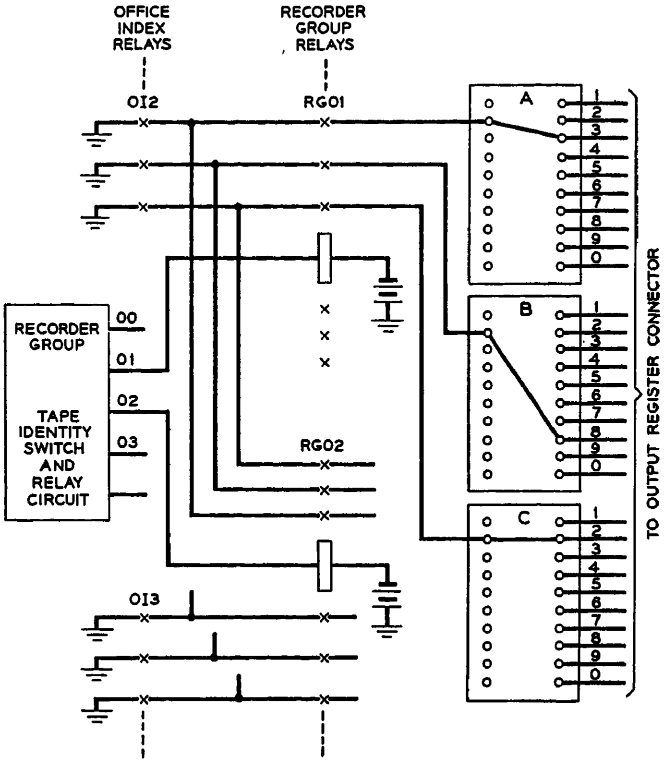

Figure 13 (right). Functional block diagram of calling office translation

registers and translators is severed. The input registers and translators are then released. The machine immediately begins to read and memorize, one by one, the lines in the next entry.

Meanwhile the card punch, in response to the first input register signal, will have advanced the card feed mechanism to the point where a card is to be punched. The card is punched, one horizontal row at a time beginning at the top, with the information stored in the output registers. Each of the output registers has assigned to it, on a flexible basis, a particular column on the output card. The four-digital calling line number registers, for example, might contain the information 1234. The corresponding card columns would then be punched during the 1, 2, 3, and 4 row punching times respectively to indicate the calling line number.

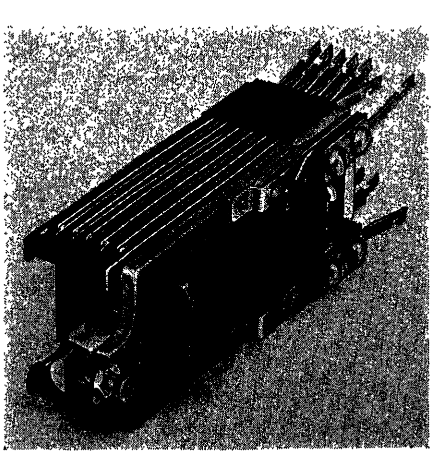

Figure 12. The general-purpose relay used in the AMA system

Since the card is punched one horizontal row at a time and since the punching cycle for a card cannot be interrupted, the complete information for a message must be available before the punching cycle begins. This dictates the need for the complete set of output storage registers.

Following the punching operation, the output registers are released. The registered and translated information for the second call entry is transferred thereto while the second card is advanced for punching. The converter thus deals with the information for consecutive message entries in an overlap operation.

The tape-to-card converter is controlled in actual operation by the manipulation of keys in the operating panel and certain other manual preparations. A tape to be fed into the reader is usually long enough to be wound on a reel which is placed in the feed position in the reader cabinet. As the tape is advanced beyond the reader it is automatically rewound on a take up reel, thus permitting the input side of the machine to run on an unattended basis. A tape is started by having the first few lines of its leading splice pattern advanced, under manual control, to engage the reader drum. A machine start key causes the reader to read and advance consecutive lines of splice pattern until the first of a group of lines known as tape identity is encountered. Figure 10 shows a representation of the leading end of an AMA toll tape and an interpretation of the numbers thereon. The machine checks tape identity items against the settings of manually controlled rotary switches on the operating panel. If there is agreement, the machine steps the tape through tape identity. Following tape identity, the machine encounters message entries and proceeds to convert the information, entry by entry, in overlap operation as described previously, to run the card punch at the rate of 100 cards per minute.

Trailing tape identity follows the last message entry and the machine rechecks to insure that switches have not been reset inadvertently during the run. Resetting of a switch might result in false accounting. The reader then skips trailing splice pattern and an alarm is sounded to indicate the end of the run.

Minor modifications in the IBM *519* Summary Punch together with a special circuit arrangement in the converter permit stopping and restarting the machine from the card punch operating panel. This facilitates the manual operation of card removal. Blank card supply may be replenished while the machine is running.

A more detailed description of the operation involved in several broad functions of the converter is given now. This will serve to illustrate the manner in which switching circuit techniques have been applied to the field of automatic message

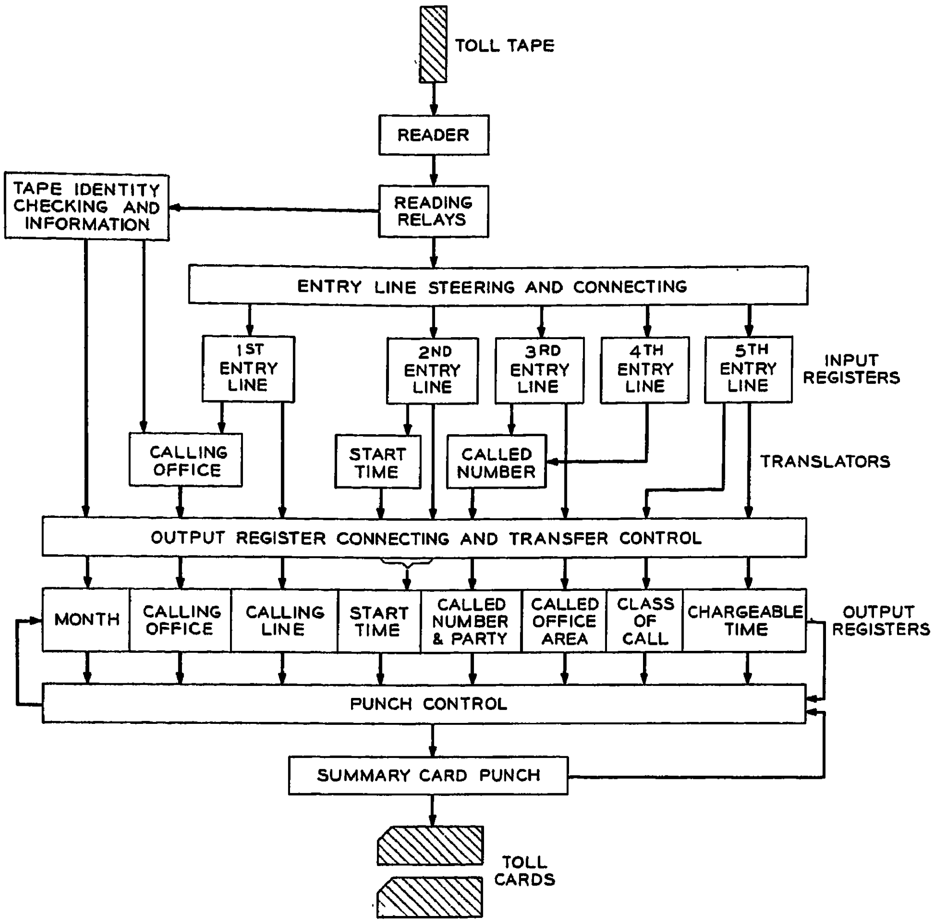

Figure 14. Functional block diagram of AMA tape-to-card converter, detailed for toll use

accounting, and at the same time give a better understanding of the tape-to-card converter.

Reading and Registering a Tape Entry

A toll message entry with an interpretation of the numbers therein is represented in Figure 10. This sample entry may be used as a reference in the ensuing descriptions.

Figure 11 is a functional block diagram of the reading and registering operations. The first step in reading and registering a tape entry is to establish a connection between the reading relays and the first line input register. The connection is made subject to the coincidence of two electrical checks:

1. All input line registers released (this signal is known as a downcheck).
2. Reading relays, *B* through *F* digits, operated on a 2-out-of-5 basis plus a 1 in the *A* digit (first line indication).

When the connection is made, the first line register is operated to store the first tape entry line. Following this, a contact network on the first line register relays will pass a signal, if the relays are operated on a 2-out-of-5 basis (such a signal is known as a 2-out-of-5 check or an upcheck), to permit the reader to step, advancing the tape by one line. The reader step signal also advances a steering circuit in preparation for making the next connection to the second line register.

A new 2-out-of-5 check on the *B* through *F* digit reading relays plus a 0 in the *A* digit (supplementary line indication) causes this second connection to be made. The first and supplementary line indications may be found in the *A* digits of the toll entry in Figure 10.

This steering, connecting, and stepping sequence is used to read and register the five consecutive lines of the tape entry in the five input line registers. It should be noted that only the *A* digit of a line need be known to the machine for determining its action in these operations. The information in the *B* through *F* digits of each of the five lines is memorized by the device of locking relays operated.

The initial downcheck (registers released signal) and the upchecks (2-out-of-5 checks), designed specifically for converter operation, are typical of AMA circuit arrangements. The upchecks guarantee that a good number has been read or registered, since a single trouble, consisting of an additional hole in the paper tape, a dirty contact in the chain, or a broken wire, will prevent the circuit from progressing. Such checks are necessary for the accuracy required in accounting work.

The relay operations necessary for the reading, connecting, registering, and reader stepping of a tape line involve a 4-stage sequence which must be completed within the reader make period of approximately 40 milliseconds. This explains the necessity for the use of the high-speed relays which have found wide application in the AMA machines. A flat type relay, of fairly recent design with upper and lower sets of card operated twin bifurcated contacts, has been used as the work horse in the AMA system. One of these relays, which has an operate time of approximately 7 milliseconds, is illustrated in Figure 12. During the break or open portion of the reader cycle, which lasts approximately 20 milliseconds, the reading, connecting, and steering relays release simultaneously.

When the first line of the second entry is read, 1 in the *A* digit indicates that the correct number of supplementary lines has been registered for the first entry. This indication, plus the five input line register upchecks, initiates two signals:

1. Signal to start card punch for punching first message card.
2. Signal to transfer input registration plus translations to output registers for punching.

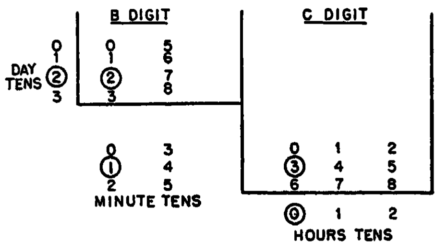
Translation in the Tape-to-Card Converter

As indicated in the foregoing, certain items in the input tape entry will be made available for punching on the output card without any change in digital value. Other items of information in the tape entry must undergo some change to be in a presentable form for punching. The function of changing the representation of an item of information from one pattern or set of numbers to another is known

Table II. Numbers and Letters in Telephone Dial Holes

1	2	3	4	5	6	7	8	9	0
	ABC	DEF	GHI	JKL	MNO	PRS	TUV	WXY	Z

Table III. Start Time Code



as translation. There are several translations, using this definition, required in the operation of the converter.

In one translation, the converter makes use of tape entry and tape identity switch information to construct a 3-digit number for calling office identification. Any three digits may be selected, by a flexible arrangement of wiring, to identify a given office. One possible arrangement is to translate to the digits that would be used in dialing that office. This translation is described now.

The *B* digit of the first line of a toll entry is the office index, which indicates the number of the calling office within a group of central offices served by a common group of AMA recorders, a common situation in metropolitan areas.

The office index, and the recorder group number as indicated by the tape identity switches, identify the calling office. The block diagram of Figure 13 shows in abbreviated form the manner in which the translation to calling office code is accomplished. The combination of an office index relay operated from the first line *B* digit, 2 in this example, and a recorder group relay corresponding to the settings of the recorder group switches, 01 in this case, passes a signal to each of three terminal strips, *A*, *B*, and *C*. Cross connections to the opposite sides of these strips perform the translation which is extended to the output registers when the connectors are operated. The calling office code for the connections shown might be *EV*2. The information, however, is placed in the output registers on a numerical basis, which for this example would be 382. The corresponding numbers and letters in the dial holes are shown in Table II.

Another translation must be made using certain numbers in the second line of the tape entry. This line contains numbers giving the start time which consists of day tens and units, hour tens and units, and minute tens and units. In the interest of confining the start time to one line, the computer is designed to compress the six digits into the five digit spaces of a tape line. This is accomplished by placing the day, hour, and minute units digits, unchanged, in the *D*, *E*, and *F* positions, respectively, of the second line. The day, hour, and minute tens digits are compressed into the *B* and *C* positions in accordance with the code shown in Table III.

The computer, for the example in Figure 10, found the start time of the call to be:

day of month	29
hour of day	07
minute of hour	17

Consulting Table III, it is found by reading on horizontal and vertical lines that for day tens 2, minute tens 1, the second line *B* digit must be 2. Similarly for hour tens 0, minute tens 1, the *C* digit is 3. The units digits in order, 977, are placed in the *D*, *E*, and *F* positions, thus giving the start time line, 23977.

The converter must re-expand the start time line for punching on the output card. The translation is made through networks of contacts on relays operated directly from the *B* and *C* digit second line input register relays. The translation to day, hour, and minute tens is rendered on a decimal basis, in preference to 2-out-of-5 code, in order to limit the number of contacts used.

A third rearrangement of numbers, which may be considered to be a special kind of translation, is concerned with called number. The called number is found in the fourth line of the entry and may consist of four or five digits. In addition a 4-digit number may be followed by a party letter.

The highest digit of called number, whether it be thousands or ten thousands, is found in the *B* position of the fourth line with lower place digits to the right in positions *C*, *D*, and so forth. When a party letter is associated with a 4-digit number it is placed in the *F* position. The party letters *J*, *M*, *R*, and *W* are represented by the corresponding dial hole numbers, 5, 6, 7, and 9 respectively. When a party letter is not used with a 4-digit number the *F* position is blanked with zero.

The converter determines the number of digits to be used by means of the *C* digit of the third line. This digit, designated called number index, may assume values of 1 or 2 to indicate a 4- or 5-digit called number. The called number index determines which of two connectors shall be operated at the time that information is transferred to the output registers. The connectors are designed to place ten thousands, thousands, hundreds, tens, units and party numbers in correspondingly designated output registers, irrespective of the number of digits in the called number. The translation therefore consists of a shift of digits.

The called number index in the sample entry of Figure 10 is 1, which indicates a 4-digit called number. The numbers in the *B* through *F* digits of the fourth line are 16145. The *F* digit value of 5 indicates party letter *J*. The called number is therefore 1614*J*.

All items of information in the tape entry, requiring special treatment involving the operation of additional relays, appear in entry lines other than the last. Translated information, therefore, as well as registered information, will be in the desired form well in advance of the time that it is needed for punching.

Transfer Control and Output Registration

When a tape entry has been completely memorized, checked, and translated, the information is ready to be transferred to the output registers for punching.

Figure 14 is a functional block diagram of the converter, which includes the input registers and translators and indicates, by arrows and the names of the various output registers, the items of information contributed by each of the input sources. It is the job of the transfer control circuit to determine when the transfer of information from input to output shall take place. The transfer control establishes connections between input and output upon the coincidence of two electric signals:

1. Output registers released and ready for call information (output downcheck).
2. Input registers filled (input upcheck).

When the connections are made between input and output, the output registers operate in response to signals from the input registers and translators. Following this an output upcheck, insuring a good registration for punching, causes the connectors and input registers to be released. Following their release, the input registers are filled with information from the succeeding message entry.

The times of the reader cycle and the

Table IV. Estimated Messages per Month in AMA Centers

punch machine card cycle are such that the input will be refilled before the completion of the punching operation. Since the transfer operation is made very quickly, new information will be available for almost immediate use after each punching cycle. The punch machine will therefore run continuously.

Punching the Output Card

Figure 15 shows a typical punched card for toll message processing. The items of information are those of the sample entry of Figure 10. The information in Figure 15 may also be compared with the details of the first entry on the toll slip of Figure 2; they are equivalent.

The punching of the card is made possible by the sequential grounding of 12 emitter leads, one for each horizontal row of punching, after an output upcheck has been detected. Figure 16 is a functional block diagram of the punch control, which shows the relationship of the emitter leads, the output registers, and the card punch. When emitter 12 lead is grounded, a check punch and punch relay will be operated in series through each register storing a 12 indication. This operation takes place shortly before the punching time and thus provides a preset pattern for the punching of the 12 row on the card. Punching is accomplished by the operation of the corresponding punch magnets, which remove interposers under the punching dies, upon the closure of the IBM circuit breaker. At the end of 12 punching time, emitter lead 11 is grounded and the punch relays which were operated for the 12 row are released. The card, moved in synchronism with the emitter pulses, is then advanced to place the 11 row under the punching dies. The remainder of the card is punched row by row in this fashion.

The construction of the check punch relays is such that they remain operated until knocked down by a signal at the end of the card-punching cycle. If a check punch relay is operated for every register, a path will be closed at 9 punching time to operate the good card punch. Thus an electrical and a visual check are provided to insure that the card has been correctly punched. The good card punch signal releases the output registers after 9 time, completing the punching cycle.

The IBM control panel, indicated in Figure 16, provides a means of plug wiring for column assignments on a flexible basis. Figure 17 shows an IBM control panel with typical toll wiring.

After a card is advanced in the summary punch beyond the punching stage, it is sensed to insure that the correct number of punches has been made. This is called double punch and blank column detection and may be assigned to columns on a flexible basis through the IBM control panel.

The card may be end-printed with quarter-inch characters in the following station of the summary card punch. Connect time and calling line number, selected by control panel wiring, are shown end printed at the left side of Figure 15. These items are used for visually selecting certain message records. The end printing completes the over-all tape-to-card conversion process.

Summary of Converter Circuit Functions

The detailed description of the tape-to-card converter has been given in connection with the handling of toll business. The broad circuit functions are similar for the processing of local message unit summaries, although the number of lines to be registered per entry and the translations to be performed are fewer.

It is interesting to note that each of the broad circuit functions of the converter, when closely examined, makes use of one or more fundamental switching circuit concepts. The novelty of the circuits, of course, is in the contact configurations, the sequences of operations, and the particular applications. The function of reading and registering, for example, makes use of steering, connecting, memory, and checking circuits. Following registration, translating circuits are employed. Checking, connecting, and memory circuits are used again in the transfer to output registers. A sequence circuit is used for generating the emitter pulses. Finally the arrangement for operating punch relays through output registers, some of which are operated on a 2-out-of-5 basis and others on a decimal basis, constitutes a translation to special and digital punch card codes.

Conclusion

The benefits of tape-to-card conversion are manifold. The process, supplemented by a system of standard punched card machines, eliminates the costly and time-consuming manual operations of ticket sorting, toll rating, toll billing, toll adding, and determination of taxes as well as the handling of message unit charges.

Tape-to-card conversion has recently been applied in the field. Four converters are collectively processing over 3,000,000 toll messages per month. The process has not as yet been used for the handling of local business, but it is in the picture for the very near future.

There are, at this writing, seven AMA accounting centers in operation handling the business of over 50 central offices throughout the country. An early estimate of the amount of local and toll business handled by six of the accounting centers working in December 1952 is indicated in Table IV. It is expected that AMA, with the advent of tape-to-card conversion, will be widely applied in a very short time.

A Graphical Method for Flip-Flop Design

R. F. JOHNSTON
NONMEMBER AIEE

A. G. RATZ
MEMBER AIEE

Synopsis: A method of design is described for flip-flops subject to any set of requirements and examples of the method are given. The method is simple and fast. It takes into consideration those variations which may occur in the values of circuit components and leads to practical values of resistance and voltage.

THE Eccles-Jordan trigger circuit, or flip-flop, is employed extensively in digital computers, binary counters, scalers, and similar devices. Some applications use a large number of flip-flops under conditions where they must function satisfactorily for long periods of time; special design techniques are required to ensure the high reliability required.

The flip-flop circuit[1] shown in Figure 1 is essentially a symmetrical 2-stage overdriven d-c amplifier coupled back on itself in such a way that it locks into one of two stable states. Suppose T_1 conducts and T_2 does not. The points *a* and *d* are therefore at lower potentials than the corresponding points *b* and *c*. If the resistors are chosen properly, the potential of *d* is sufficiently negative to keep T_2 cut off, while the potential of *c* is above ground and T_1 continues to conduct. Thus the circuit settles into a state in which T_1 conducting renders T_2 nonconducting and T_2 nonconducting permits T_1 to conduct. It also can settle into a state with T_2 conducting and T_1 cut off.

Stability, that is, the continued ability of the circuit to settle in either of its two stable states when suitably triggered, is the most important characteristic of a flip-flop. In addition, the flip-flop may have to meet certain other requirements; for example, the magnitude of the voltage difference between states at a plate or grid may have to have a specified value, or the transition from one state to the other may have to be sufficiently fast. It is also essential that performance does not depend critically on any circuit quantities.

The method of design described in this paper can be applied to a flip-flop subject to any such set of requirements. The method is simple and fast, takes into consideration the variations which may occur in the values of circuit components, and leads to practical values of resistance and voltage.

Design Tolerances and Tube Characteristic Safety Factors

The quantities involved in the design are the resistances R_1, R_2, R_3, the voltage levels E_1, E_2, and the characteristics of the tube. (T_1 and T_2 are usually the two halves of a double triode.) Because variations in these quantities affect the circuit in different ways, two types of safety factors must be used.

Tolerances

A resistor can cause the circuit to fail if its resistance is either too large or too small. Considering manufacturer's tolerance and drifts due to temperature, aging, and so forth, it is usually possible to find a quantity Δ_r such that all resistors of a given make are certain to have a resistance lying between $R(1-\Delta_r)$ and $R(1+\Delta_r)$, if R is the nominal resistance. The design must be arranged to meet specifications with resistors lying anywhere in this range.

The power supplies can cause the circuit to fail if either E_1 or E_2 is too large or too small. The characteristics of the

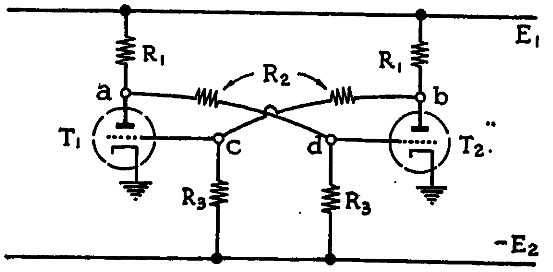

Figure 1. Basic flip-flop circuit

Paper 53-60, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted April 14, 1952; made available for printing December 3, 1952.

R. F. Johnston and A. G. Ratz are at the University of Toronto, Toronto, Ontario, Canada.

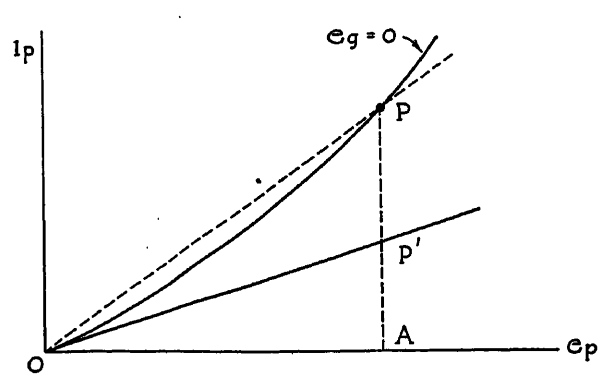

Figure 2 (left). Tube characteristics

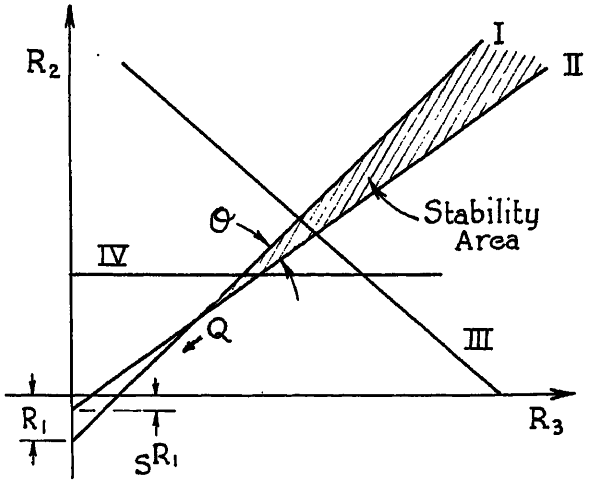

Figure 3 (right). Representation of inequalities

supplies to be used will enable a voltage tolerance Δ_e to be established so that the voltages are certain to lie between $E_1(1\pm\Delta_e)$ and $E_2(1\pm\Delta_e)$.

The tolerances Δ_r and Δ_e should be made as large as is practical without making design impossible. For example, with 1-per-cent resistors, a value of Δ_r of about 0.05 (that is, 5-per-cent tolerances) might be used.

TUBE FACTORS

The tube can cause the circuit to fail in two ways. First, if the current drawn by the conducting tube is too small, the other tube will not be cut off. A good design ensures that the grid of the conducting tube is positive with respect to the cathode (grid-cathode current limits the difference to 1 or 2 volts), so that the zero-grid plate characteristic determines conservatively the current drawn by this tube. Figure 2 shows this characteristic for a typical triode. The curve is almost linear and can be approximated by the straight line OP. As the tube ages, the slope of OP decreases; the limit of active life in the flip-flop is determined by the decrease which can be tolerated. The flip-flop should be designed using a zero-grid characteristic such as line OP'; the larger the ratio: $r=(AP/AP')$, the longer the tube life. The conducting tube can then be represented as a resistor

$$R_t=(OA/AP')=r\left(\frac{OA}{AP}\right) \tag{1}$$

Secondly, the circuit can fail if too great a negative grid voltage is required to keep the nonconducting tube cut off. This cutoff voltage is proportional to plate voltage, which usually is not known at the beginning of a design; it is certainly safe to assume that the full value of E_1 is applied at the plate. Thus, if $(-E_{co})$ is the grid cutoff obtained from the characteristic curves for any particular plate voltage equal to E_1, the ratio (E_{co}/E_1) is assumed constant for that tube type. Since E_{co} increases with tube life, the design must be based on a ratio

$$e_c=(E_c/E_1)=m(E_{co}/E_1),\quad m>1 \tag{2}$$

The safety factors r and m should be made as large as possible without making the design too difficult. Values of r and m of about 2 have been found satisfactory in most cases.

Stability Design

Every flip-flop must satisfy two stability conditions for all values of resistances and voltage levels within the tolerance ranges previously defined.

CONDITION 1

To keep the grid of the conducting tube positive, it is necessary that

$$\frac{(R_1+R_2)}{R_3}\,\frac{(1+\Delta_r)}{(1-\Delta_r)}<\frac{E_1}{E_2}\,\frac{(1-\Delta_e)}{(1+\Delta_e)} \tag{3}$$

or

$$R_2<g\left(\frac{E_1}{E_2}\right)R_3-R_1 \tag{4}$$

where

$$g=\left(\frac{1-\Delta_e}{1+\Delta_e}\right)\left(\frac{1-\Delta_r}{1+\Delta_r}\right) \tag{5}$$

$$\simeq 1-2(\Delta_e+\Delta_r) \tag{6}$$

CONDITION 2

To keep the nonconducting tube cut off it is necessary that

$$\frac{\left(\dfrac{R_tE_1}{R_t+R_1(1-\Delta_r)}+E_c\right)(1+\Delta_e)}{E_2(1-\Delta_e)-E_c(1+\Delta_e)}<\frac{\left(\dfrac{R_tR_1}{R_t+R_1(1-\Delta_r)}+R_2\right)(1-\Delta_r)}{R_3(1+\Delta_r)} \tag{7}$$

or

$$R_2>\frac{1}{g}\left(\frac{s+e_c}{\dfrac{E_2}{E_1}-e_c}\right)R_3-sR_1 \tag{8}$$

where

$$s=\frac{R_t}{R_t+R_1} \tag{9}$$

(While equation 8 derives from equation 7 by an approximation, the difference is negligible if the values of r and m exceed about 1.1.)

A design is obtained by solving inequalities 4 and 8. To do this, tube, resistor, and power supply characteristics must be known well enough to determine Δ_r, Δ_e, R_t, and e_c. If values are then assumed for R_1 and (E_1/E_2), relations 4 and 8 reduce to linear inequalities in R_2 and R_3.

The usual method of solving these relations[2] is to replace the inequality signs by equality signs and to solve the resulting pair of equations. This is equivalent to plotting

line I

$$R_2=g\left(\frac{E_1}{E_2}\right)R_3-R_1 \tag{10}$$

line II

$$R_2=\frac{1}{g}\left(\frac{s+e_c}{\dfrac{E_2}{E_1}-e_c}\right)R_3-sR_1 \tag{11}$$

and reading the co-ordinates R_2, R_3 of the point of intersection (point Q in Figure 3). In general, the values of R_2 and R_3 obtained in this way are not practical and it is necessary to test the nearest available values by substitution in relations 4 and 8 to ensure that these relations are satisfied.

Properly interpreted, however, Figure 3 is a graphical representation of inequalities 4 and 8: all points below line I satisfy equation 4, all points above line II satisfy equation 8 and all points in the shaded region, called the stability area, satisfy both relations 4 and 8. Thus a practical design is obtained im-

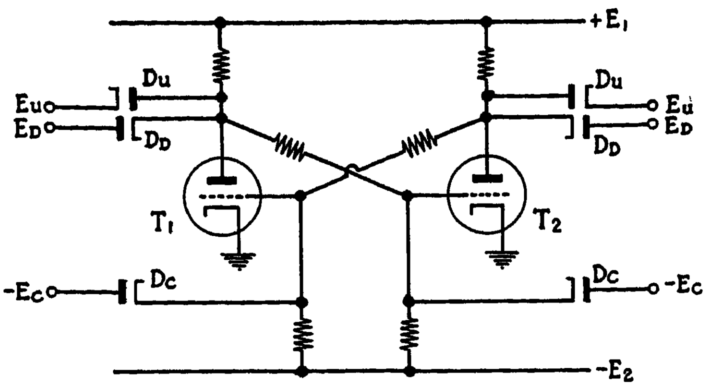

Figure 4. Flip-flop with clipping diodes

mediately by choosing any point in the stability area whose co-ordinates R_2 and R_3 are equal to available resistor values.

If the initial assumptions regarding (E_1/E_2) and R_1 do not lead to a satisfactory design, the effects of new assumptions are determined easily through their effects on lines *I* and *II* in Figure 3. Anything that is done to move the point *Q* downward in the direction of the arrow or to increase the angle between the lines makes it easier to find satisfactory values of R_2 and R_3.

The switching speed of a flip-flop depends to a considerable extent on the value of R_1; for a high-speed circuit R_1 should be small.[3] By equating the slopes of equations 10 and 11, the smallest possible value of R_1 is seen to be

$$\mathbf{R}_1 = R_t\left[\frac{1+\Delta_r}{g^2\left(1-e_c\dfrac{E_1}{E_2}\right)-e_c}-1\right] \qquad (12)$$

However, if R_2 and R_3 are to be reasonably small, it is generally required that

$$R_1 \geq 2\mathbf{R}_1 \qquad (13)$$

Equation 12 shows that R_1 is particularly sensitive to R_t, Δ_r, and Δ_e and somewhat to e_c. If a tube is available which is capable of passing more current or which has a lower value for e_c, or if resistors or power sources of better stability can be used, a considerable reduction can be made in R_1.

In the same way, it can be shown that the minimum possible value for E_1/E_2 is

$$\frac{E_1}{E_2} > \frac{1}{e_c}\left(1-\frac{s+e_c}{g^2}\right) \qquad (14)$$

A value of E_1/E_2 in the range 0.5 to 2 is generally satisfactory.

General Design

Besides the basic stability conditions discussed so far, many flip-flop applications require that voltages and impedances throughout the circuit satisfy additional conditions. While only the more common cases will be treated here, it is possible to extend this graphical method to meet any set of specifications.

The most common examples of such additional conditions concern plate voltage swings. It is often required that the difference between the voltage at the plate of the nonconducting tube (the up-plate) and that at the plate of the conducting tube (the down-plate) shall not be smaller than a given minimum value ΔE_M. This is so if:

(1) The up-plate is always more positive than a voltage E_U; that is, if

$$R_2 > \left(\frac{E_U}{E_1}\right)\left(\frac{R_1}{g-\dfrac{E_U}{E_1}}\right) \qquad (15)$$

(2) The down-plate is always more negative than a voltage E_D; that is, if

$$R_2+R_3 < \frac{g(sR_1)\left(\dfrac{E_2}{E_1}+\dfrac{E_D}{E_1}\right)}{s-g\dfrac{E_D}{E_1}} \qquad (16)$$

(3) $|\Delta E_M| \leq E_U - E_D$ (17)

Extending the first method mentioned under the section entitled "Stability Design," a design could be obtained by solving the five (nonlinear) equations derived from equations 4, 8, 15, 16, and 17 for R_1, R_2, R_3, E_1, and E_2. This involves a great deal of arithmetical labor and, in general, leads to inconvenient values of voltage and unavailable values of resistance.

The graphical method described in the preceding can be extended easily to solve these inequalities directly. Values of E_1, E_2 and R_1 are assumed as before, also values E_U and E_D satisfying equation 17. The straight lines derived from equations 15 and 16, that is,

line *III*

$$R_2 = \left(\frac{E_U}{E_1}\right)\left(\frac{R_1}{g-\dfrac{E_U}{E_1}}\right) \qquad (18)$$

line *IV*

$$R_2+R_3 = \frac{g(sR_1)\left(\dfrac{E_2}{E_1}+\dfrac{E_D}{E_1}\right)}{s-g\dfrac{E_D}{E_1}} \qquad (19)$$

are plotted on the same graph, see Figure 3, as the stability area obtained from equations 4 and 8. Then the co-ordinates R_2, R_3 of any point in the stability area, above line *III* and below line *IV*, satisfy all the conditions. The choice of a point whose co-ordinates equal available resistor values completes the design.

In some circuits the up-plate must be exactly at a voltage E_U; this can be ensured by designing as previously for the up-plate to be more positive than E_U then adding a clipping diode from this point to a fixed voltage E_U. Similarly the down-plate may be clipped at E_1 or the down-grid at $-E_c$; one diode must be used at each point for each voltage leve at which it is desired to clip.

Figure 4 shows a flip-flop complete with clipping diodes at both plates and grids. Diodes D_D are used to limit the excursions of the down-plates to E_D, diodes D_U hold the up-plates to E_U and diodes D

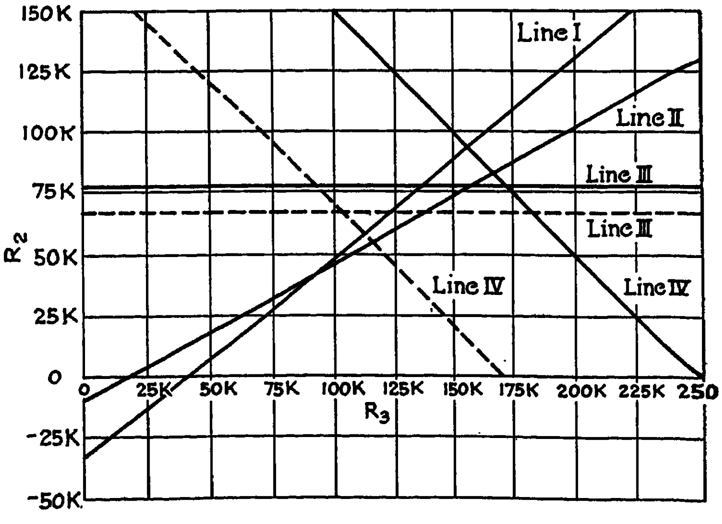

Figure 5. Illustrating the examples in Appendix II

hold the down-grids to $-E_c$. (Note that the up-grid is always clipped by grid current if relation 4 is satisfied.)

There are many variations of the basic flip-flop circuit depending on which of D_D, D_U, and D_c are used. Some of these require changes in stability conditions 4 and 8. For example, to satisfy the stability condition at the up-grid of a flip-flop which uses diodes D_U, equation 4 must be altered to

$$R_2 < g\frac{E_U}{E_1}\frac{E_1}{E_2}R_3 \tag{20}$$

Equation 20 is then used instead of equation 4 in finding the stability area in Figure 3. If diodes D_D are used, equation 8 becomes

$$R_2 > \frac{1}{g}\left(\frac{\frac{E_D}{E_1}+e_c}{\frac{E_2}{E_1}-e_c}\right) \tag{21}$$

It is noteworthy that the use of diodes D_U increases the tube cutoff safety factor m. In the definition of m, equation 2, E_1 was used as a conservative estimate of the plate voltage of the nonconducting tube. If the up-plate is clipped, however, the plate voltage cannot exceed E_U, and the effective value of m is increased by the ratio (E_1/E_U).

In still other applications of flip-flops, it is desired to use a voltage tapped off the transfer resistor R_2. If this voltage is E_T, then it is required that

$$E_T \geq E_{TU} \tag{22}$$

for one state of the flip-flop and that

$$E_T \leq E_{TD} \tag{23}$$

for the other state.

If R_2 is tapped at a point such that there is a resistance fR_2 $(f<1)$ between the grid end of R_2 and the point, leaving a resistance $(1-f)$ R_2 between this point and the plate, then relation 22 is satisfied if

$$R_2 > R_1\left[\frac{\frac{E_{TU}}{E_1}}{fg-\frac{E_{TU}}{E_1}}\right] \tag{24}$$

and relation 23 is satisfied if

$$R_2 > \left|\frac{sR_1-xR_3}{fx-(1-f)}\right| \tag{25}$$

where

$$x = \frac{1}{g}\left[\frac{s-\frac{E_{TD}}{E_1}}{\frac{E_2}{E_1}+\frac{E_{TD}}{E_1}}\right] \tag{26}$$

All points in the stability area above the horizontal line derived from relation 24 and above the line derived from relation 25 satisfy relations 22 and 23. Relations 24 and 25 are correct only if no clipping diodes are used.

In this way, too, voltage conditions applying to any points on the plate or grid resistors can be met. Each additional condition adds one more line in Figure 3 and further restricts the part of stability area from which satisfactory designs can be obtained.

For convenience, the most important of these relations are assembled in the summary of Appendix I. To simplify the expressions and calculations, a change in notation has been made: all voltages are divided by E_1 and the resulting "normalized" voltage ratio represented by a small letter, thus

$$\frac{E_U}{E_1} = e_U$$

Appendix II shows two examples of flip-flop design to illustrate the use of this method.

Appendix I. Summary of Design Relationships

Let

$$\frac{E_U}{E_1} = e_U, \quad \frac{E_D}{E_1} = e_D, \quad \frac{E_2}{E_1} = e_2, \quad \frac{E_c}{E_1} = e_c$$

Also

$$s = \frac{R_t}{R_t+R_1}; \quad g = \left(\frac{1-\Delta_r}{1+\Delta_r}\right)\left(\frac{1-\Delta_e}{1+\Delta_e}\right)$$

Stability Conditions at Up-Grid

No clipping diode at up-plate (from relation 4)

$$R_2 < \frac{g}{e_2}R_3 - R_1 \tag{27}$$

Up-plate clipped at E_U (from relation 8)

$$R_2 < g\left(\frac{e_U}{e_2}\right)R_3 \tag{28}$$

Stability Conditions at Down-Grid

No clipping diode at down-plate (from relation 20)

$$R_2 > \frac{1}{g}\left(\frac{s+e_c}{e_2-e_c}\right)R_3 - sR_1 \tag{29}$$

Down-plate clipped at E_D (from relation 21)

$$R_3 > \frac{1}{g}\left(\frac{e_D+e_c}{e_2-e_c}\right) \tag{30}$$

Condition that Up-Plate Be More Positive than E_U (from Relation 18)

$$R_2 > \left(\frac{e_U}{g-e_U}\right)R_1 \tag{31}$$

Condition that Down-Plate Be More Negative than E_D

No clipping diode at down-grid (from relation (19)

$$R_2+R_3 < gs\left(\frac{e_2+e_D}{s-ge_D}\right)R_1 \tag{32}$$

Down-grid clipped at $-E_c$

$$R_3 < gs\left(\frac{e_c+e_D}{s-ge_D}\right)R_1 \tag{33}$$

Appendix II. Examples of Flip-Flop Design

To illustrate the application of the method described in Appendix I, an example is worked out.

Example I

Suppose it is desired to design a flip-flop using a *6J6* double triode for an application which requires high reliability and a time constant at the plate of less than 0.5 microsecond and assuming an output capacity of 10 micromicrofarads. Resistors in Radio Manufacturers Association sizes and having manufacturer's tolerance of ±1 per cent are to be used: the available power supplies have 200 volt outputs, accurate to ±1 volt.

PRELIMINARY DECISIONS

Tolerances: To ensure trouble-free performance during the life of the resistors take

$\Delta_r = 5\times 1$ per cent $= 5$ per cent $= 0.05$

Since the power supplies are (nominally) accurate to 0.5 per cent, take

$\Delta_e = 10\times 0.5$ per cent $= 5$ per cent $= 0.05$

Tube: For a *6J6*: from equation 2, $\frac{E_c}{E_1} = 0.10$ with $m=2$, and from equation 1, $R_t = 15K$ with $r=2$.

Choice of R_1: On the basis of the discussion

Table I. Table of Correct Combinations of Relationships

Required Conditions of Voltage at			Stability Conditions	Conditions Other Than Stability
Up-Plate	Down-Plate	Down-Grid		
Free	free	free $L-E_c$	27, 29	
Free $>E_U$	free	free $L-E_c$	27, 29	31
Free	free $<E_D$	free $L-E_c$	27, 29	32
Free $>E_U$	free $<E_D$	free $L-E_c$	27, 29	31, 32
Clipped at E_U	free$<E_D$	free $L-E_c$	28, 29	31, 32
Free $>E_U$	clipped at E_D	free $L-E_c$	27, 30	31, 32
Clipped at E_U	clipped at E_D	free $L-E_c$	29, 30	31, 32
Clipped at E_U	clipped at E_D	clipped at $-E_c$	28, 30	31, 33

concerning equations 12 and 13, choose

$R_1=33K$

(The time constant governing transition is then less than 0.3 microsecond.[3])

DESIGN

From the preceding values: $g=0.82$; $s=0.31$; $e_c=0.10$; $e_2=1.0$. Substitution of these in relations 27 and 29 yields for line *I*

$R_2<0.82R_3-33$

and for line *II:*

$R_2>0.56R_3-10$

Note that all resistor values are expressed in thousands of ohms. These lines are plotted in Figure 5.

Any one of the points:

P_1: $R_2=47K$, $R_3=100K$
P_2: $R_2=62K$, $R_3=120K$
P_3: $R_2=75K$, $R_3=150K$
P_4: $R_2=87K$, $R_3=150K$

and many others would represent a satisfactory design. In general, faster transition will be obtained with smaller values of R_2 and R_3, so the choice of P_1 is indicated.

The design can be summarized thus: $E_1=E_2=200$ volts; $R_1=33K$, $R_2=47K$, $R_3=100K$.

Example II

Suppose the flip-flop in the previous example also is required to have a plate swing of at least 50 volts.

DESIGN

The stability conditions for this example already are represented by the stability area in Figure 5. For this additional condition, relations 17, 31, and 32 must be used, with $E_M=50$ volts.

A first assumption for E_U and E_D satisfying equation 18 might be

$E_U=110$ volts; $E_D=60$ volts

This yields for line *III*

$R_2>67K$

and for line *IV*

$R_2+R_3<170K$

These lines are shown dashed in Figure 5; clearly there is no part of the stability area above this line *III* and below this line *IV*.

If the new assumptions are made

$E_U=115$ volts; $E_D=65$ volts

then line *III* becomes

$R_2>77.5K$

and line *IV* becomes

$R_2+R_3<250K$

These lines are plotted on Figure 5 and it is seen that there is a part of the stability area, containing P_4, which satisfies all the conditions imposed. Thus the design derived from P_4 will satisfy the stability conditions and will guarantee a plate swing of at least 50 volts (from 65 volts to 115 volts) between states. The final design, then, is: $E_1=E_2=200$ volts; $R_1=33K$, $R_2=87K$, $R_3=150K$.

Automatic Call Recording and Accounting in the SATT System

J. E. OSTLINE
FELLOW AIEE

Introduction

AUTOMATIC SWITCHING

When the first automatic telephone office was placed in public service at La Porte, Ind., in 1892, automatic switching and subscriber dialing became established facts. During the years following this notable event in the history of telephone communication, Automatic Electric Company through constant research and development of switching equipment and operating methods expanded the field of automatic switching from local exchange areas to suburban and toll networks. By 1910 operator toll dialing was introduced whereby originating toll operators were enabled to complete calls to automatic stations in distant towns by toll dialing.[1] Operator toll dialing was then expanded to provide switching of toll circuits through tandem and switching centers. During the period from 1920 to 1940, several regional automatic toll switching networks were established in various parts of the United States and Canada.

Although during that period operator toll dialing became an accepted method of toll switching, subscriber dialing of toll calls was not as yet available for several basic reasons, some of which were:

1. The numbering plans used by operators were not universal and therefore not suitable for public use.

2. If a universal numbering plan for toll switching had been available, common control switching equipment would have been required to make use of it.

3. All toll calls had to be recorded (ticketed) for billing purposes. This is one of the functions performed by toll operators.

THE DIRECTOR

With the introduction of the Director[2] in 1923 for the London, England, metropolitan area network universal numbering and common control operation became available for Strowger (step-by-step) automatic switching in local exchange networks. The Director also made available a number of other controls, and thus it became possible to design equipment suitable for subscriber dialing of short-haul and long-distance toll calls with automatic call recording.

SUBSCRIBER DIALED AUTOMATIC TOLL SWITCHING

In 1937, Régie des Télégraphes et des Téléphones (Belgian Telecommunication Authority) (R.T.T.) requested Automatique Electrique, S.A. (Belgian affiliate of the Automatic Electric Company) to present plans for subscriber national toll dialing with automatic recording (ticketing) of each dialed toll call. As a basic part of this undertaking, the R.T.T. had established a nation-wide area code numbering plan; see Figure 1.

The various common control facilities available in the Director provided the solution for all phases of this request, in-

cluding automatic call recording (ticketing) with cost computation for each call; see Figure 2. The first installation of this system was made at Mons, Belgium, where it proved entirely satisfactory. A similar installation was placed in service at La Louviere in 1950.[3]

Further Developments

After the completion of the Belgian automatic toll ticketing plan in 1938, research was continued further to expand the automatic toll switching and call recording facilities contained therein. This resulted in a design which contained the following added facilities and methods of operation:

1. Detector (identifier) operation was arranged to provide subscriber dialing for party line subscribers up to five stations per line.
2. Central office toll call recording was arranged to permit the introduction of punched card accounting techniques, thereby making available complete automatic bill processing and accounting of toll messages.

Tee system resulting from the foregoing development is now referred to as the SATT (Strowger Automatic Toll Ticketing) system. When used with punched card accounting, this system is completely automatic from the dialing of toll calls by a subscriber to the printing of the bill for such calls.

A small trial unit containing most of the facilities in this system was installed in an office in the Los Angeles metropolitan network in 1944. Since that time

Figure 2 (left). Automatic toll ticket

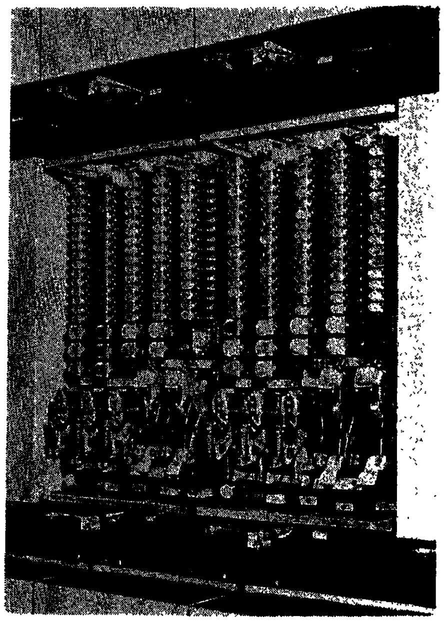

Figure 4 (right). Two ticketer units

SATT system facilities have been incorporated in several automatic central offices in the Chicago and Los Angeles metropolitan areas, thus providing subscriber dialing of short-haul toll calls.[4]

The subscriber dialing range will eventually cover the entire nation when the facilities of the gigantic Bell System project now in progress, generally referred to as nation-wide automatic switching,[5] become available to local and regional automatic networks. When this time arrives, offices having SATT facilities will find themselves prepared to take full and complete advantage of subscriber national toll dialing.

This paper describes in outline the equipment and the automatic call recording (ticketing) and accounting (bill processing) methods used in the SATT system.

SATT Components and Functions

SATT (type *A*) facilities are provided when the following basic components are added to Director-controlled local exchange equipment: 1. call recorder; 2. detector; 3. ticketer; 4. tabulator and tape perforator; and 5. dater-clock. The method of arranging these units in a Director office is shown in functional block diagram form in Figure 5.

The Components

The call recorder is composed of relays and rotary switches and is added to each Director. Its function is to assemble and transmit to the ticketer the following data for each toll call:

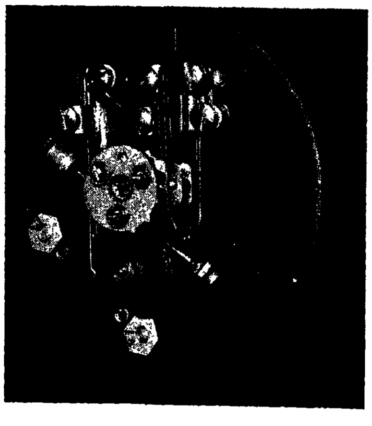

Figure 3. Identity dial

1. Calling station terminal number.
2. Class of service.
3. Called station directory number.
4. Rate index.
5. Director identity number.

These items are transmitted to a ticketer in codel code pulses when a toll connection is established.

The detector is composed of relays, rotary switches, and neon lamps. Its function is to detect, under the control of the call recorder, the terminal (connector) number of a station making a toll call. This unit is common to each exchange. The operating time for each detector cycle is about 100 milliseconds.

The ticketer is composed of relays and rotary switches; see Figure 4. The function of a ticketer is to store ticket data transmitted to it from a Director and to record conversation time when a called station answers. This call timing facility consists of a self-contained unit, which always starts from a zero position, thereby eliminating fractional errors resulting from fixed time pulses. A definite timing delay is also provided to permit a calling station to check if the correct called station has been obtained. This delay can be adjusted in 1-second steps from 3 to 10 seconds as desired by the operating company. Storage of conversation time is provided up to 5 hours. If a toll connection is kept established beyond this period, a supervisory trunk automatically extends the call to an operator for observation and action.

Each tabulator is a unit composed of relays and rotary switches. The function of a tabulator is to tabulate call data received from a ticketer, to add thereto the calling office code, tabulator identity number, date and clock time, and finally to produce a perforated tape record of each completed toll call. Permanently associated with each tabulator is a tape perforator similar to those used in telegraph services. Standard perforator tape is used. Each tabulator contains strapping facilities into which the code of the office unit in which it is located and the identity number of the tabulator are strapped.

The dater-clock is common to all tabulators in a central office and provides the date and clock time for each completed toll call. Clock time is expressed in Navy figures—the 24 hours of each day being numbered continuously instead of in two 12-hour cycles. It operates on a 4-year cycle so that the extra day in leap year is automatically provided for.

By a similar facility, ticket items can be transmitted to the tape in any sequence desired by the operating company when manual accounting by tickets is used. Regardless of the item sequence, tape perforation occurs in reverse order. After all items are recorded, the tabulator adds a start symbol. This arrangement permits the use of the tape from the outside of a storage reel when final accounting records are made, thus avoiding rewinding. As indicated in the next section, the initial record data of incompleted toll calls are always wiped out when the calling station hangs up. Therefore, the only recordings in the tape will be those of completed calls. Each call recording requires about 3 inches of tape.

Station Identity Dial

A basic facility of SATT service to party-line stations is provided by a station identity dial; see Figure 3. This is a standard dial to which has been added a pulsing arrangement which identifies up to five stations on a party line. This facility does not alter the normal mechanical structure or function of the dial.

In operation, this dial transmits station identity pulses during each pull, but these pulses are inserted between the regular dial pulses and do not in any way interfere with them. The Director contains a facility which records th's station identity code. If the call is local, this recording is not used, but if the call is toll, it is transferred to the call recorder, Figure 5.

Therefore, when a call recorder tests for a calling station terminal number, it already knows what service a calling station has, that is, individual line or party line. If party line, it knows which station of a maximum of five on the line has dialed the call. It will, therefore, make the terminal number detection (identification) test accordingly.

SATT System Code

All call data transmitted and recorded in the SATT system consist of numerals in a code pattern referred to as the codel code. Each digit is represented by combinations of four elements for transmission pulses, storage relays, or tape perforations as shown in Table I.

When data from the call recorder are pulsed out to the ticketer (see the next section), each digit is composed of four high and low pulses. When digits are stored on relays, a codel relay group is used with the relays marked *W*, *X*, *Y*, and *Z*, which are operated for each digit as indicated in the table. The tape code is a 4-channel type with perforations in the same relative positions as the high pulses in each code digit, Figure 8. When a tape is processed, the start symbol is used to start transfer of tape data into either a ticket printer (manual accounting) or into a card punch (automatic accounting). The blank symbol is used to fill in the third office code digit space when combined 2-4 and 2-5 numbering is used in an exchange area.

SATT System Operation

This section deals with the automatic call recording (ticketing) facilities in the SATT (type *A*) system. The methods of establishing subscriber dialed speech connections and other functions are not described except as required to explain call recording operations. The outline of SATT components in the preceding section describes most functions of each component in more detail.

Call Recording from Party-Line Stations

The initial versions of the SATT system provided subscriber dialed toll service for individual line subscribers only. As relatively large portions of subscribers in telephone exchanges in the United States use party-line service, it became apparent that in order to make full use of the service and economic advantages of subscriber dialing which are available in the SATT system, service had to be provided for party-line as well as individual line stations.

Table I. Functional Chart of Codel Code Pulsing, Storage, and Tape Recording

	Pulse Position				Relays Operated				Tape Channel			
Digit	1	2	3	4	W.	X.	Y.	Z.	1	2	3	4
1	H	H	L	L	*	*			.	.		
2	H	L	H	L	*		*		.		.	
3	H	L	L	H	*			*	.			.
4	L	H	H	L		*	*			.	.	
5	L	H	L	H		*		*		.		.

Start									.	.	.	.
Blank										.	.	.

Surveys of the independent operating field indicate that in most cases where party-line service is provided, it is of the 4-party type, although in a comparatively few cases 5-party service is also provided. The SATT equipment is therefore arranged for completely automatic individual and 5-party terminal per station automatic call recording.

Automatic Recording of Call Data

When a call is initiated in an automatic exchange containing SATT system facilities, it is extended to a Director which is composed of several common control units, Figure 5. After receiving dial tone, the calling subscriber dials the directory number of the called station. This is stored in the call register. If the office code portion of this number indicates that the terminating office is a toll point, the resulting directive (translation) obtained from the common translator will always establish a trunking path to the called office via a ticketer. This directive will also alert the call recorder. This unit of the Director assembles the major portion of the toll call data.

The call recorder upon being alerted first of all receives from the call register an indication as to whether the calling station is on an individual or party line, and if on a party line, which particular station on that line has initiated the call. The call recorder now calls for the common detector (identifier). As soon as the detector responds, the call recorder informs the detector in which particular group of station terminals it should search for the calling station. In the case of an office

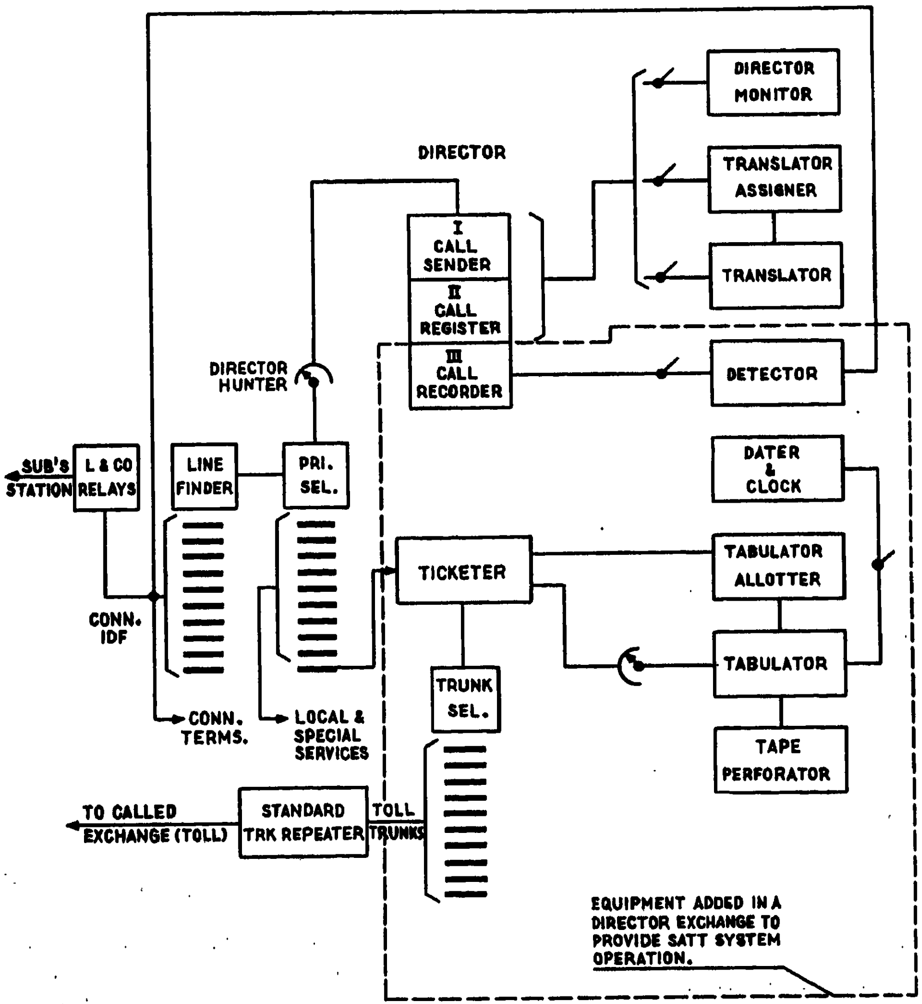

Figure 5. Central office SATT system functional block diagram

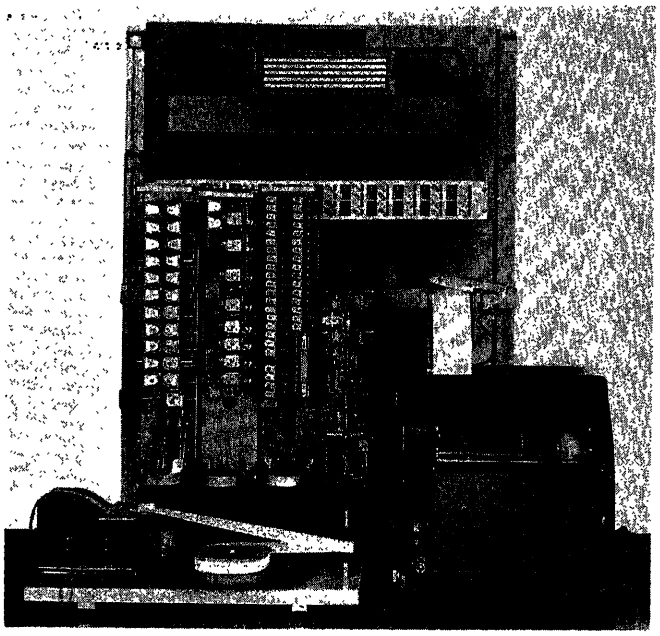

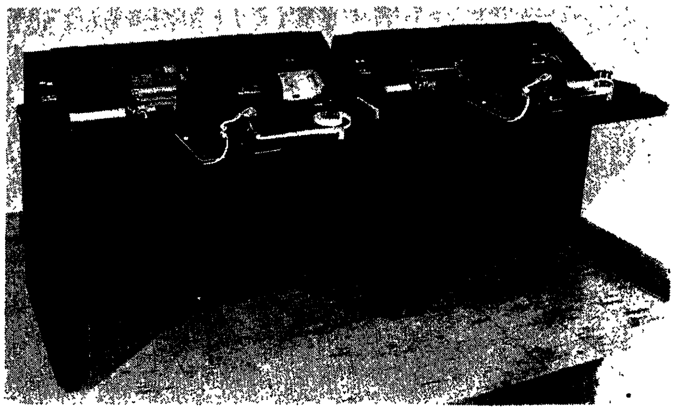

Figure 6 (left). Tape reader and ticket printer

Figure 7 (above). Card punch with tape-to-card control unit

providing individual and 5-party service, this means one of six different number groups. The detector then tests in the indicated group for the terminal number of the calling station, and transmits this number to the call recorder where it is stored. The detector then releases.

The call sender unit of the Director will be establishing the desired connection while the foregoing cycle in the call recorder takes place. As soon as the call recorder has dismissed the detector, it will start sending the ticket data now available in the Director to the ticketer where it is stored. This transmission, which is in codel code, takes place simultaneously with the establishing of the trunk (speech path) connection to the called office.

The call data transmitted to the ticketer from the call recorder consists of the following:

1. Calling station terminal number.
2. Called station directory number.
3. Rate index.
4. Class of service.

In addition to these call items, the call recorder also transmits the identity number of the Director handling the call.

After a connection has been established to the called central office terminal, the Director releases. The calling station is now connected to the called station connector terminal via a ticketer in the originating office, and the call (ticket) particulars accumulated up to this point are written up (recorded) in the ticketer. At this stage, the call may result in a busy signal or no answer. Should this occur, the calling subscriber replaces the handset, whereupon all equipment involved in the connection is released, and the accumulated call data are wiped out.

TIMING OF CONVERSATION

When a call is answered by a called station, timing of conversation begins after a fixed delay to permit the calling subscriber to ascertain that the correct called station has been obtained. The conversation time is recorded in minutes.

TABULATION OF CALL DATA

When a conversation is completed, the calling subscriber replaces the handset. This results in the following operations:

1. All switching equipment and trunks held by the call are released except the ticketer which locks up and makes itself busy to other calls.
2. The ticketer calls for a tabulator via the tabulator assigner. The assigned tabulator connects itself to the calling ticketer.

The ticketer now transmits the following items to the tabulator where they are stored:

1. Calling station terminal number.
2. Called station directory number.
3. Rate index.
4. Class of service.
5. Conversation time.
6. Director identity number.
7. Ticketer identity number.

At the end of this transmission the ticketer is released, thereby removing its busy condition.

FINAL CALL DATA RECORDING

As soon as a tabulator has received the call data from a ticketer, its associated tape perforator starts to perforate the data into its tape. Such data may be, for instance, in the following sequence:

1. Ticketer identity number.
2. Director identity number.
3. Date.
4. Clock time.
5. Called station directory number.
6. Conversation time.
7. Rate index.
8. Class of service.
9. Calling station directory number.
10. Tabulator identity number.

To this series of items is always added a start symbol. This is followed by the restoration to normal of all tabulator components thus making the tabulator available for another call. The punched tape is automatically wound up on a storage reel from which it is removed periodically and forwarded to an accounting center for processing.

SATT Accounting (Bill Processing) Methods

GENERAL

A basic requirement in connection with the provision of short- and long-haul toll services to telephone subscribers is that of obtaining a ticket or call record for each completed call in order to enable the telephone company to bill the subscriber for this service. Therefore, in automatic networks without automatic toll call recording facilities, subscribers desiring toll connections are required to dial an operator so that the telephone company may obtain the data required to bill subscribers for such calls. Otherwise these connections could in many cases be subscriber dialed the same as local calls.

A manual toll ticket, as prepared by an operator, generally contains:

1. Date and clock time.
2. Calling station directory number.
3. Called station directory number.
4. Conversation time.

Items 1, 2, and 3 are recorded when the call is initiated and item 4 when the call is completed.

Completed toll tickets are forwarded to the accounting or commercial department of an operating company where they are put through a routine referred to as bill

processing. This routine is to a large extent a manual procedure, consisting primarily of computing the cost of each call from the ticket data, adding federal (and sometimes local) taxes, and so forth. These calls are then transcribed to and added up on a toll service statement which is attached and added to the regular monthly bill. The amount of detail shown for each call is usually prescribed by the state or federal regulatory commissions under whose jurisdiction the telephone company operates.

Some of these regulatory bodies require all toll calls to be billed in more or less detail, while some permit calls within certain metropolitan areas to be reduced to message units. All message units are then added and bulk-billed for each billing period as one item without detail. In detail billing each call may show not only the called station, the date and total cost, but may also show rate and conversation time to permit subscribers to check each call in detail for themselves.

No matter what rules govern the manual toll billing process of an operating company, it is always a function which requires considerable organization details and manual labor. The use of various labor-saving devices has assisted in making manual accounting very efficient, but complete mechanization of this process will considerably reduce billing costs to telephone companies.

As described in previous sections, each toll call completed in a SATT system central office is recorded in a perforated tape. This tape is the equivalent of the call tickets obtained in manual operation and is therefore the primary record of each call.

Completed tapes from central offices are sent to an accounting center by mail or by other means. However, when trunk facilities are available, the tape data are also suitable for transmission by wire to an accounting center. This can in many cases speed up processing operations.

To obtain subscribers' toll statements from ticket tapes, two methods are available: manual or automatic bill processing.

Manual Processing

When it is desired to obtain subscribers' bills from SATT tapes by manual methods, a tape-to-ticket assembly is provided; see Figure 6. This assembly consists of a printer controlled by a tape reader. This assembly prints a standard size toll ticket for each call contained in the tape. These tickets are then processed in the same manner as regular manual tickets.

If desired, this process can be made partly automatic. A unit termed a computer can be included with the tape reader. When this is done, the cost of each call will be automatically computed from the tape data and printed on the ticket in addition to other data.

As previously described, the tabulator can be strapped in such a manner as to record each item in the tape in the same sequence as used on tickets prepared by manual operators. This will avoid manual errors in processing tickets from two sources.

Automatic Processing

Automatic accounting (processing) of SATT system call data is accomplished by means of punched card accounting equipment. This type of equipment has proved satisfactory over many years for almost every known kind of accounting requirement.

It may be of interest at this point to relate that surveys of accounting methods by independent telephone companies have disclosed the fact that some of them are already using punched card equipments to speed up and simplify manual accounting processes. When these companies adopt SATT operation, they will therefore be able to continue using their present facilities and methods by merely adding a tape-to-card unit to each card punch.

The first and basic step in obtaining printed subscribers' bills and auditing records with punched card equipment is to produce a punched card from the call data in a ticket tape. This is done by using a tape-to-card unit with a regular card punch, Figure 7. After a punched card has been obtained, it is used to control subsequent processes from which the basic end result will be a printed subscriber's bill, Figure 8. However, in this process, various other types of records are also obtained, depending on the amount and kinds of accounting data an operating company may require.

An interesting by-product obtainable from punched cards is toll traffic data. Computation machines can be set to sort out the particular items desired such as busy hour calls, average holding times, and from what classes of subscribers calls originate.

Conclusion

When the SATT system was designed, one of the primary aims was to use as far as possible tried and proved circuitry arrangements, and only such components as had been proved satisfactory in other fields and were commercially available. Thus the system described herein contains common control (Director) circuitry which has been used for many years in metropolitan areas. The record tape is of the same type as the message tape used in telegraph services. The punched card accounting equipment is also a well-known and proved equipment used in many commercial fields.

SATT system facilities are basically of such a nature that they can also be provided for non-Director step-by-step automatic central offices of all types and sizes, but special numbering and dialing methods must then be employed for subscriber dialed toll traffic. However, the end result is the same in each office: each completed subscriber dialed toll call is recorded in a ticket tape in exactly the same manner as in a Director-controlled office.

One interesting fact is already becoming apparent. Operating companies now providing SATT system service have found that mechanical accounting is not only a very desirable method as compared with manual processing, but also more economical.[6]

As automatic telephone switching eventually became the accepted mode in providing local telephone service, subscriber dialing, automatic call recording, and automatic accounting will without a doubt be the accepted mode in providing regional and national toll telephone service in the future.

Analysis of a Comb Filter Using Synchronously Commutated Capacitors

W. R. LePAGE
MEMBER AIEE

C. R. CAHN
ASSOCIATE MEMBER AIEE

J. S. BROWN
NONMEMBER AIEE

THE possibility of constructing a comb filter by commutating the input signal to a bank of capacitors through a series resistor has been suggested in the literature.[1] A theoretical investigation of the properties of such a filter is given in the following analysis.

The general scheme of the filter is shown in Figure 1. Rotating brush A is fed by the input signal (a zero impedance potential source) through a resistor R in series. While A is in contact with any one segment, the capacitor begins to change its charge, so that its potential begins to approach that of the input signal at that instant. However, the time constant RC is much longer than the time of dwell of the brush on one segment, so that the capacitor potential cannot change much during one duration of contact. If the signal frequency is a multiple of the frequency of rotation, the signal will have the same value each time the brush is in contact with a given segment, so that after many revolutions the potential across the capacitor can finally attain the value of the signal at the instant when the brush touches the segment. Random signals, aperiodic signals, and signals which are periodic but not of a frequency which is a multiple of the rotational frequency will not benefit from this storage process. Therefore, if the commutator is then scanned by an infinite impedance contact brush B, it will pick out a signal in which periodic components of the input signal are strongly predominant. In order not to affect the wave shape appreciably, it is necessary to have many commutator segments which will approximate a continuous distribution of segments.

One use of a comb filter is to improve the signal-to-noise ratio of a periodic signal mixed with noise. In the analysis to follow, the filter is regarded both as a frequency selective device and as a device which averages the noise over a large number of cycles of the periodic signal. The analysis shows that the signal-to-noise ratio may be improved approximately by the square root of the number of cycles over which the averaging extends, a result equivalent to that obtained by Harrington and Rogers.[2]

Analysis for Steady-State Response to a Sinusoidal Signal

The theoretical analysis is approximate, being based on the assumption that the input signal is "quantized" by resolving it into a staircase approximation, as shown in Figure 2(A). For convenience in the analysis, assume that the input signal is switched on at $t=0$, the instant that brush A is in the center of segment O, and that all capacitors are initially uncharged. The following is a partial list of notation:

f = input signal frequency
f_r = frequency of rotation of the brushes
N = number of capacitors and commutator segments
T_i = time required for a brush to pass from the center of one segment to the center of the next segment
T_d = time of dwell of a brush on one commutator segment
k = an index number for counting revolutions of the brushes
p = an index number for indicating capacitor position
$e(t)$ = the input signal as a function of time
$e_p(k)$ = potential difference of capacitor p after brush A has rotated past it k times

The analysis begins by considering the transient process by which a certain capacitor p changes its charge during the k'th revolution of brush A. Consider p fixed for successive values of k. For the general k'th revolution t lies in the time interval

$$\left(p+kN-\frac{1}{2}\right)T_i \leqq t \leqq \left(p+kN+\frac{1}{2}\right)T_i \quad (1)$$

during which time interval the quantized input signal remains constant. For the transient state under consideration the potential difference of the capacitor is $e_p(k-1)$, at the beginning of the k'th contact of segment p with the brush. Also, during the interval (1) the quantized input signal is constant at the value $e[(p+kN)T_i]$. The charging circuit is shown in Figure 2 (B) for which the transient analysis gives

$$e_p(k)=(1-h)e[(p+kN)T_i]+he_p(k-1)$$

where

$$h=\epsilon^{-T_d/RC} \quad (2)$$

Similar equations can be written for $e_p(k-1)$, $e_p(k-2)$, . . . and then substituted into each other to give the terminating series

$$\begin{aligned} e_p(k) &= (1-h)\{e[(p+kN)T_i]+ \\ &\quad he[(p+kN-N)T_i]+ \\ &\quad h^2e[(p+kN-2N)T_i]+\ldots+h^ke[pT_i]\} \\ &= (1-h)\sum_{r=0}^{k} h^r e[(p+kN-rN)T_i] \quad (3) \end{aligned}$$

To obtain the steady-state response to a sinusoidal input, assume that the input signal is a sine wave, to be written

$$e(t)=E \sin 2\pi ft=EIm\epsilon^{j2\pi ft} \quad (4)$$

where Im stands for the "imaginary part of." The intermediate steps are simplified by writing

$$a=\frac{2\pi f}{f_r}=2\pi NfT_i; \quad w=\frac{p}{N} \quad (5)$$

so that $2\pi f(p+kN-rN)T_i=a(w+k-r)$. Then

$$e[(p+kN-rN)T_i]=EIm\epsilon^{ja(w+k-r)} \quad (6)$$

Equation 3 can now be written

$$\begin{aligned} e_p(k) &= (1-h)EIm\epsilon^{ja(w+k)}\sum_{r=0}^{k} h^r\epsilon^{-jar} \\ &= (1-h)EIm\epsilon^{ja(w+k)} \times \\ &\qquad \left[\frac{1-h^{k+1}\epsilon^{-ja(k+1)}}{1-h\epsilon^{-ja}}\right] \quad (7) \end{aligned}$$

by noting that the sum on the left is a geometric series of ratio $h\epsilon^{-ja}$. Equation 7 gives the distribution of potential around the commutator after each revolution of the brush.

We are primarily interested in the distribution of potential after many revolutions. Therefore, we note that as k becomes large the term h^{k+1} approaches zero, so that ultimately we can write

$$\begin{aligned} e_p(k) &= Im\bar{E}_0\epsilon^{ja(w+k)} \\ &= E_O \sin [2\pi f(p+kN)T_i+\theta] \quad (8) \end{aligned}$$

where $\bar{E}_O$ is the complex quantity

$$\bar{E}_O=E_O\epsilon^{j\theta}=E\left(\frac{1-h}{1-h\epsilon^{-ja}}\right) \quad (9)$$

Equations 8 and 9 embody the essential characteristics of the steady-state response and so bear further analysis. In practical cases h may be only slightly less than 1, in which cases a very large value of k must be attained before equation 8 can be used. In any case, equation

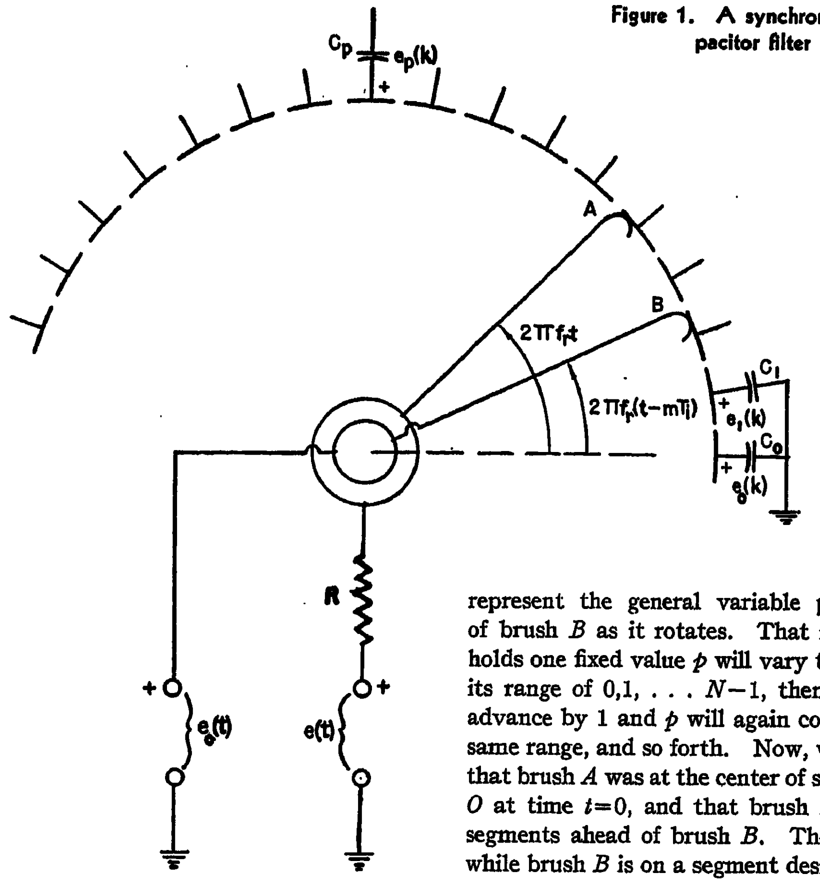

Figure 1. A synchronous capacitor filter

8 is the steady-state response and an h near unity means that the filter has a long build-up time.

Next, we are interested in discovering what sort of a signal brush B will pick up as it sweeps over the segments without drawing current. Equation 8 provides this information if $p+kN$ is allowed to represent the general variable position of brush B as it rotates. That is, as k holds one fixed value p will vary through its range of 0,1, . . . $N-1$, then k will advance by 1 and p will again cover the same range, and so forth. Now, we note that brush A was at the center of segment O at time $t=0$, and that brush A is m segments ahead of brush B. Therefore, while brush B is on a segment designated by $p+kN$ time will lie in the interval

$$(p+kN+m)T_i-\frac{T_d}{2}\leq t\leq(p+kN+m)+\frac{T_d}{2} \tag{10}$$

since brush A is on the segment designated by $p+kN+m$. At this point there is no longer a need for counting time intervals in terms of segment positions p and number of rotations k. Accordingly, we can let

$$n=p+kN+m \tag{11}$$

where n is the total number of segments passed over up to the time when t lies in the interval 10, not counting the starting position. Now, from equation 8 we obtain the simplified result

$$e_0'(t)=E_0\sin[2\pi f(n-m)T_i+\theta]$$

when

$$nT_i-\frac{T_d}{2}\leq t\leq nT_i+\frac{T_d}{2} \tag{12}$$

By allowing n to take on successive integral values, t progresses continuously, and equation 12 specifies a discontinuous output function which remains undefined for those time intervals when brush B is not on a segment. In a practical device the signal may be clamped at the value of the output for the immediately previous segment, or it may be reduced to zero by a blanking circuit. A typical graph of equation 12 is shown in Figure 3. In practice, the output can be smoothed by a low pass filter to yield an approximate sinusoid. For example, let $e_0(t)$ be the sinusoid

$$e_0(t)=E_0\sin(2\pi ft+\theta')$$

where

$$\theta'=\theta-2\pi fmT_i \tag{13}$$

It is noted that $e_0(nT_i)=e_0'(nT_i)$, and so it is concluded that equation 13 is a sinusoid passing through the mid-points of the steps of equation 13, and is approximately the smoothed output function.

Appraisal of the Response Function

As long as we remain within the frequency limit that allows the output function to be considered a sinusoid, the further study of the filter can be reduced to a consideration of Figure 4, where the response function $F(a)$ is obtained from equation 9 as

$$F(a)=\frac{1-h}{1-he^{-ja}} \tag{14}$$

which is a periodic function of the fre-

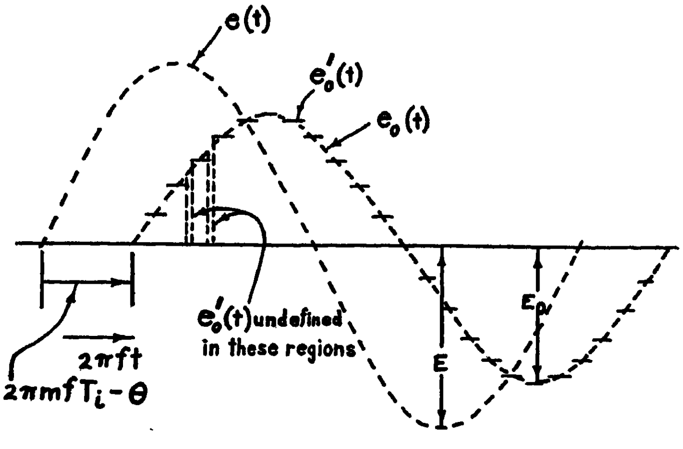

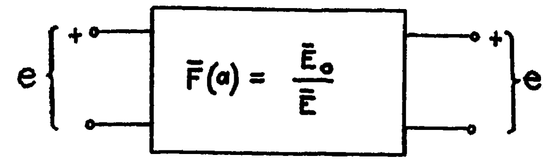

Figure 4. Definition of terms for treating the filter as a transmission system

$e = Im\bar E\epsilon^{j\omega t}$, where $\bar E = E\underline{/0}$ degrees

$e_0 = Im_r\bar E_0{}^{j\omega(t-mTt)}$, where

$\bar E_0 = E_0\underline{/\theta}$

quency parameter a. Note that the time delay due to the separation of m segments between the two brushes has been excluded from $\bar F(a)$. A routine procedure shows that equation 14 can be written

$$\bar F(a) = \frac{1}{\sqrt{1+\frac{2h}{(1-h)^2}(1-\cos a)}}\underline{/\theta} \qquad (15)$$

where

$$\theta = -\tan^{-1}\frac{h\sin a}{1-h\cos a}$$

Equation 15 exhibits a maximum response whenever a is an integral multiple of 2π. The general form of the response function is shown in Figure 5.

By the analysis given in the Appendix, it is found that the bandwidth between the half-power points of any one of the response peaks is

$$B = \frac{T_d}{\pi RC}f_r = \frac{T_d/T_t}{\pi NRC} \qquad (16)$$

It is recalled that the formulation of the response characteristics of the network represented by equation 15 is valid only after a sufficient number of revolutions to make the term h^{k+1} negligible compared with 1, in equation 7. Let us return now to equation 7 and define the response function

$$\bar F(a,k) = \frac{(1-h)[1-h^{k+1}\epsilon^{-ja(k+1)}]}{1-h^{-ja}} \qquad (17)$$

which approaches equation 14 as k becomes large. We are primarily interested in the build-up time at an integral multiple of f_r, for which a is an integral multiple of 2π. In that case equation 17 reduces to

$$1-h^{k+1} = 1-\epsilon^{-(k+1)Td/RC} \qquad (18)$$

The response has risen to within $(1/\epsilon)^2$ of the maximum response when the exponent of ϵ on the right of equation 18 is -2, which gives

$$k_b = \frac{2RC}{T_d}-1 \approx \frac{2RC}{T_d} \qquad (19)$$

as the necessary number of revolutions. The corresponding build-up time t_b is

$$t_b = \frac{2RC}{T_d}\left(\frac{1}{f_r}\right) = \frac{2}{\pi B} \qquad (20)$$

which shows an understandable relationship between build-up time and bandwidth.

The response function given by equation 14 can be further analyzed by writing

$$\bar F(a) = \frac{1-h}{1-h\epsilon^{-ja}} = \frac{1-h}{2}\left[1+\frac{1+h\epsilon^{-ja}}{1-h\epsilon^{-ja}}\right] \qquad (21)$$

and noting that

$$\bar G(a) = \frac{1+h\epsilon^{-ja}}{1-h\epsilon^{-ja}} \qquad (22)$$

is similar in form to the equation for the impedance of a transmission line with a real reflection coefficient h. Therefore, the known geometric properties of a transmission line impedance chart can be used to interpret equation 22 as a function of a.[8]

A typical plot of $\bar F(a)$ is given in Figure 6 for $h=7/8$. Much larger values of h will probably be used in practice. Loci of constant h are circles with centers on the real axis, and loci of constant a are circles centered on the line perpendicular to the real axis at $(1-h)/2$. The dimensions of the circles and locations of the centers are indicated in Figure 6.

As the frequency varies over the spectrum, the point of operation travels repeatedly around the circle of constant h. This fact is indicated by labeling values of a with the additive term $2s\pi$, where s is a positive integer. The number of times the chart may be encircled depends upon the upper frequency limit of validity of the analysis, which in turn depends upon the number of segments. A plot of one peak of the response function and its associated angle function for the case $h=0.99$ is shown in Figure 7.

Approximate relations for the response properties can be given for certain important limiting cases. When h is approximately 1, the important part of the response curve occurs for small deviations of a from multiples of 2π. If such a deviation is denoted by δa, we can use the approximate relations $\cos a \approx 1-(\delta a)^2/2$ and $\sin a \approx \delta a$ in equation 15 to give

$$\bar F(a) = \frac{1}{\sqrt{1+\frac{h(\delta a)^2}{(1-h)^2}}}\underline{/\theta} \qquad (23)$$

where

$$\theta = -\tan^{-1}\frac{1}{\frac{1-h}{(\delta a)h}+\frac{\delta a}{2}}$$

Continuing to assume h close to unity, for large derivations of a from an integral multiple of 2π the first equation of 15 becomes

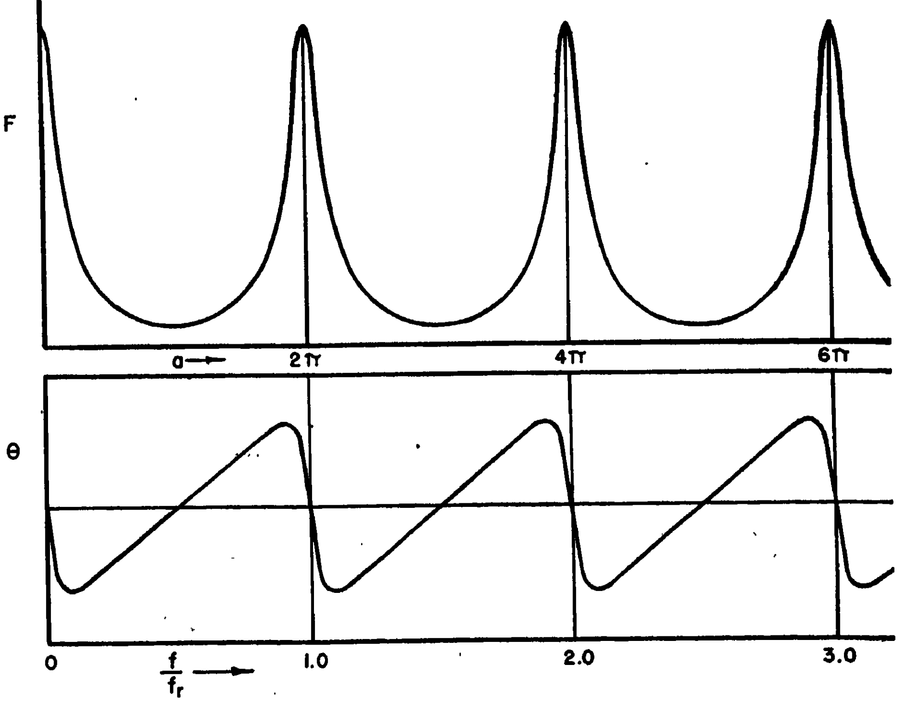
$$\bar F(a)\frac{1}{\frac{2\sqrt{h}}{1-h}\sin\left(\frac{\delta a}{2}\right)}\underline{/\theta} \qquad (24)$$

where θ continues to be given by the second equation of 15. It is interesting to note that $|\theta|$ has a maximum value given by

$$|\theta| = \sin^{-1}h \qquad (25)$$

as may be seen by referring to Figure 8,

Figure 5. Application of transmission-line chart technique to the filter transmission function



which is derived from Figure 6. Thus, the maximum absolute value of the phase angle is very nearly 90 degrees.

It should be noted that superposition holds for the synchronous filter, as a result of the linearity of equation 3. Therefore, by using the Fourier series or integral in the usual way, the transmission properties for a sinusoidal wave can be extended to include nonsinusoidal signals. However, in this connection, it is important to realize that the filter cannot transmit a periodic function of frequency higher than $Nf_r/2$, and that as this limiting frequency is approached the response loses its accuracy.

Noise-Reducing Properties of the Synchronous Comb Filter, Analysis Using the Frequency Spectrum of Noise

One use of the synchronous filter is to increase the signal-to-noise ratio of a periodic signal mixed with noise. Because the response characteristic of the synchronous filter has narrow passbands about each harmonic of the rotational frequency f_r, there is less noise in the output of the filter than in the input. However, the periodic signal is passed with substantially no attenuation if its frequency is a multiple of f_r, provided that the filter has been operating for a time longer than t_b. If the average power per cycle of the input noise is given by the spectrum function $N(f)$ and the response characteristic of the filter has a magnitude $T(f)$, the average power (or mean square value) of the output noise over a bandwidth W is given by

$$\sigma_0{}^2=\int^{W}N(f)[T(f)]^2df \tag{26}$$

assuming that W is less than the upper frequency limit of the filter. A quantitative estimate of the noise-reducing properties of the filter is made by assuming that the noise spectrum is flat with frequency in the range 0 to mf_r and is zero outside, where m is a positive integer such that mf_r is below the upper frequency limit of the filter. If the average power of the input noise is σ^2

$$N(f)=\frac{\sigma^2}{mf_r},\quad 0\leqq f\leqq mf_r \tag{27}$$

According to equation 15, for frequencies below the upper frequency limit, the magnitude of the response function of the filter as a function of frequency is

$$T(f)=\frac{1-h}{\sqrt{1+h^2-2h\cos\left(\frac{2\pi f}{f_r}\right)}} \tag{28}$$

If equations 27 and 28 are substituted into equation 26, subsequent simplification yields

$$\sigma_0{}^2=\sigma^2\left(\frac{1-h}{1+h}\right)=\sigma^2\left[\frac{1-\epsilon^{-T_d/RC}}{1+\epsilon^{-T_d/RC}}\right]$$
$$=\sigma^2\left[\tanh\left(\frac{T_d}{2RC}\right)\right] \tag{29}$$

Thus, the rms noise reduction factor is

$$\frac{\sigma}{\sigma_0}=\frac{1}{\sqrt{\tanh\left(\frac{T_d}{2RC}\right)}}\approx\sqrt{\frac{2RC}{T_d}} \tag{30}$$

since ordinarily $T_d<<RC$. Using equation 20, equation 30 may be written

$$\frac{\sigma}{\sigma_0}\approx\sqrt{\frac{2f_r}{\pi B}}=\sqrt{t_bf_r} \tag{31}$$

If the periodic signal has a frequency which is a multiple of f_r, σ/σ_0 is the ratio of the signal-to-noise ratio at the output divided by the signal-to-noise ratio at the input. Note that t_bf_r is the build-up time measured in revolutions of the brush.

Noise with a nonflat spectrum will experience about the same reduction, provided that the noise spectrum varies slowly from peak to peak of the transmission function.

Analysis Using Statistical Properties of Noise in Time

An alternative point of view of the noise reduction process is obtained from an analysis in time rather than frequency. The assumption is continued that the highest frequency component of the noise is below the upper frequency limit of the synchronous filter. In the time domain this means that the noise cannot change significantly during the time of dwell of a brush on a segment. The assumption is also continued that the filter has been in operation for a time exceeding its build-up time. Since the operation of the filter is linear, the noise may be considered separately from the useful signal, so that it may be assumed that the input signal is a random noise function. The resulting potential difference across the p'th capacitor after k'th revolution is still given by equation 3. Since $e_p(k)$ is the sum of a number of random variables, it is itself a random variable.

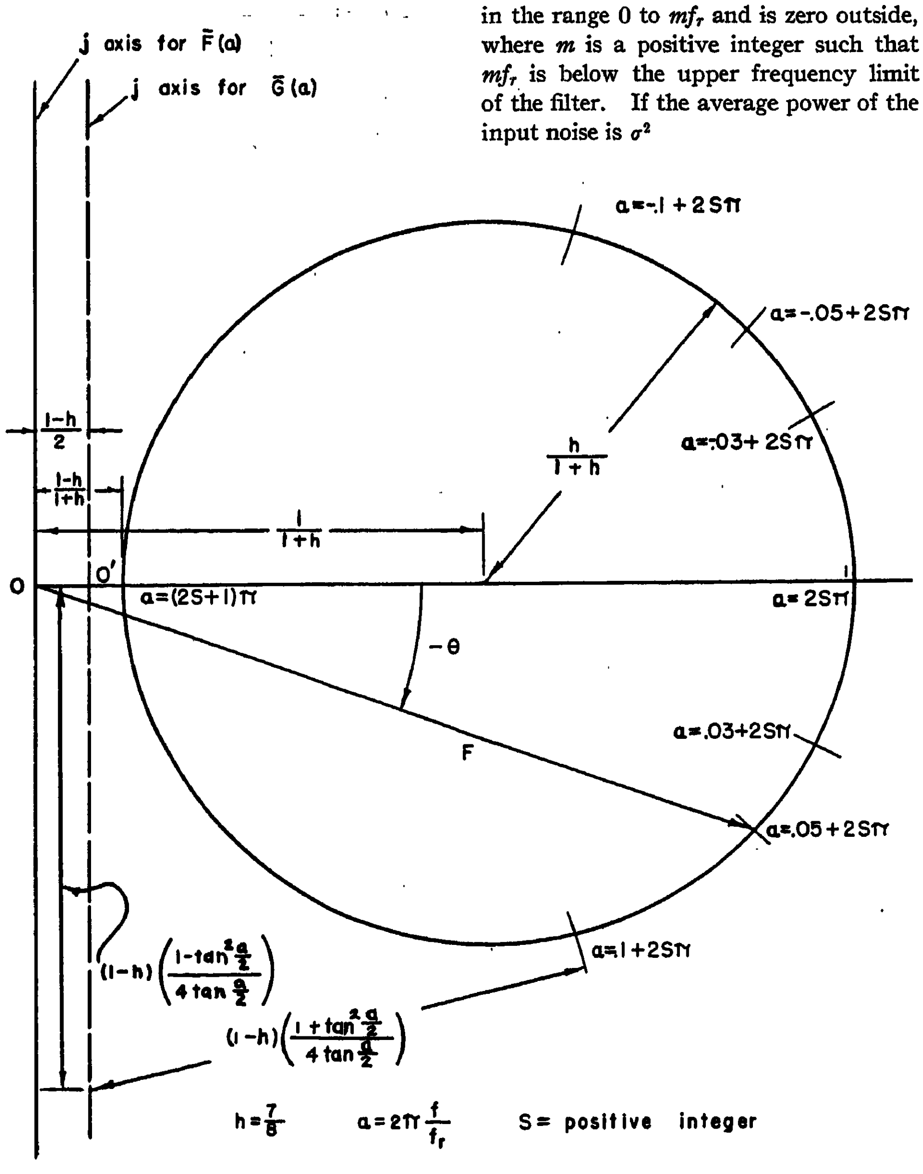


Figure 6. Construction for finding the maximum angle of the transmission function

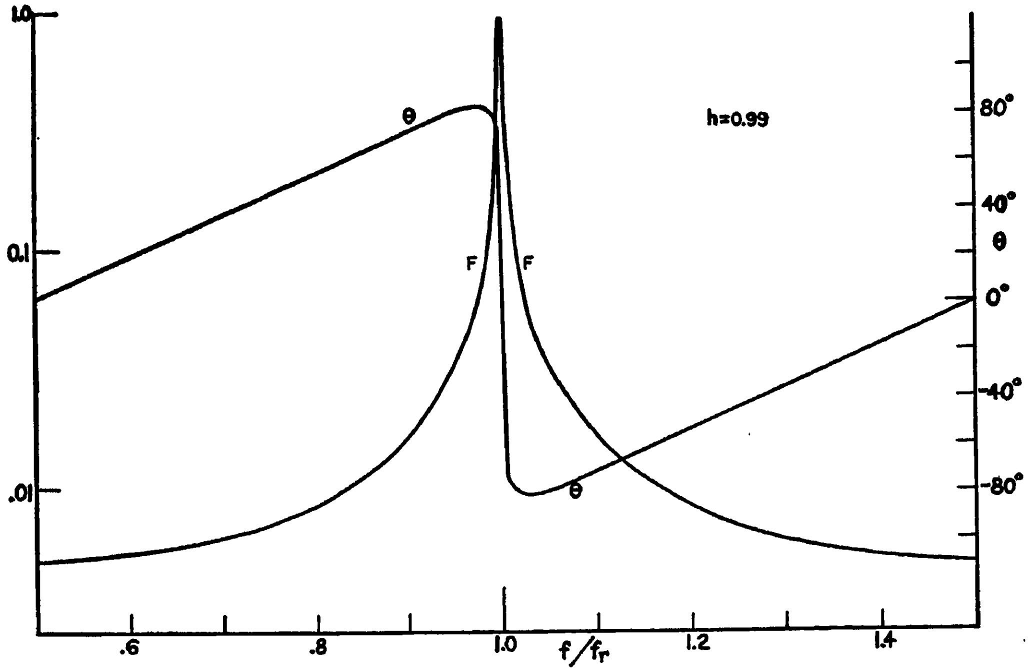
Figure 7. A typical "cycle" of the magnitude and angle of the transmission function



Inspection of equation 3 reveals that the individual terms in the summation for $e_p(k)$ are samples of $e(t)$ taken at a sequence of instants of time separated by the period of rotation. This summation starts at the time of observation and runs back toward zero time. However, for practical purposes, the summation can be considered stopped at the value of r for which h^r is reduced to $1/\epsilon^2$. According to equation 18, such a value of r is also the number of revolutions required for a sinusoidal response to build up. Therefore, the conclusion is reached that for k greater than the build-up time in revolutions $e_p(k)$ will be substantially independent of the values of k and p. Recalling that the output signal obtained from brush B consists merely of samples of $e_p(k)$, it follows that the output noise can be considered as the result of a stationary random process. By the ergodic hypothesis, for a stationary random process the mean square value considered as an average in time equals the mean square value considered as an ensemble average. This latter value may be obtained by making the assumption that the samples of $e(t)$ mentioned previously are statistically independent. This is accurately true for "white" noise and approximately true for noise which varies slowly from peak to peak of the transmission characteristic. By a fundamental theorem for the sum of a number of independent random variables

$$\overline{[e_p(k)]^2}=(1-h)^2\sum_{k=0}^{k}\overline{\{h^r e[(p+kN-rN)T_1]\}^2} \tag{32}$$

where the bar over a quantity means the ensemble average. However, the mean square value of the input noise, considered either as a time or ensemble average, is σ^2 so that equation 32 can be written

$$\overline{[e_p(k)]^2}=(1-h)^2\sum_{r=0}^{k} h^{2r}\sigma = {}^{2}\frac{(1-h)^2}{1-h^2}\times \sigma^2[1-h^{(2k+1)}\ ] \tag{33}$$

Then, as k becomes very large, the left-hand side of equation (33) becomes $\sigma_0{}^2$, and the right-hand side simplifies to give the final result

$$\sigma_0{}^2=\left(\frac{1-h}{1+h}\right)\sigma^2 \tag{34}$$

which is the same answer as was obtained by the analysis in the frequency domain.

The synchronous filter is now seen to be a device which uses an averaging process to increase the signal-to-noise ratio of a repetitive signal mixed with noise. To understand this more fully, consider an idealized hypothetical process whereby M cycles of the input signal are stored and then averaged. The result would consist of one cycle of the desired periodic signal plus the averaged noise. Now suppose this averaging process is performed continuously so that each cycle of the output signal would be the average of the previous M cycles of the input signal. Then the output signal is the sum of the desired signal and the averaged noise. Using an argument similar to the one which precedes equation 32 and making a similar assumption about the character of the input noise, the noise in the output signal of this hypothetical process may be shown to have an rms values $1/\sqrt{M}$ times the rms value of the input noise. Thus, the signal-to-noise ratio at the output would be $\sqrt{M}$ times the signal-to-noise ratio at the input. This conclusion for the idealized process is interesting because it shows that this is the best result that can be obtained with an averaging process if the delay is limited to M cycles of the periodic signal. Essentially the same result was obtained for the actual device.

Appendix. Estimate of Bandwidth

An estimate of the bandwidth can be obtained from the first equation of 15 by observing that the half-power points occur when

$$\frac{2h}{(1-h)^2}(1-\cos a)=1 \tag{35}$$

which reduces to

$$\cos a=1-\frac{(1-h)^2}{2h} \tag{36}$$

From the definition of h in equation 2 we can write

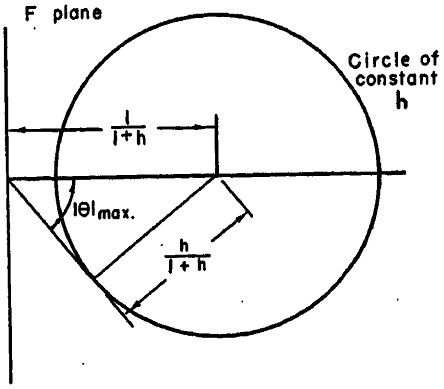


Figure 8. Maximum absolute value of the phase angle

$$h=1-\alpha+\frac{1}{2}\alpha^2-\frac{1}{6}\alpha^2+\ldots \qquad (37)$$

where $\alpha=T_d/RC$. In practical cases α is very small, and so the preceding series converges rapidly. Keeping three terms, we get

$$\frac{(1-h)^2}{2h}=\frac{\left(\alpha-\frac{\alpha^2}{2}\right)^2}{2-2\alpha+\alpha^2}=\frac{\alpha^2}{2}\left[\frac{1-\alpha+\frac{\alpha^2}{4}}{1-\alpha+\frac{\alpha^2}{2}}\right]\approx\frac{\alpha^2}{2} \qquad (38)$$

The cos a term is modified by writing

$$a=2\pi s+\delta a \qquad (39)$$

where s is an integer. Then, cos $a=$ cos δa, and if δa is small, we can write

$$\cos\delta a=1-\frac{1}{2}(\delta a)^2 \qquad (40)$$

Equations 38 and 40 can then be used in equation 36 to give

$$\delta a=\alpha \qquad (41)$$

Recalling the definition of a, we can replace δa by $2\pi(\Delta f/f_r)$, where Δf is the frequency deviation from a point of maximum response, to give

$$\Delta f=\frac{\alpha}{2\pi}f_r=\frac{T_d}{2\pi RC}f_r \qquad (42)$$

Equation 16 follows from equation 42 by noting that the bandwidth is $2\Delta f$.

Synopsis: Capacitors whose capacitance is a function of voltage can be made using commercially available barium strontium titanate ceramics. Such nonlinear capacitors can be used as controllable impedances to form a dielectric amplifier. Using nonresonant circuits without transformers or feedback, amplifiers have been tested and found to give a large power amplification. but with an output voltage less than the input voltage. Using resonant circuits a voltage amplification of four has been obtained with the same materials.

THE idea of a dielectric amplifier using nonlinear capacitors as the controllable impedance has been suggested before.[1,2] The development of the device has recently been stimulated by improved materials and by increased emphasis on more reliable electronic components for military equipment. High permittivity ceramics such as the barium strontium titanates provide dielectrics having both a high permittivity and a marked nonlinearity at ordinary temperatures. While further development of these materials is needed, samples now available are reasonably usable. The characteristics of amplifiers using commercial barium strontium titanates are being investigated experimentally and theoretically at Carnegie Institute of Technology.

The dielectric used in these studies was a barium strontium titanate ceramic available in sheets approximately 1 inch by 3 inches by 0.007 inch thick with a silver coating on each face for convenience in making electric connections. The Curie temperature is slightly below room temperature. Such materials are in an early stage of development. The one chosen seems to be the best that is available, but it is hoped that further development will result in dielectrics having higher electrical breakdown, lower losses, a greater nonlinearity, and especially more uniform properties. At present pieces cut from a given sheet show considerable variation.

The nonlinearity of the dielectric requires a modification of the usual definition of capacitance. In general one can use definitions of capacitance paralelling definitions of inductance. The characteristics of several barium strontium titanate capacitors have been determined by measuring current, voltage and frequency and calculating the capacitance. The capacitance measured varies with applied voltage. As the voltage is reduced to small values (1 to 5 volts) the capacitance becomes constant and approaches the differential capacitance dQ/dV.

Values of this differential capacitance have been determined as a function of d-c bias or control voltage for various temperatures and frequencies. Figure 1 shows the change in capacitance as a function of control voltage as measured at 25 degrees centigrade and 655 kc. Figures 2 and 4 show capacitance as a function of temperature and frequency. In Figure 4 at 300 kc there is a marked decrease in capacity. Since Von Hippel[3] has observed similar phenomena this has not as yet been investigated further. If capacitance is expressed as a percentage of that measured at zero control voltage and plotted as a function of control voltage, the variation with temperature and frequency appears less serious. This is shown by the curves of Figures 3 and 5.

If the experimental plot of differential capacitance versus control voltage is integrated with respect to voltage, the resulting curve may be used to better advantage for the analytical predetermination of dielectric amplifier characteristics. Such a plot of charge per unit area D as a function of direct potential gradient E is shown in Figure 6. A plot of D = 0.052 tanh 0.84E is shown for comparison.

The Nonresonant Amplifier in Steady State

Circuital applications of nonlinear reactors have been many and varied, especially during the last several years when refinement of the magnetic amplifier has greatly broadened its realm of usefulness. This section is a discussion of the use of nonlinear capacitors as variable reactive circuit elements, and as such it presents representative amplifier circuits, their general performance, and analytical methods for the predetermination of operating characteristics.

In order to establish a common basis of terminology, the term "dielectric amplifier" will be used in accordance with the following definition which is consistent

---

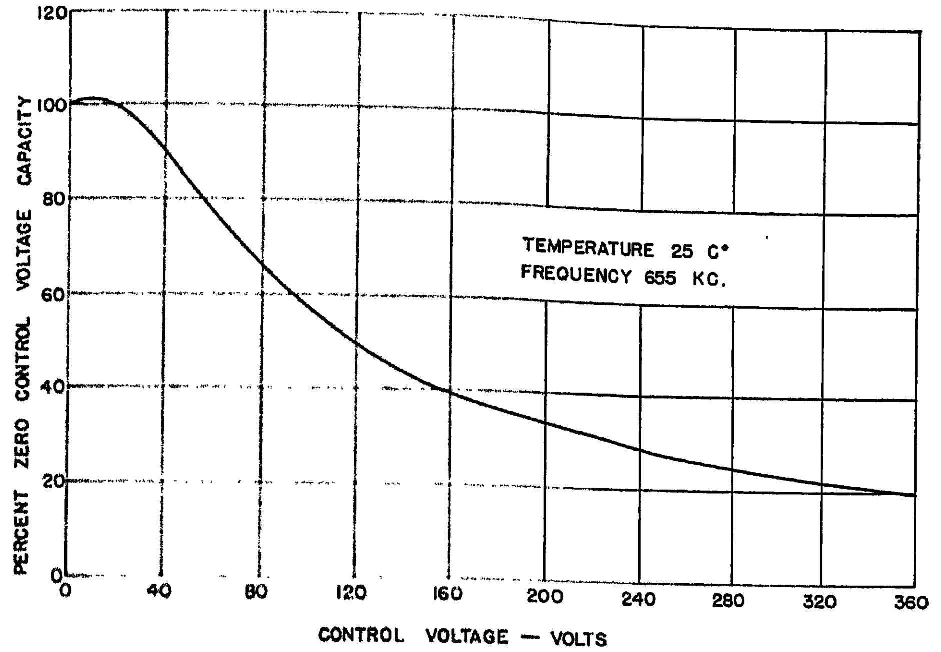

Figure 1. Change in capacitance as a function of control voltage

with general reactance amplifier terminology. "A dielectric amplifier is a device which in order to obtain amplification or control uses nonlinear capacitors either alone or in combination with other circuit elements."

An elementary circuit which exploits dielectric nonlinearity is that shown in Figure 7, but passage of load current by the input device is required. A better arrangement is to use blocking reactive elements to isolate the input and load circuits to prevent unwanted interaction. Figure 8 shows such a circuit. Capacitor C; which may also be made nonlinear for maximum gain performs the vital function of preventing voltage division of the biasing voltage by resistors R_P and R_L; this means that full bias is applied to the capacitor at all times.

The need for the blocking reactance L_B which prevents passage of supply frequency currents through the control circuit can be obviated by a further refinement shown in Figure 9. Here all voltages of fundamental frequency or odd harmonics thereof cancel from points 1 to 2; hence currents of these frequencies do not flow in the input circuit when the nonlinear capacitors are a matched pair. Thus only even harmonics of supply frequency flow through the input device. Since, as Figure 5 shows, these titanate elements exhibit a slowly varying ratio of D to E, they generate harmonics of small magnitude and consequently the input device of Figure 9 experiences little effect from the load circuit.

Superficial considerations seem to dictate that since a dielectric–magnetic analogy can be derived, it would be possible simply to transfer present information concerning magnetic amplifier circuits to those containing nonlinear dielectrics. Further investigation shows that while an analogy exists under certain conditions, there is one important difference. With a given magnetic core the simple expedient of adding and changing windings allows for any desired multiplications, additions, and isolation of magnetomotive forces. This cannot be duplicated with electromotive forces in a given capacitor; rather separate circuit elements must be introduced to perform this function if indeed it can be done at all. Although the use of a nonlinear capacitor consequently is less flexible than the use of a nonlinear inductive reactor, this limitation in many cases seems to be more than overcome by advantages of the dielectrics such as high leakage resistance which allows high power gain without feedback, light weight, extremely small size, and relatively low losses which permit tuned circuit operation.

The curve of Figure 1 shows a possible ratio of maximum to minimum differential permittivity of 5 to 1. This compares with a maximum usable ratio of differential permeabilities of about 25 to 1 for high-frequency ferromagnetic materials and 6,000 to 1 for alloys such as Deltamax. This comparatively small nonlinearity of dielectrics is a disadvantage

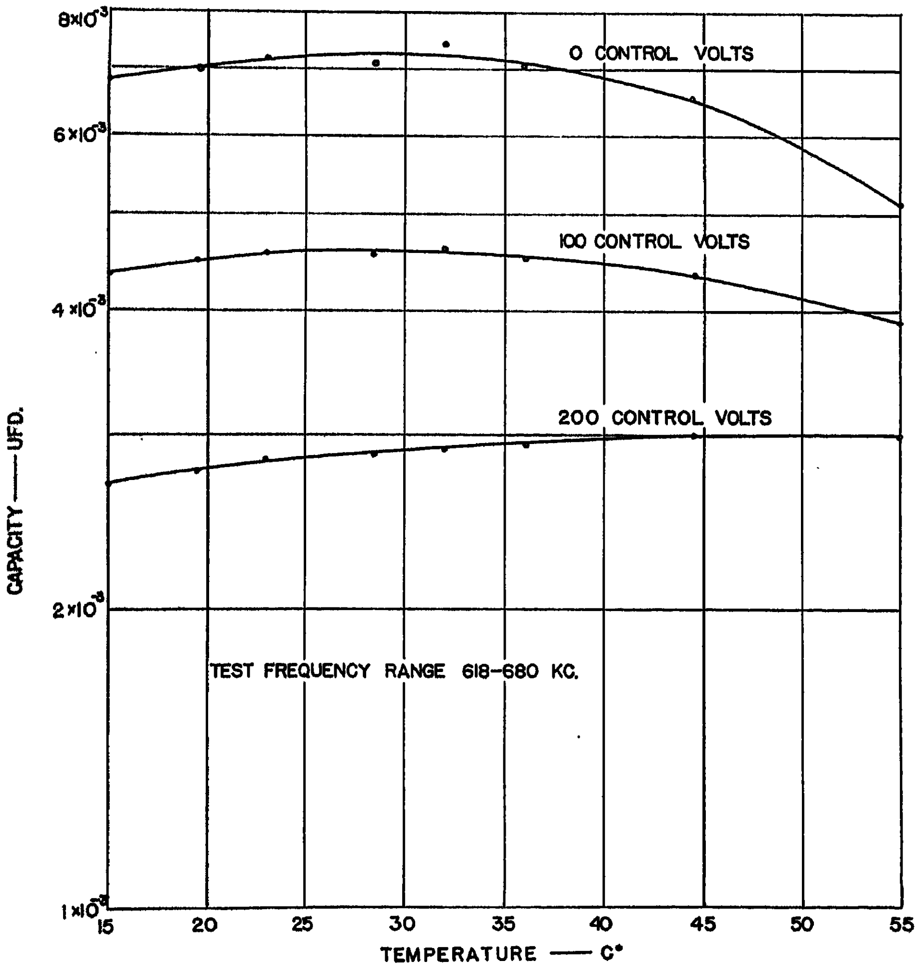

Figure 2. Capacitance of a nonlinear element as a function of temperature for various values of control voltage

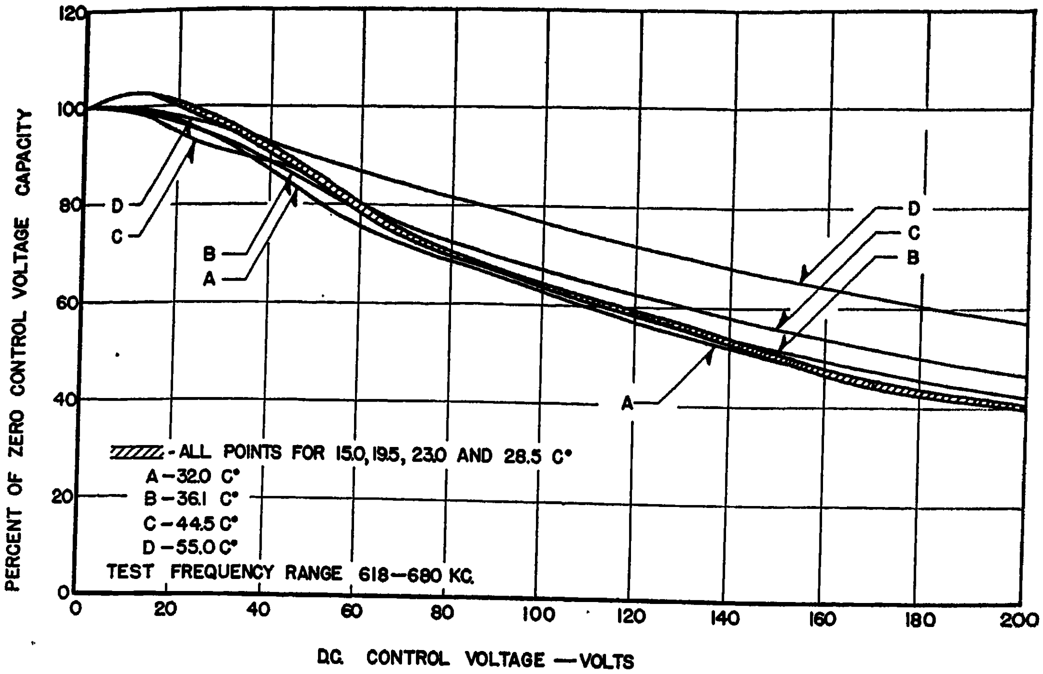

Figure 3. Change in capacitance as a function of control voltage for various temperatures

from the standpoint of amplification but since harmonic generation is a direct function of nonlinearity, the harmonic content of a dielectric amplifier output is small as compared to that of magnetic amplifiers.[4]

Typical no-load performance curves of the circuit of Figure 9 are shown in Figure 10. These show the variation with control voltage of the crest value of the fundamental component of 500-cycle output current I_{m_1} for titanate capacitors 1 by 3 by 0.006 inch held at a constant temperature of 35 degrees centigrade by means of a controlled oil bath. In contrast with the control characteristics of a magnetic amplifier, dielectric amplifier output decreases as a state of saturation is approached.

Since the curves of Figure 10 show the performance of only one particular amplifier, they give no definite information concerning the effect of a change in material characteristics, size, or frequency. For this purpose universal curves have been calculated from a representation of the curve of Figure 6 by means of the function

$$D = A \tanh(aE) \tag{1}$$

where

A and a are constants of the particular dielectric material under consideration, hence independent of capacitor size and connection

D is electric displacement, which for a parallel plate is equal to the charge per unit area on the plates

E is the gradient of the applied electromotive force

For a given capacitor of surface area S and thickness l

$$D = q/S \tag{2}$$

$$E = v_N/l \tag{3}$$

where q is the instantaneous charge on the capacitor and V_N is the applied voltage.

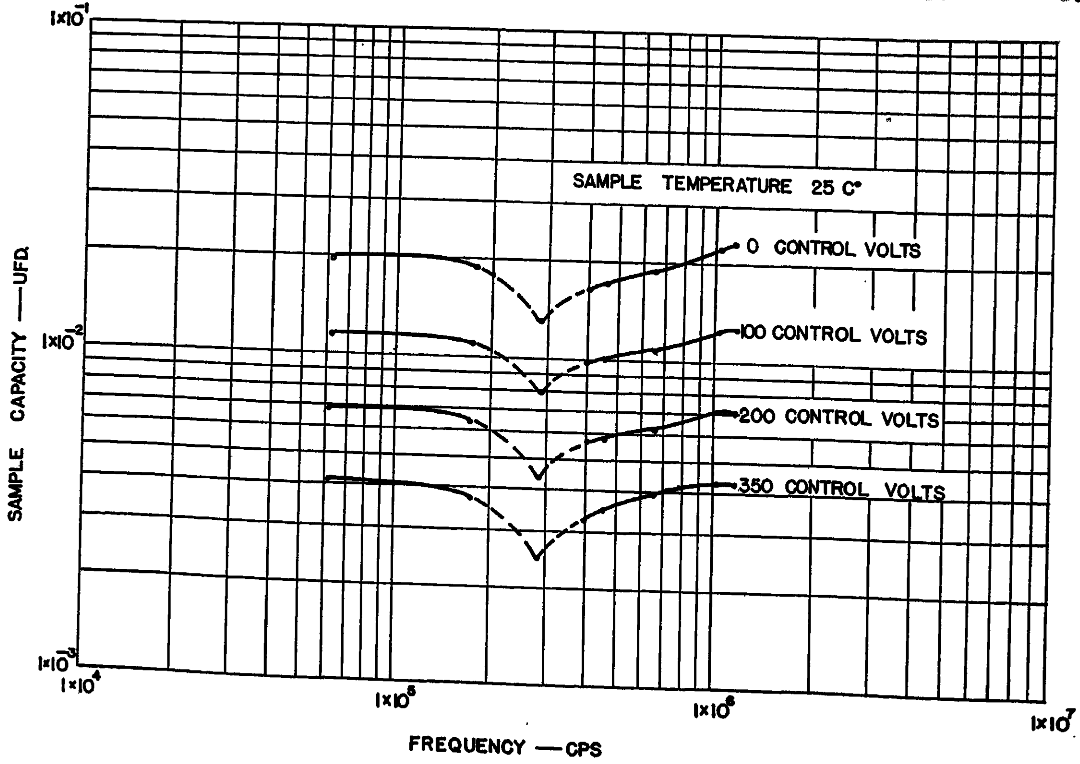

Figure 4. Capacitance of a nonlinear element as a function of frequency for various values of control voltage

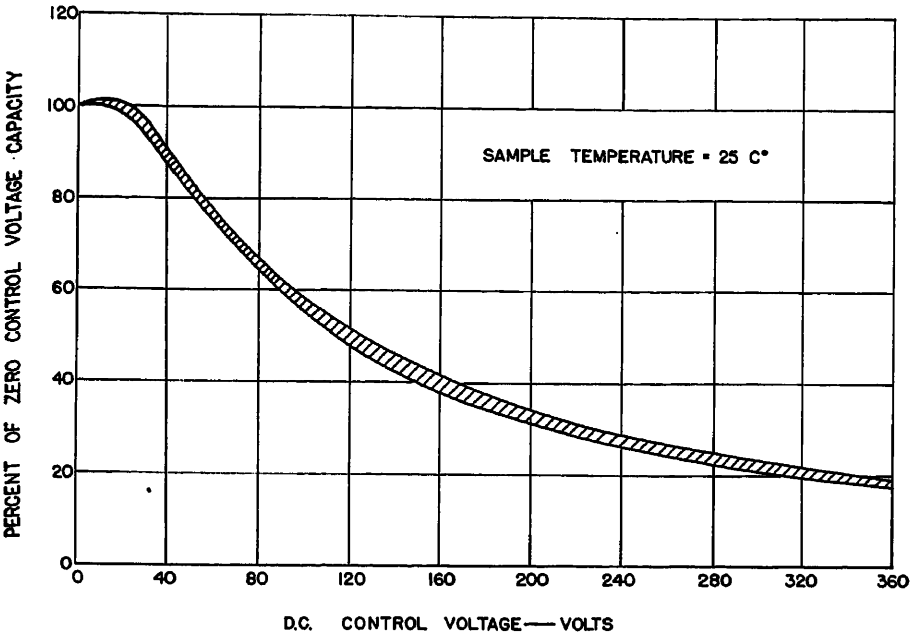

Figure 5. Change in capacitance as a function of control voltage. Range of values as measured at 61.7, 172.4, 286, 400, 455, 655, 1,025, and 1,166 kc

Thus

$$q/SA = \tanh(av_N/l) \tag{4}$$

In order to translate charge into current, q must be differentiated with respect to time. When V is harmonic and periodic, q is given by the Fourier series

$$q = Q_0 + Q_{m_1}\sin(\omega t + \varphi_1) + Q_{m_2}\sin(2\omega t + \varphi_2) + \ldots \tag{5}$$

Thus

$$i = \dot{Q}_0 + \omega Q_{m_1}\cos(\omega t + \varphi_1) + 2\omega Q_{m_2}\cos(2\omega t + \varphi) + \ldots \tag{6}$$

Since q/SA is dimensionless, $i/\omega SA$ is also dimensionless and on the universal curves is denoted as I_d.

In the single element circuit of Figure 8, the instantaneous value of load current contains both even and odd harmonics, so that

$$i_L = I_{m_1}\cos(\omega t + \varphi_1) + I_{m_2}\cos(2\omega t + \varphi_2) + I_{m_3}\cos(3\omega t + \varphi_3) \tag{7}$$

In the double element circuit of Figure 9, however, only odd harmonics flow as load current and the even harmonics flow in the signal circuit.

$$i_L = I_{m_1}\cos(\omega t + \varphi_1) + I_{m_3}\cos(3\omega t + \varphi_3) + \ldots \tag{8}$$

$$i_C = I_{m_2}\cos(2\omega t + \varphi_2) + \ldots \tag{9}$$

These harmonic components are expressed in general form in the following equations

$$\begin{aligned} I_{m_1} &= \omega SAI_{d_1} \\ I_{m_2} &= 2\omega SAI_{d_2} \\ I_{m_3} &= 3\omega SAI_{d_3} \end{aligned} \tag{10}$$

Higher harmonics are usually negligible. The dimensionless coefficients I_d are derived in Appendix I and plotted in Figures 11, 12, 13, and 14.

Johnson and Latson[5] have shown a graphical technique which determines the effect of resistive loading from no-load reactance amplifier curves. For small amounts of harmonic generation by the nonlinear device, a resistive load prescribes an elliptical load line. The dotted ellipse of Figure 9 serves for one particular value of load. The phase angle φ_1 is determined by the ratio of resistive to reactive voltage drops.

As a means of demonstrating a dielectric amplifier, the audio amplifier of Figure 15 was constructed. Figure 16 shows the signal volt-ampere input and power output as functions of signal frequency when a 50-kc carrier is used. The power factor of the signal circuit is estimated to be about 2 per cent so that the watts input is about 1/50th of the volt-ampere input. The power amplification can be high for low-frequency signals and varies inversely with the signal frequency. With adequate cooling the power amplification can be further increased by increasing the carrier frequency since output is approximately proportional to this frequency. While power amplification of the nonresonant circuit is high the output voltage is less than the input voltage.

Series Resonant Amplifier

In the preceding section the carrier current control results from the change in impedance of the nonlinear capacitor as the control voltage varies. In such circuitry the carrier current can change no more, percentagewise, than the capacitance of the nonlinear element changes. It has been found that using the nonlinear capacitor as part of a tuned circuit permits a much greater degree of current control.

To investigate the series resonant circuit an analysis was chosen which is one compromise between rigor and convenience. This analysis considers the nonlinear element to have a capacitance whose magnitude cannot be changed by the carrier voltage appearing across it but can be varied by the control voltage. It is to be expected that although this procedure should permit a good approximation to the circuit response when the carrier voltages across the element remain small, it can serve only as a guide to experimental work when larger voltages are encountered.

The basic circuit for this investigation is shown in Figure 17. The analysis requires that all circuit components except C_N and R_N be linear elements. It assumes that a differential capacitance versus control voltage curve (C_N versus V_c) and an equivalent loss resistance versus control voltage curve can be defined for the nonlinear dielectric element but that the latter shows very little variation in R_N over the control voltage range that is of interest. In addition it assumes that the source impedance is negligible, and that the applied carrier potential V is sinusoidal with fixed frequency and magnitude.

The carrier circuit is said to be in resonance when

$$\omega L_T=\frac{1}{\omega\left(\dfrac{C_{N_r}C_T}{C_{N_r}+C_T}\right)}$$

Subscript r denotes circuit conditions at this point.

It is desired to compare the percentage variation of carrier current with control voltage in the tuned circuit with that variation which could be obtained in the nonresonant circuit. By writing *a-c* circuit theory equations for the carrier loop it is possible to express this variation in the form

$$\frac{I_L}{I_{L_r}}=\frac{1}{\sqrt{1+P^2\left(\dfrac{1}{C_N/C_{N_r}}-1\right)^2}}. \tag{11}$$

where

$$P=\frac{QF}{\left(\dfrac{C_{N_r}}{C_T}+1\right)} \tag{55}$$

$$QF=\frac{\omega L_T}{R_N+R_{cT}+R_{L_T}} \tag{40}$$

The derivation of this relation is shown in Appendix II, section 1. *QF* for the dielectric element is closely analogous to the familiar "quality factor" of linear circuitry so long as the carrier voltage across the nonlinear element remains small.

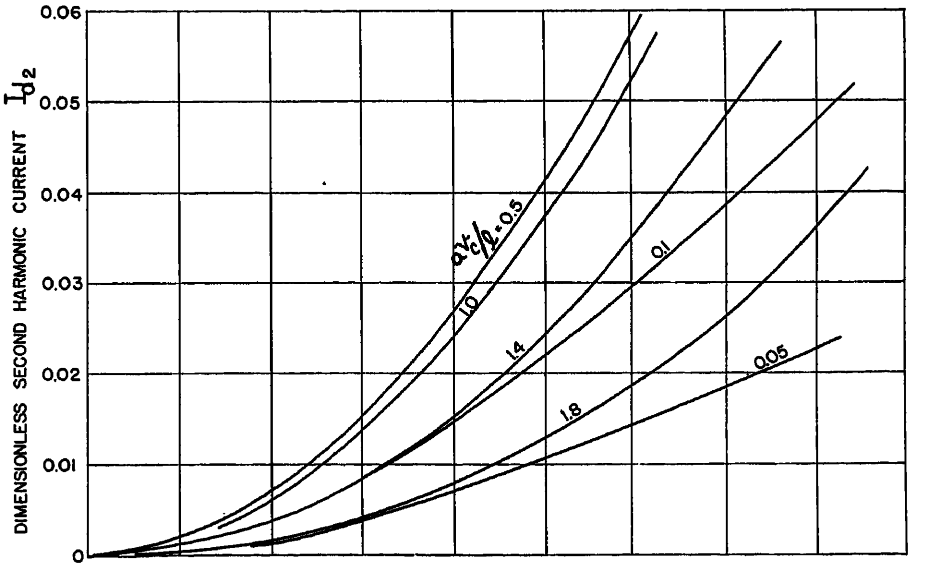
Figure 13 (below). Dimensionless no-load second-harmonic characteristics



versus C_N/C_{N_r} can be constructed for various values of P. Elimination of C_N/C_{N_r} between these curves and the C_N/C_{N_r} versus v_c curve gives a family of "detuning characteristics" which shows I_L/I_{L_r} versus v_c. Figure 18 compares detuning characteristics for various values of P with the experimental C_N/C_{N_r} versus v_c plot on which they are based. If the dielectric element were used in the nonresonant circuit the per cent current versus control voltage curve for that circuit could never fall below this per cent capacitance plot. It is seen that for all values of P shown which are greater than one there is a region on the detuning characteristics which exhibits a greater percentage change in carrier current for a given control voltage change than would be possible in the nonresonant circuit.

In certain applications of the tuned circuit such as a dielectric voltage amplifier, it is desirable to maintain the circuit P as large as possible (that is, to maintain the maximum slope for the detuning characteristic) while making the tuning capacitance C_T as small as possible. Referring to equation (55) it would appear that so long as circuit QF remained constant decreasing C_T would have the undesirable effect of reducing the maximum slope of the detuning characteristic. It can be shown, however, that if the losses in the dielectric element dominate total carrier circuit losses, then inserting increasingly smaller values for C_T in the circuit does not change P and hence does not change the shape of the detuning characteristic. As the denominator of the expression for P increases with decreased C_T the circuit QF is increased in a manner which tends to offset any change in the quotient.

For the losses in the nonlinear capacitor to remain dominant the restriction

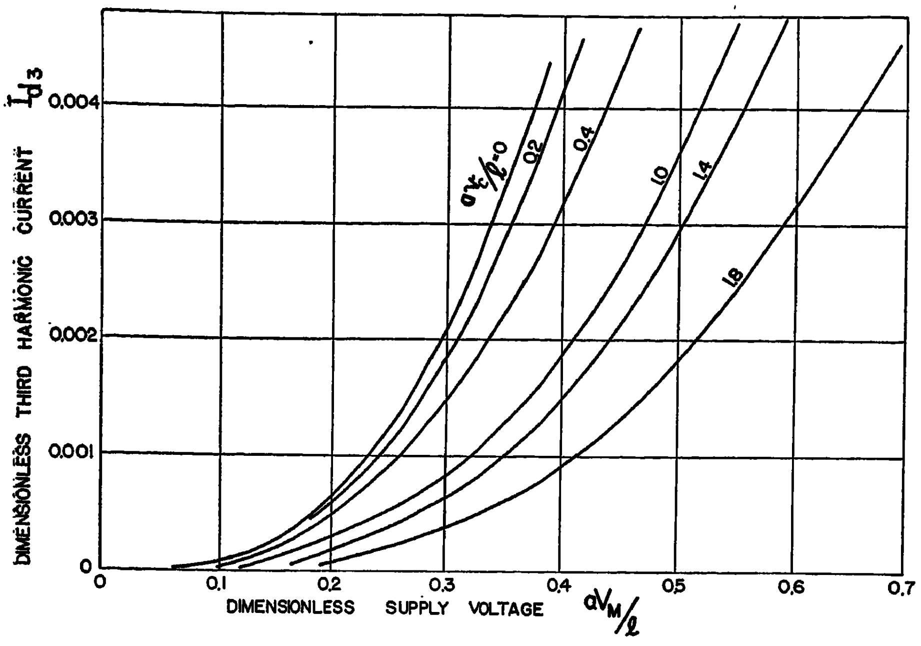


Figure 14 (above). Dimensionless no-load third-harmonic characteristics

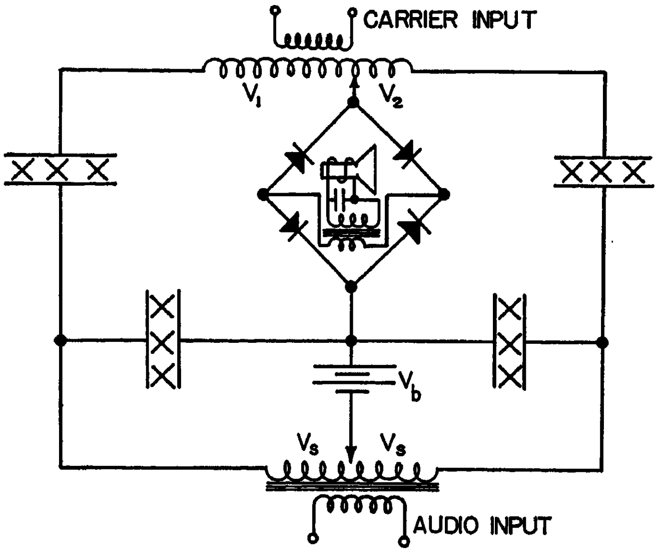

Figure 15 (left). Nonresonant audio amplifier circuit

$$\frac{R_{CT}+R_{LT}}{R_N}=\left[\frac{pf_{CT}C_{N_r}}{pf_{N_r}C_T}+\frac{\frac{C_{N_r}}{C_T}+1}{pf_{N_r}QF_L}\right]<<1 \qquad (12)$$

must be satisfied. Here

pf_{CT} is the power factor of the tuning capacitor

QF_L is the quality factor of the tuning inductance

pf_{N_r} is the power factor of the nonlinear element for that value of control voltage at which the circuit is in resonance

The derivation in Appendix II, section 2, shows that if this restriction is met the expression $P = 1/pf_{N_r}$ holds for all values of C_T. When the restriction is no longer satisfied the maximum slope of the detuning characteristic will decrease. The dielectric voltage amplifier is one application of the tuned circuit for which such a decrease is more than compensated by an advantage gained through the use of a smaller tuning capacitor.

There are at least two characteristics of the dielectric element tuned circuit which make it quite suitable for use in voltage amplification. The first is the relatively steep slope which is exhibited by the circuit detuning curves. The second is the fact that large voltages may exist across the reactive elements of a series circuit operating near resonance even though the driving potential remains relatively small.

The carrier current in the tuned circuit must flow through the linear tuning elements L_T and C_T. Thus the large percentage change in carrier current which accompanies a small change in the control voltage is matched by an equally large percentage change in the carrier voltages across the linear elements. Since the magnitudes of these voltages can be quite large to begin with, the absolute change in their values may be greater than the initiating change in v_c.

In Figure 19 the necessary components have been added to the basic dielectric element tuned circuit to adapt it for voltage amplification. Germanium rectifier GR, carrier frequency filter C_f, R_f, and d-c blocking capacitor C_0 constitute a simple demodulator. L_B is chosen to present negligible impedance to the signal in comparison with C_N. If V_c is a signal whose frequency is much lower than the carrier frequency, the carrier voltage appearing across the linear inductance L_T assumes the familiar amplitude modulated wave form. The modulation envelope of this voltage has essentially the shape of the input signal. By demodulating this voltage it is possible to obtain an output potential whose amplitude is greater than the input voltage amplitude. In general if the slope of the circuit detuning characteristic remains essentially constant for some range of v_c about a fixed bias point, and if an ideal demodulator is placed across one of the linear tuning elements, then for input signals whose amplitude does not exceed the prescribed range in v_c and whose frequency is small in comparison with the carrier frequency, $VA = 1.414GV_{T_r}$. Here

VA is the ratio of the output signal voltage to the input signal voltage

G is the magnitude of the slope of the detuning characteristic

V_{T_r} is the rms value of the carrier voltage that appears across the linear tuning element at resonance

The derivation for this expression is shown in Appendix II, section 3.

In a preceding paragraph it was noted that inserting small values for C_T into the carrier circuit may not greatly reduce the slope of the detuning characteristic, and, indeed, if the losses in the dielectric element dominate circuit losses it will not change the slope at all. Figure 20 compares experimental characteristics for circuits having $C_T = 10\ C_{N_r}$, $C_T = C_{N_r}$, and $C_T = 0.1\ C_{N_r}$ with the analytical detuning characteristic for $P = 40$. These circuits were constructed using commercially available coils and capacitors. It can be seen that decreasing C_T to the point where $C_T = C_{N_r}$ makes only a negligible change in the slope of the detuning curve, and decreasing C_T to the point where $C_T = 0.1\ C_{N_r}$ reduces the slope by a factor of only 2.8. At the same time if the carrier potential across C_N is maintained at a fixed value the resonant carrier voltage across C_T and C_N in series and hence across L_T is increased as C_T is reduced. Herein lies the significant advantage of adding a

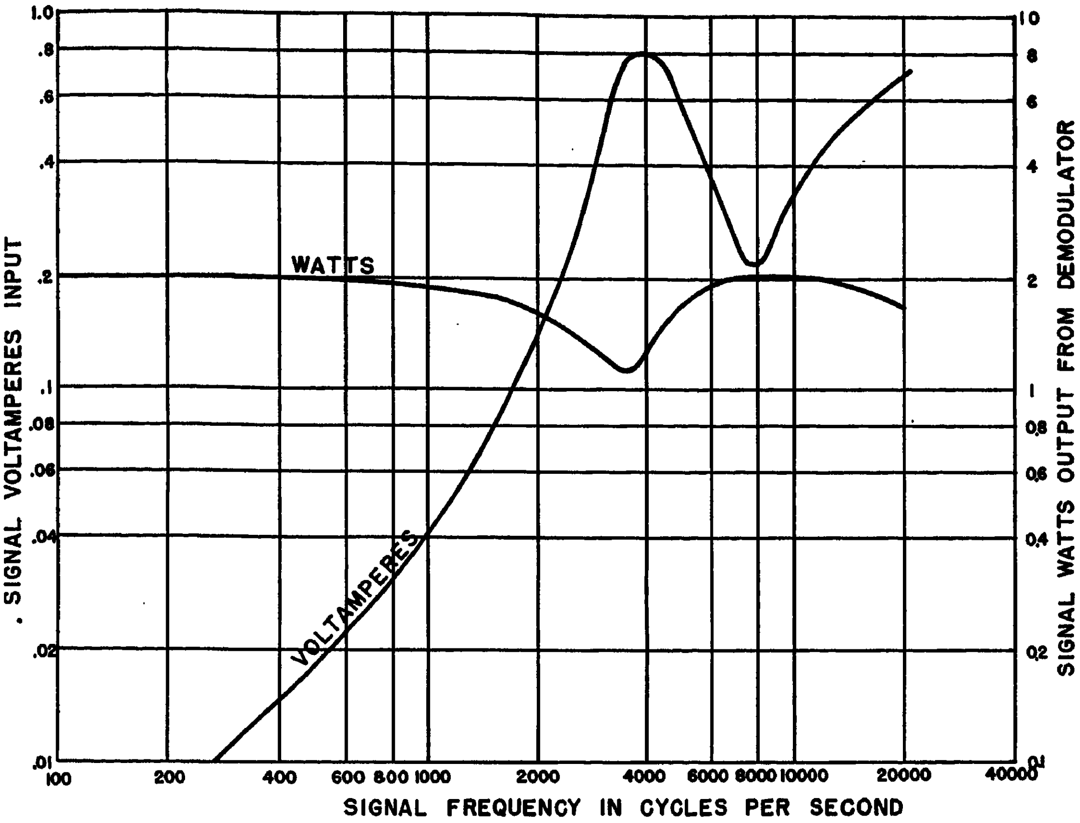

Figure 16 (left). Frequency characteristics of audio amplifier shown in Figure 15 when $V_1 = 30$ volts, $V_2 = 20$ volts, $V_b = 5$ volts, $f_c = 50$ kc

Figure 17 (below). Basic nonlinear element series resonant circuit

C_N is the nonlinear dielectric element

C_T is a linear tuning capacitor which also serves to prevent the flow of control current in the carrier circuit

R_N, R_{C_T}, and R_{L_T} are the equivalent loss resistances of the dielectric element, tuning capacitor, and tuning inductance respectively

L_T is a linear tuning inductance

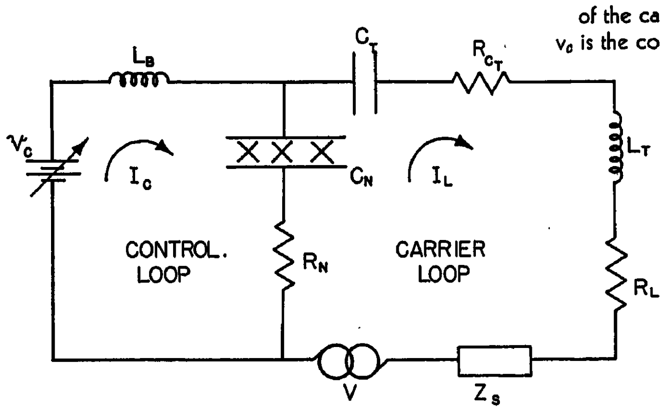
L_B is a blocking choke used to make I_C negligible in comparison with I_L

Z_s is the impedance of the carrier oscillator V

I_L is the carrier current

ω is the angular frequency of the carrier

V_C is the control voltage



linear tuning capacitor to the circuit. For a given carrier potential across C_N the signal voltage can exert the same percentage control over a significantly larger voltage as C_T is decreased. This results in a greater absolute change in the carrier potential across L_T for a given signal voltage variation, and the amplification is increased. Consideration of the expression for ideal gain, $VA = 1.414 G V_{T_r}$ shows that in the experimental case noted, placing $C_T = C_{N_r}$ results in double the gain possible when no tuning capacity is used. Although G is decreased by a factor of 2.8 when one-tenth this value of C_T is inserted, V_{T_r} is increased by a factor of 11 so that the over-all improvement in voltage gain is about 400 per cent.

The opportunity to control large tuned circuit voltages which is afforded by the inclusion of the tuning capacitor assumes even more importance when it is noted that the magnitude of the carrier voltage appearing across the nonlinear capacitor is seriously limited by various factors. As the voltage across the element becomes large the element loses percentage control of the carrier current. Harmonic generation in the circuit is greatly accentuated by increased carrier potential swings, and circuit stability suffers due to larger dielectric capacitor losses. Finally, erratic puncture, edge sparking, and fracture are found to occur at surprisingly low values of carrier potential with materials presently available.

In experimental work completed thus far the greatest circuit gain observed has been four. This gain was obtained under circumstances which approached the upper limit on operating conditions for the dielectric material. Maintaining the carrier voltage across the nonlinear condenser at a more reasonable value has given gains of at least three for the several amplifiers which have been constructed. The frequency response of a representative amplifier with a high impendance load is shown in Figure 21.

Figure 22 shows the tuned circuit modified for use as a general stage in a cascade arrangement of dielectric voltage amplifiers. In this circuit a portion of the direct plus signal voltage appearing at the carrier filter output is picked off by the potentiometer R_b. C_b acts to by-pass the signal component in this voltage and the direct component appears across C_N, thus eliminating the need for a bias battery. The steady-state response of an amplifier consisting of three such stages is given in Figure 23.

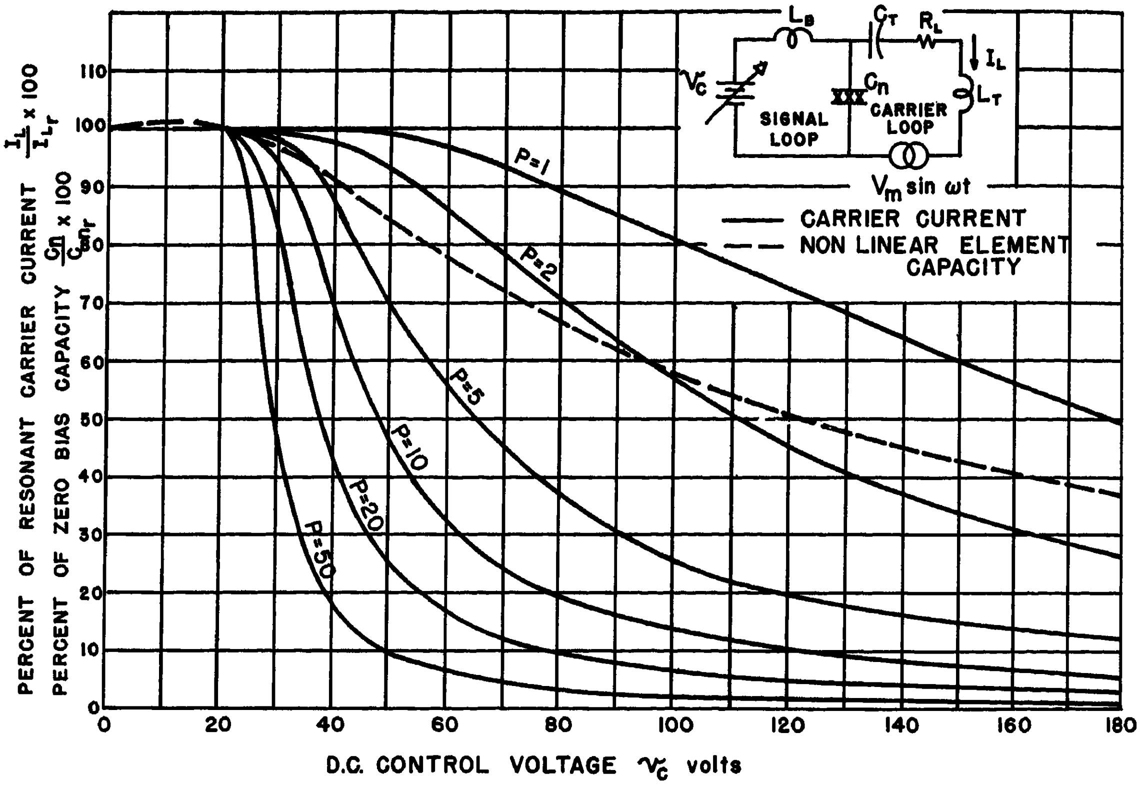
At present the investigation of the voltage amplifier is being continued along several lines. Consideration is being given to the real and reactive power output capabilities of the circuit, to improvement in amplifier frequency response, to the use of positive and negative feedback, and to a more exact analysis of nonlinear element resonant circuit characteristics.

List of Symbols

$V_m \sin \omega t$ = harmonic potential applied to load or carrier circuit

$V = 0.707 V_m$

Figure 18. Detuning characteristics compared with the capacitance change of the nonlinear element, where $P = (\omega L_T/R_L)/(C_{Nr}/C_T+1)$



V_b = d-c bias potential
V_s = rms value of periodic signal voltage
v_s = instantaneous value of signal voltage
v_N = instantaneous voltage across nonlinear capacitor
v_c = instantaneous value of control voltage
v_f = instantaneous voltage across carrier filter
v_T = rms voltage across linear tuning element
V_{out} = rms output voltage
E = instantaneous value of potential gradient
i_L = instantaneous value of load or carrier circuit current
i_c = instantaneous value of control circuit current
I_{m_n} = crest value of nth harmonic component of current
I_{d_n} = crest value of dimensionless nth harmonic component of current
I_L = rms value of load or carrier current
q = instantaneous value of charge on nonlinear capacitor
Q_0 = average value of charge on nonlinear capacitor
Q_{m_n} = crest value of nth harmonic component of charge
q_L = instantaneous value of load circuit circulating charge
q_c = instantaneous value of control circuit circulating charge
D = electric displacement = charge per unit area for parallel plate capacitor
R_L = load circuit resistance
R_B = control circuit resistance
R_b = bias circuit resistance
R_N = equivalent resistance to represent losses in nonlinear element
R_{C_T} = equivalent resistance to represent losses in tuning capacitor
R_{L_T} = equivalent resistance to represent losses in tuning coil
R_0 = input resistance
L_B = blocking inductance
L_T = linear tuning inductance
L_f, C_f, R_f = carrier filter components
C = linear capacitor in load circuit
C_N = differential capacitance of nonlinear capacitor
C_T = linear tuning capacitance
C_b = bias circuit capacitor
C_e = equivalent tuned circuit capacitance
C_0 = blocking capacitor
pf_N = power factor of the nonlinear element
pf_{C_T} = power factor of the linear tuning capacitance
S = surface area of nonlinear capacitor

P = a factor which determines the shape of the detuning characteristics
QF = quality factor of the tuned carrier circuit
QF_L = quality factor of the linear tuning inductance
GR = germanium diode rectifier
Z_s = carrier source impedance
G = slope of detuning characteristic
VA = voltage amplification
Subscript r denotes circuit conditions at resonance

Appendix I. Derivation of General Characteristics

An analytical determination of the characteristics of a dielectric amplifier circuit must presume a functional form relating dielectric displacement and applied potential gradient. While this functional form can be made accurate to any desired degree, a proper balance must be struck between accuracy of representation and operational ease in solving the equations which result from this choice. The wide latitude of variation of this balance in modern analysis indicates that no small number of factors are involved; however, it may be said that complexity of analysis is an increasing function of accuracy.

Currently available dielectrics have been found to possess capacitances which vary from sample to sample and temperature to temperature in such fashion that any one of several functions may be used to advantage to represent the mean polarization curve. Suitable functions are

$$E=a_1D+a_3D^3 \tag{13}$$

$$D=A\tanh(aE) \tag{14}$$

$$D=A\sinh^{-1}(aE)^6 \tag{15}$$

Equation 14 has been chosen in order to permit the following derivation of the no-load general characteristics of the dielectric amplifier.

Consider again the circuit of Figure 8. Equations of this circuit are

$$V_m\sin\omega t=q_L/C+R_L\dot{q}_L+v_N \tag{16}$$

$$v_c=-L_B\ddot{q}_c-R_B\dot{q}_c+v_N \tag{17}$$

$$q=q_L-q_c=SA\tanh av_N/l \tag{18}$$

In all cases which appear destined to find practical application

$$\dot{q}_L>>\dot{q}_c \tag{19}$$

because ω_{LB} is made very large compared to the greatest value of reactance of the nonlinear capacitor. Thus

$$\dot{q}\cong\dot{q}_L;\ q_c\cong 0 \tag{20}$$

No-load conditions require that

$$R_L=0;\ \frac{1}{\omega C}\rightarrow\infty \tag{21}$$

which dictates that

$$R_L\dot{q}_L=0;\ q_L/C=-v_c \tag{22}$$

Equations 16 and 17 become

$$V_m\sin\omega t+v_c=v_N \tag{23}$$

whence equation 18 can be written

$$q=SA\tanh\frac{a}{l}(V_m\sin\omega t+v_c) \tag{24}$$

This function can also be written as a Fourier series because of its periodicity.

$$q=Q_0+Q_{m_1}\sin\omega t+Q_{m_2}\cos 2\omega t+ Q_{m_3}\sin 3\omega t+\ldots \tag{25}$$

Here Q_{2K} and Q_{2KH} are functions of both V_m and v_c. It should be noted that the general dimensionless currents I_{dn} are the quotients of Q_{m_n} and SA.

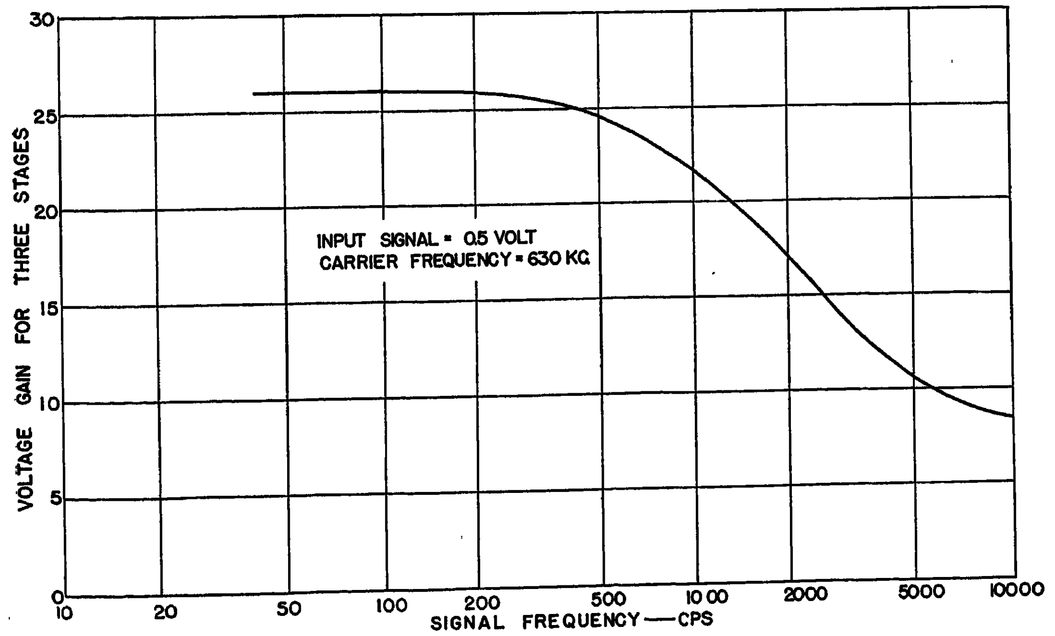

Figure 23. Frequency response curve for a 3-stage dielectric voltage amplifier

Rapid convergence of this series for existing dielectrics permits the use of the fundamental term alone in computing the effect of capacitive and resistive loads in the special case where

$$V_m << v_c \qquad (26)$$

A quasi-linear analysis can be used to better advantage to determine the effect of resistive loading. For this method the functional form 3 is used.

For C large

$$v_c + V_m \sin \omega t = v_N + R_L \dot{q} \qquad (27)$$

But since

$$\dot{q} = \frac{d}{dt}\left[SA \sinh^{-1} \frac{av_N}{l}\right] \qquad (28)$$

$$v_c + V_m \sin \omega t = v_N + \frac{R_L SAa}{\sqrt{a^2 v_N{}^2 + l^2}} \frac{dv_N}{dt} \qquad (29)$$

In view of equation 26

$$v_c + V_m \sin \omega t = v_N + \frac{R_L SAa}{\sqrt{a^2 v_c{}^2 + l^2}} \frac{dv_N}{dt} \qquad (30)$$

which is linear in v_N and has as its steady-state solution

$$v_N = v_c + \frac{V_m}{\sqrt{1 + \dfrac{\omega^2 R_L{}^2 S^2 A^2 a^2}{a^2 v_c{}^2 + l^2}}} \sin(\omega t + \varphi) \qquad (31)$$

where

$$\varphi = \tan^{-1}\left[-\frac{R_L \omega SAa}{\sqrt{a^2 v_c{}^2 + l^2}}\right] \qquad (32)$$

From this expression for the instantaneous voltage of the capacitor, the current i_L is readily determined, since

$$i_L = \frac{V_m \sin \omega t - (v_N - v_c)}{R_L} \qquad (33)$$

Appendix II

1. Variation in Carrier Current with Nonlinear Element Capacitance for Series Resonant Carrier Circuit of Figure 17

Let

$$R_L \equiv R_N + R_{C_T} + R_{L_T} \qquad (34)$$

$$C_e \equiv \frac{C_N C_T}{C_N + C_T} \qquad (35)$$

For the series circuit

$$V = I_L \sqrt{R_L{}^2 + \left(\omega L_T - \frac{1}{\omega C_e}\right)^2} \qquad (36)$$

$$I_L = \frac{V}{R_L} \frac{1}{\sqrt{1 + \left(\dfrac{\omega L_T}{R_L} - \dfrac{1}{\omega R_L C_e}\right)^2}} \qquad (37)$$

At resonance

$$I_{L_r} = \frac{V}{R_L} \qquad (38)$$

Hence

$$\frac{I_L}{I_{L_r}} = \frac{1}{\sqrt{1 + \left(\dfrac{\omega L_T}{R_L} - \dfrac{1}{\omega R_L C_e}\right)^2}} = \frac{1}{\sqrt{1 + \left(\dfrac{\omega L_T}{R_L} - \dfrac{1}{\omega R_L C_{e_r}} \dfrac{C_{e_r}}{C_e}\right)^2}} \qquad (39)$$

But

$$QF \equiv \frac{\omega L_T}{R_L} = \frac{1}{\omega R_L C_{e_r}} \qquad (40)$$

Thus

$$\frac{I_L}{I_{L_r}} = \frac{1}{\sqrt{1 + QF^2\left(\dfrac{C_{e_r}}{C_e} - 1\right)^2}} \qquad (41)$$

Now

$$\frac{C_{e_r}}{C_e} = \left(\frac{C_{N_r} C_T}{C_{N_r} + C_T}\right) \bigg/ \left(\frac{C_N C_T}{C_N + C_T}\right) \qquad (42)$$

$$\left(\frac{C_{e_r}}{C_e} - 1\right) = \frac{C_{N_r} C_T (C_N + C_T) - C_N C_T (C_{N_r} + C_T)}{C_N C_T (C_{N_r} + C_T)} = \frac{\dfrac{C_{N_T}}{C_N} - 1}{\dfrac{C_{N_r}}{C_T} + 1} \qquad (43)$$

so that

$$\frac{I_L}{I_{L_r}} = \frac{1}{\sqrt{1 + \left[\dfrac{QF}{\dfrac{C_{N_r}}{C_T} + 1}\right]^2 \left(\dfrac{1}{\dfrac{C_N}{C_{N_r}}} - 1\right)^2}} = \frac{1}{\sqrt{1 + P^2 \left(\dfrac{1}{\dfrac{C_N}{C_{N_r}}} - 1\right)^2}} \qquad (11)$$

2. Expression for P when Nonlinear Element Losses Dominate Carrier Circuit Losses

By definition

$$QF = \frac{\omega L_T}{R_N + R_{C_T} + R_{L_T}}$$

At resonance

$$\omega L_T = \frac{1}{\omega C_{e_r}} \qquad (44)$$

Then by equations 35 and 44

$$QF = \frac{1}{\left(\dfrac{R_{C_T}}{R_N} + \dfrac{R_{L_T}}{R_N} + 1\right) \omega R_N C_{N_r} \left(\dfrac{C_T}{C_{N_r} + C_r}\right)} \qquad (45)$$

The power factor of a capacitor whose equivalent circuit is a resistance R in series with a capacity C is given by

$$pf = \frac{R}{\sqrt{R^2 + 1/\omega^2 c^2}} = \frac{1}{\sqrt{1 + (1/\omega RC)^2}} \qquad (46)$$

If $(1/\omega RC)^2 >> 1$, then

$$pf \cong \omega RC \qquad (47)$$

Measurements indicate that the power factor of the nonlinear dielectric material is generally less than 3 per cent while the tuning capacitor with mica or air dielectric should have a power factor much smaller than this. Thus

$$pf_{N_r} \cong \omega R_N C_{N_r} \qquad (48)$$

$$pf_{C_T} \cong \omega R_{C_T} C_T \qquad (49)$$

Then

$$\frac{R_{C_T}}{R_N} \cong \frac{pf_{C_T} C_{N_r}}{pf_{N_r} C_T} \qquad (50)$$

Since

$$QF_L \equiv \frac{\omega L_T}{R_{L_T}} \qquad (51)$$

$$\frac{R_{L_T}}{R_N} \cong \frac{\omega L_T \omega C_{N_r}}{QF_L pf_{N_r}} \frac{C_{e_r}}{C_{e_r}} = \frac{1}{QF_L pf_{N_r}} \times \frac{C_{N_r}(C_{N_T} + C_T)}{C_{N_r} C_T} = \frac{\left(\dfrac{C_{N_r}}{C_T} + 1\right)}{QF_L pf_{N_r}} \qquad (52)$$

Substituting equations 48, 50, and 52 into equation 45

$$QF \cong \frac{1}{\left[\dfrac{pf_{C_T} C_{N_r}}{pf_{N_r} C_T} + \dfrac{\left(\dfrac{C_{N_r}}{C_T} + 1\right)}{pf_{N_r} QF_L} + 1\right] \times pf_{N_r}\left[1 \bigg/ \left(\dfrac{C_{N_r}}{C_T} + 1\right)\right]} \qquad (53)$$

If components are chosen such that

$$\frac{R_{C_T} + R_{L_T}}{R_N} = \left[\frac{pf_{C_T} C_{N_r}}{pf_{N_r} C_T} + \frac{\left(\dfrac{C_{N_r}}{C_T} + 1\right)}{pf_{N_r} QF_L}\right] << 1 \qquad (12)$$

then

$$QF \cong \frac{\left(\dfrac{C_{N_r}}{C_T} + 1\right)}{pf_{N_r}} \qquad (54)$$

and, from equation 11

$$P \cong \frac{1}{pf_{N_r}} \qquad (55)$$

3. Approximate Linear Analysis of Voltage Amplifier Gain

In Figure 19 if v_c is constant

$$V_T = \omega I_L L_T = \frac{I_L}{I_{L_r}} \omega L_T I_{L_r} \qquad (56)$$

But

$$V_{T_r} = I_{L_r} \omega L_T \qquad (57)$$

Thus

$$V_T = \frac{I_L}{I_{L_r}} V_{T_r} \qquad (58)$$

If the demodulator is ideal, then

$$v_f = \sqrt{2} V_T = \frac{I_L}{I_{L_r}} \sqrt{2} V_{T_r} \qquad (59)$$

If v_c is changed by an amount Δv_c

$$\Delta v_f = \Delta\left(\frac{I_L}{I_{L_r}}\right)\sqrt{2}V_{T_r} \qquad (60)$$

Dividing by Δv_c

$$\frac{\Delta v_f}{\Delta v_c} = \frac{\Delta(I_L/I_{L_r})}{\Delta V_c}\sqrt{2}V_{T_r} \qquad (61)$$

If for some range in v_c about a fixed bias point V_b the magnitude of the detuning characteristic slope G remains essentially constant, then for any Δv_c within this range

$$\frac{\Delta v_f}{\Delta v_c} = G\sqrt{2}V_{T_r} \qquad (62)$$

From Figure 19

$$v_c = v_s + V_b \qquad (63)$$

$$\Delta v_c = \Delta v_s \qquad (64)$$

If v_s is varied sinusoidally with a frequency that is sufficiently small in comparison with the carrier frequency, the magnitude of the carrier current will vary in accordance with the steady-state detuning characteristics of Figure 18. Under these circumstances

$$VA = \frac{V_{\text{out}}}{V_s} = G\sqrt{2}V_{T_r} \qquad (65)$$

No Discussion

Some Fluorinated Liquid Dielectrics

N. M. BASHARA
NONMEMBER AIEE

Synopsis: The properties of some fluorinated liquids are reviewed. They have low dielectric constants and low power factors over wide frequency and temperature ranges. They also have high dielectric strengths. A range of boiling points is available to make possible high vapor densities at relatively low temperatures. Utilization of this in electrical applications is feasible with these compounds since they meet requirements of nonflammability, stability, and compatibility with metals and insulation which are not satisfied entirely by other materials. Low water absorption and high thermal stability are additional reasons for interest in these materials.

THE replacement of hydrogen by fluorine in organic compounds results in many changes in the properties of liquids. Many of the changes are such as to make the materials of interest for electrical uses. For example, the fluorine is able to change a compound from one having considerable fire and explosion hazard to a stable material, inert to a great variety of conditions.

Some of the compounds whose electrical properties have been studied are listed in Table I. Vapor pressure curves for two of the compounds are shown in Figure 1.

The comparison of fluorocarbon and hydrocarbon pentanes by Burger and Cady[1] typifies the differences between the two classes of materials. While the following conclusions are based on that report they generally apply to the compounds whose electrical properties have been studied here. It should be emphasized that the similarity in properties to fluorocarbons is being stated as a generalization only for the particular liquids studied in this report. Attention is called to this point by referring to these specific materials as fluorinated liquids. Comparing similar compounds the fluorocarbons have a greater density. Their absolute viscosity is greater but the kinematic viscosity is less. The fluorocarbons boil at lower temperatures. The coefficient of expansion of the fluorocarbons is greater, as is the change of density and viscosity. The over-all general impression is that the fluorocarbons are considerably more volatile.

The characteristic volatility of the fluorocarbons plus the generally low range of boiling points for the compounds of Table I direct emphasis to applications related to these factors, which complement the good electrical properties and fireproof nature of the materials. For example, many improvements in performance can be realized where appreciable vapor densities exist. Operation in the range up to 200 degrees centigrade would result in pressures of up to four or five atmospheres for some of the materials listed in Table I. Heat transfer and dielectric strength of the vapors are generally benefited with increase of vapor pressure. It is only possible to take advantage of such properties in these compounds because certain other requirements for electrical uses are met. In contrast, low boiling hydrocarbons and chlorinated compounds do not find such uses, failing to meet one or more of the requirements. Hydrocarbons are unsatisfactory due to the aggravated fire hazard of the low boiling compounds. Low boiling chlorinated materials, where available, are objectionable due to their deteriorating effect on many types of insulation and metals and because of their toxicity. The fluorinated liquids have none of these objections. They are also much more stable to other conditions.

Obviously, for the same reasons that new design variations become possible with these materials there must be alterations in design to accomodate them. The liquids discussed here require a closed system to prevent evaporation. More room for expansion is required, this becoming even more of a problem at elevated temperatures. The coefficient of volume expansion increases by 75 per cent for $(C_4F_9)_3N$ at 150 degrees centigrade and by 25 per cent for c-$C_8F_{16}O$ at 75 degrees centigrade as compared to the values at room temperature. The low surface tension makes it more difficult to make a tight seal. In certain cases the increased weight for a given

volume might be objectionable. The large temperature coefficients of density and viscosity are also factors to be considered.

Electrical Properties

Table II, which lists some electrical properties at 25 degrees centigrade, indicates that these liquids are unusual, with very low dielectric constants and refractive indices, low conductivities, and power factors which, it will be seen, remain small over a wide range of frequencies.

The average values of dielectric strength are somewhat higher on the American Society for Testing Materials test than those ordinarily listed for transformer oils. However, a comparative check of equally pure samples of these liquids and transformer oils has not been made.

Since there is a difference between the square of the refractive index and the low frequency dielectric constant, energy absorption is expected. Figure 2, which plots the dielectric properties to the microwave region, shows the presence of dissipation factor peaks at the upper end of the spectrum. The tests were made on samples which had undergone considerable purification. The relatively small change of dielectric constant (less than 1 per cent) to the upper microwave range anticipates a large change in the infrared which is confirmed experimentally.[2,3]

Some of the effects of temperature and moisture on the electrical behavior have been determined. There was no consistent change in the dielectric strength between 30 and 90 degrees centigrade for dry samples. Figure 3 shows the decrease in resistance with temperature for typical, dry samples of two of the liquids with different boiling points. There is a decrease of dielectric constant of approximately 0.0016 per degree for c-$C_8F_{16}O$ between 30 and 90 degrees centigrade and about 0.0012 per degree for $(C_6F_{13})_2O$ between 30 and 150 degrees centigrade.

Table III summarizes the effects of water. There appears to be a larger effect on the electrical properties of these materials than on commonly used trans-

† Two different samples of c-$C_8F_{16}O$ and $(C_6F_{13})_2O$ were tested. Results for samples (a) are at the end of 80 days, samples (b) at the end of 10 days.

‡ Absolute accuracy poor at these low concentrations since measurement was made by Karl Fischer method. The difference between the two samples is probably real. There was good reproducibility on a large number of tests.

former oils even though the maximum water saturation appears to be no greater than 25 parts per million for these liquids at 90-per-cent relative humidity. At this same humidity a hydrocarbon transformer oil would show 73 parts per million and an Askarel 108 parts per million. These results are from Clark.[4] His tests at room temperature and a water content corresponding to 90-per-cent relative humidity show that the dielectric strength of the Askarel dropped to about 40 per cent of the dry value. Mineral oil showed a decrease to about 80 per cent of the dry value. The fluorinated liquids tested in Table III decreased in dielectric strength in about the same ratio as the Askarels for the same test conditions. The resistance also shows a greater decrease for the fluorinated liquids despite their lower water absorption. The apparently greater change of resistance may be due to effects related to lower viscosity, such as ion mobility, and so forth. The solubility of water in perfluorodimethylcyclohexane was found to be 13.6 parts per million at 25 degrees centigrade.[5,6]

It might be well to point out that the comparison of the effect of water has neglected what is in practice a more serious problem for hydrocarbon oils, condensed water which can accumulate at the bottom of apparatus. No such problem would occur in the use of the fluorinated liquids since there would be no accumulation of condensed vapor. Comparative tests on the dielectric strength of a hydrocarbon oil provided an example of what can occur. The oil sample, while exposed to 90-per-cent relative humidity, underwent slight but sufficient temperature cycling to result in accumulation of condensed vapors. The test samples contained sufficient amounts of occluded water to lower the dielectric strength to about one-fourth of the dry value. The overall comparison should certainly take this into account since the total amount of water which can accumulate in a hydrocarbon oil under temperature cycling is considerably greater than that obtained when the sample is exposed to a given humidity at a constant temperature. On the other hand, for the fluorinated liquids, only the maximum saturation for any given humidity could occur. Water droplets did not form even when a layer of water was placed over the test material.

Because of the small amount of water absorbed by the fluorinated liquids, the apparatus used in the resistivity and dielectric strength tests were conditioned at the humidity under test to avoid loss of water to the equipment.

An inverted-V type curve is obtained for the change of resistance with temperature for a sample containing water. In this case the test apparatus was not maintained at a constant high humidity during this test. Diffusion is rapid in these liquids. The characteristic curve obtained may indicate the loss of the small amount of water present and a rise in resistance until increased ion mobility causes a decline to take place. A hydrocarbon oil shows the same behavior although the mechanism is probably different.[7] There the initial rise is explained as indicating a transition from water in suspension to a condition where increasing amounts go into solution.

With the range of boiling points available, considerable vapor densities can exist at relatively low temperatures, depending on the choice of material. For example, while the pressure of the vapor above a hydrocarbon transformer oil is very low at a temperature of 90 degrees centigrade, many of the fluorinated liquids studied would have an appreciable pressure at this temperature.

Figure 4 shows the differences in dielectric strength of the vapors of two of the liquids. Comparison is also made with a fluorocarbon gas and nitrogen. The vapors of carbon tetrachloride would show a dielectric strength similar to c-$C_8F_{16}O$ on Figure 4.

High vapor densities at relatively low

Table IV. Effect of c-$C_8F_{16}O$ and $(C_6F_{13})_2O$ on Metals and Insulation at 90 Degrees Centigrade*

	Liquid Phase	NC	NC	NC	NC	NC	NC	NC
Water present, no air (1 week and 11 weeks)	Vapor Phase	Sev. Cor.	Sl. Cor.	Sl. Cor.	NC	Varn. Ext.	NC	NC
	Liquid Phase	Sl. Cor.	Sl. Cor.	NC	NC	Varn. Ext.	NC	NC

* The test sample was partly immersed in the liquid. Two sets of tests were made for each liquid. There was approximately 50 per cent relative humidity air above the liquid in one series and a layer of water above the liquid in the other. Little or no change occurred after the first week.

† NC—no change.

temperatures can be obtained from the two fluorinated liquids of Figure 4, c-$C_8F_{16}O$ and $(C_4F_9)_3N$. The vapor phase above the liquid can therefore have an appreciable dielectric strength in the temperature range of 50 to 150 degrees centigrade. In contrast, the vapors of the commonly used transformer oils would have little or no dielectric strength at these temperatures because of low vapor densities. Low boiling hydrocarbons and chlorinated liquids which would allow high vapor concentrations are undesirable for the reasons given.

Stability

There are basic reasons related to molecular structure for expecting the fluorocarbons to be stable materials. Experimental verification of this has been obtained in a large number of experiments. A good treatment was recently published by Stuenenberg and Cady[8] which deals with the heat stability of fluorocarbons. Their results showed that the fluorocarbons tested were more stable than the corresponding hydrocarbons, decreasing in the order CF_4, C_2F_6, C_3F_8, and so forth. Figure 1 in their article gives a concise summary.

Tests have been done on many of the compounds listed in Table I by passing them through carbon-lined tubes. Appreciable decomposition does not occur until temperatures of 450 to 600 degrees centigrade are reached. At temperatures above 500 degrees centigrade some toxic products are found.

Since in certain types of operation the liquid is subject to arcing, it is necessary to know about the behavior of these materials under such conditions. Decomposition due to the high temperature of the arc is, of course, expected. The by-products formed are obviously related to the metals and insulation present which can react when free radicals are produced. Strips of commonly used materials were included in the arc tests. In arcing the types of fluorinated liquids studied here lower molecular weight saturated and unsaturated fluorocarbons were produced as well as CO, CO_2, COF_2, and various fluorides, probably including acid fluorides. These acid fluorides would be expected to have a deteriorating effect on metals and insulation. No by-products which are known to be toxic were identified. Although every attempt was made to trap all by-products, until extensive testing is done the absence of toxic components cannot be an absolute certainty.

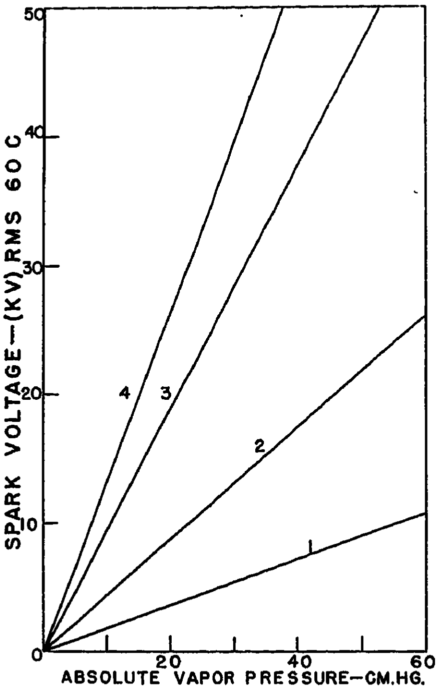

Figure 4. Dielectric strength of the vapors of:

1. Nitrogen	3. c-$C_8F_{16}O$
2. C_3F_8	4. $(C_4F_9)_3N$

0.25-inch diameter spheres, 0.25-inch gap

The effects of corona on gases have been studied.[9] Breakdown into lower and some higher molecular weight products was observed. No toxic products were noted. Perfluoropropane was found to yield smaller amounts of corrosive products than sulphur hexafluoride, which is itself a very stable compound. Fluorocarbons would be expected to be more stable to corona than the Freons.

Differences in the amount of carbon produced from arcing various fluorinated liquids, a hydrocarbon transformer oil, and a chlorinated oil are indirectly shown in Figure 5. A relatively low current arc (0.050 ampere) was initiated by high voltage breakdown. The light transmission after arcing is a measure of the darkening due to formation of carbon. The Askarel carbonized most severely, followed by the hydrocarbon oil. The fluorinated liquids show the least carbonization. It should be pointed out that the decomposition products from these fluorinated liquids and the Askarels are more objectionable than those obtained from a hydrocarbon in one respect. Products could be obtained which would have a deteriorating effect on insulation and metals, such as hydrogen chloride and acid fluorides. Of course, the breakdown of a hydrocarbon can produce hydrogen, accompanied by the explosion hazard.

Table IV summarizes tests on metals and plastics sealed in glass ampoules at 90 degrees centigrade. The greatest effect was observed in the ampoule containing a sample of varnished cambric. Extraction and darkening of the varnish was observed. The small amount of water present in the liquid is evidenced by severe corrosion of the iron in the vapor phase and only slight corrosion of the part immersed in the liquid.

Pure samples of c-$C_8F_{16}O$ have been tested in a stainless steel autoclave at 300 degrees centigrade to determine the thermal stability. There was no detect-

able breakdown of the material. Not more than 1 part per million of fluoride was present, which was the lower limit of the analytical method.

All of the materials reviewed here are nonflammable, and this is probably true for all completely fluorinated liquids. Carbon tetrafluoride has been proved to be an effective inhibitor of explosions over a considerable range in tests on anesthetics.[10] Isolated tests involving arcing mixtures of 6 and 25 per cent oxygen in C_3F_6 produced no explosions at room temperature. No explosions have resulted in passing vapors of these and other fluorocarbons through hot tubes up to temperatures of 1,000 degrees centigrade even in the presence of steam. These materials show little or no solubility with hydrocarbon and chlorinated solvents and oils.[11]

Applications

The properties of these materials suggest their use in new and unusual ways. For the first time there are available stable, inert liquids which cover a range of boiling points up to 178 degrees centigrade and which have no fire hazard in either the vapor or liquid phase. Neither hydrocarbon nor chlorinated liquids have been satisfactory on all points, the hydrocarbons because of their flammability and the chlorinated compounds because of their solvent action. For such applications certain limitations of low boiling materials must be accepted, as for instance the need for closed-system operation. However, advantage can be taken of a coexistent factor such as high vapor density.

HEAT TRANSFER

The best-known electrical application to date is the Westinghouse patent for cooling power transformers by utilizing the heat of vaporization.[12] Other operating requirements of high dielectric strength of the vapors, thermal stability, and compatability with metals and insulation are met.

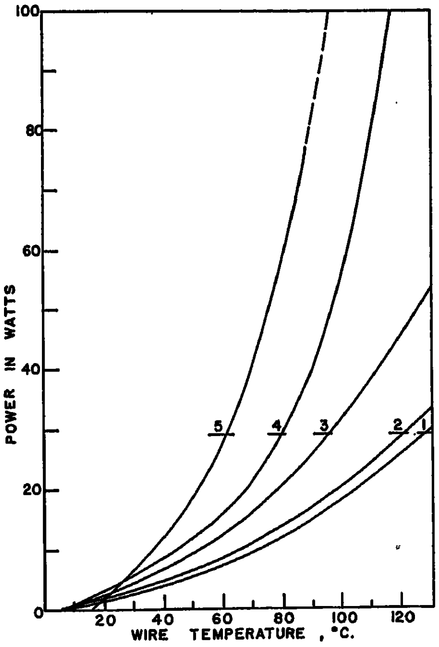

Figure 7. Efficiency of heat transfer

1. Silicone oil, high viscosity
2. Transformer oil
3. $(C_4F_9)_3N$
4. c-$C_8F_{16}O$
5. c-$C_6F_{12}O$

Next to heat of vaporization, convection is generally the most effective technique of heat removal. The compounds studied in this report have superior autoconvection properties. Table V lists the natural convection modulus[13] for various materials. While the heat transfer is not directly proportional to the differences in modulus, the compounds studied here would all be expected to be better than transformer oil when autoconvection is utilized. The improved heat transfer by autoconvection arises mostly out of differences in density, viscosity, and coefficient of expansion. While it might reasonably be argued that an improvement in heat transfer by autoconvection can also be realized by using low boiling hydrocarbons and chlorinated compounds, it is impractical to do so for the reasons outlined. An analysis by Robinson[14] relates both theoretically and experimentally those properties of cooling media, including liquids, to heat removal from practical electronic constructions.

Figure 6 shows equipment used in heat-transfer tests. The test liquid surrounds a small radio-frequency coil. Obviously, the apparatus is not of the best design to take full advantage of streamline flow

Table V. Natural Convection Modulus, Centimeter-Gram-Second Units, 25 Degrees Centigrade

$$a = \frac{p^2 g c_p b^*}{kn}$$

	Density	Specific Heat	Coefficient Vol. Exp.	Thermal Conductivity	Kinematic Viscosity (n/p)	Nat. Con. Modulus
c-$C_8F_{16}O$	1.760	0.26	1.6×10^{-3}	27.6×10^{-5}	0.82×10^{-2}	317,000
c-C_8F_{16}	1.835	0.243	1.36	30	0.975	202,000
$(C_4F_9)_3N$	1.872	0.27	1.2	25 (est.)	2.74	87,000
$C_{14}H_{30}$	0.732	0.523	0.893	33	3.0	34,000
Transformer oil	0.8 (est.)	0.45 (est.)	1.0 (est.)	27	21	7,000 (approx.)
DC 200	0.971	0.35	1.6	37	200	850

* where

a = natural convection modulus (1 per centimeter^3, degrees centigrade)
p = density (grams per centimeter^3)
g = gravity constant (centimeters per second^2)
c_p = specific heat (calories per gram, degrees centigrade)
b = coefficient volume expansion (1 per degree centigrade)
k = thermal conductivity (calory-centimeters per second-centimeters^2-degrees centigrade)
n = viscosity (dyne-seconds per centimeter^2)

so that full utilization of autoconvection has not been realized.

Figure 7, which summarizes the results obtained on various liquids, shows that considerably more power can be put into the system when the fluorinated liquids surround the coil. The heat-transfer efficiency follows in the same order as the autoconvection factor. For the system used an increase in efficiency over transformer oil of from 50 to 300 per cent or more is possible.

CIRCUIT BREAKERS

Many of the characteristics of these liquids suggest their application to circuit breakers. Foremost is the fact that they are nonflammable. Also, the results of Figure 5 indicate less carbon formation with arcing than with hydrocarbon oils and Askarels. In addition, certain basic properties of fluorine in general and the volatility characteristic of the fluorinated liquids studied in this article favor their use. Thermal ionization for a given arc temperature would be less due to the higher ionization potential of fluorine. The greater recombination coefficient of fluorine would enter importantly into the neutralization of ions formed in the arc. Perhaps even more important, the volatile nature of many of the compounds would encourage the formation of eddies. This has been shown to be very important to cooling the arc stream.[15]

c-$C_8F_{16}O$ and a hydrocarbon transformer oil were compared in tests in a plain-type circuit breaker. The oval-shaped circuit-breaker tank required 6 gallons of liquid for filling. The tests were made on a 2,600-volt a-c system. Currents of 275, 900, and 3,450 amperes were interrupted in the fluorocarbon. The highest current was also interrupted in the transformer oil. Figure 8 shows the oscillograms obtained. The point of direct interest is that apparently a larger arc drop occurred in the fluorinated liquid. Comparing the 3,450-ampere test it can be seen that there is a considerably larger drop across the contacts just before complete interruption in the fluorinated liquid. Compare (C) and (D) on Figure 8. The bottom curves show the voltage drop across the contacts. Of particular interest is the voltage drop just before extinction. Of course, after extinction the voltage across the contacts is full line voltage. The arc drop is considerably greater in (C) than in (D). This difference in arc drop could indicate a more unstable arc stream in the fluorinated liquid for the reasons suggested. The apparent differences in current density suggest constriction of some parts of the arc stream. In the experiments of Suits[16,17] the higher arc drop in hydrogen resulted in an arc more unstable in nature and reduced in diameter compared to other gases.

New design problems would be introduced in the use of these materials in circuit breakers. Some of the decomposition products of arcing would attack insulating materials and metals. The amount of such products would depend on the number of arcs and the energy contained in them. Absorbents would be necessary for some conditions. Also, the density of these liquids is less favorable to the settling of carbon.

IMPREGNANTS

There is an acknowledged need for impregnants which are stable at temperatures above 150 degrees centigrade. As pointed out in the section entitled "Stability," there is no chemical breakdown of pure c-$C_8F_{16}O$ in a stainless-steel autoclave at 300 degrees centigrade. Further work needs to be done to establish upper limits for these materials.

Attention is also called to the fact that the surface tensions of these liquids are among the lowest known.

LOW CAPACITANCE

The low dielectric constants of these materials suggests their use in applications where interelectrode capacitance effects, which may be introduced by the liquid, need to be minimized.

DIELECTRIC STRENGTH OF VAPORS

The use of these liquids would give increased protection at relatively low ambient temperatures to the parts of equipment above the liquid. The high dielectric strength of the vapors would make it possible to operate at higher voltage gradients than are allowable with conventional transformer oils.

No Discussion

Dynamic Hysteresis Loops of Several Core Materials Employed in Magnetic Amplifiers

HAROLD W. LORD

FELLOW AIEE

Any good magnetically soft type of core material is suitable for low- and medium-performance magnetic amplifiers. For these types, the permeability and core loss have only minor effects upon the control characteristic of the magnetic amplifier. If the saturation density is reasonably high and the core loss is reasonably low, then the material probably will be suitable for such amplifiers.

For high-performance magnetic amplifiers the situation is very different. When the positive feedback approaches 100 per cent, as it does in the self-saturated types,[1] the core material used for the amplifier plays a major role in determining the control characteristics of the magnetic amplifiers.

An ideal magnetic material for high-performance magnetic amplifiers would have a hysteresis loop such as that shown in Figure 1(A). However, most magnetic amplifier designers would be happy if they could obtain a core material whose hysteresis loop is rectangular and corresponds to that shown in Figure 1(B). This is the actual d-c hysteresis loop of a specimen core composed of 0.005-inch laminations of 65 Permalloy. But, if he chooses this material for use in a 400-cycle magnetic amplifier, he will be disappointed in its performance. The 400-cycle dynamic hysteresis loop of this specimen is shown in Figure 1(C). The 400-cycle dynamic loop departs considerably from rectangularity and is much wider than the d-c loop.

This example might be classed as an extreme case. However, it does emphasize the need for a study of the dynamic hysteresis loops of various magnetic materials in order to determine their relative suitability for magnetic amplifiers. Some of the results of such a study, carried out in the Research Laboratory of the General Electric Company, will be presented in this paper.

The method used for obtaining the dynamic hysteresis loops shown herein has been described in detail in an earlier paper.[2] Figure 2 shows a block diagram of the excitation circuit and the means for displaying a Lissajous figure representing the dynamic hysteresis loop upon the screen of a cathode-ray tube where it can be recorded photographically. Before presenting the dynamic hysteresis loops of several magnetic materials, it is desirable to review briefly the conditions under which they were recorded and to give some justification for imposing these conditions. In the previous paper[2] it was suggested that the flux wave in the core be essentially sinusoidal. All of the major dynamic hysteresis loops shown here were recorded with flux waves such that the voltage induced in the B coil had less than 10-per-cent harmonic distortion. This was done for two reasons. First, it complies with the suggested AIEE standards for testing such cores, and

second, our experience indicates that such dynamic hysteresis loops provide a means for evaluating their usefulness in high-performance magnetic amplifiers.

A detailed description of the manner in which the shape and width of the dynamic hysteresis loops influence the magnetic amplifier characteristics is beyond the scope of this paper. However, the composite oscillogram of Figure 3(A) will serve to indicate the value of such data. The 60-cycle major loop shown was recorded with an essentially sinusoidal flux wave. The peak value of magnetomotive force was approximately 20 times the coercive force and hence deflected the beam beyond the limits of the screen. After recording this major loop, the same core specimen was incorporated as one of the inductor elements in a 60-cycle self-saturated magnetic amplifier circuit whose control circuit had a low impedance to the flow of even harmonic components of current. The three minor hysteresis loops shown on Figure 3(A) were then recorded for three levels of output current to a resistive load as controlled by the magnetic amplifier. These indicate that for this type of circuit the minor dynamic hysteresis loops traced over in actual operation coincide with the sinusoidal flux wave major loop in portions of the second and third quadrants. Since these are the portions traced over during the period in which the level of control flux is being established or reset for the next cycle, it is reasonable to conclude that the major dynamic hysteresis loop will play a principal role in the control characteristic and performance of this type of magnetic amplifier.

The correspondence between the minor operating loops and the major dynamic loop in other types of magnetic amplifiers is not this good over the whole control range. Figure 3(B) shows a similar composite oscillogram for a 60-cycle self-saturated half-wave magnetic amplifier with a high impedance control circuit. It should be noted that as the cutoff point is approached the correspondence becomes better, hence the sinusoidal flux wave major loop is still a significant factor in determining the control characteristics of this type of magnetic amplifier.

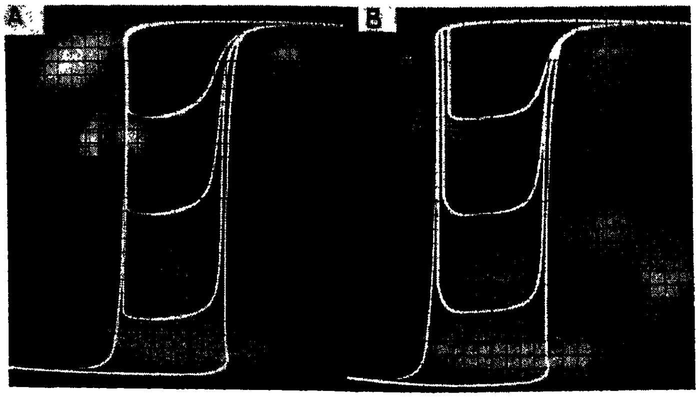

Figure 3. Major and minor dynamic hysteresis loops

Comparisons of several oscillograms with each other and with plotted curves are often difficult. Data taken from two or more oscillograms have therefore been plotted to suitable scales on a single set of co-ordinates to provide a more convenient means for comparing them. Data shown in the following figures were taken on spirally wound tape cores with toroidally wound coils.

Figure 4 shows the hysteresis loops for 0.002-inch Supermalloy. This is a high nickel content, unoriented alloy characterized by high values of maximum permeability, a rounded knee, and relatively low values of saturation flux densities. The loops are extremely narrow. This alloy is particularly suited for use in magnetic amplifiers for amplifying very low levels of signal power. (Note: The portions of the dynamic curves above the knee are probably in error since the d-c loop normally should fall inside or coincide with the a-c loops in this region. Also, observe that both scales of this figure are different from those of the following figures.)

Figure 5 shows hysteresis loops for 0.002-inch highly oriented silicon steel. This material is suited to medium and large power handling magnetic amplifiers. In comparable thicknesses it costs less than any of the other alloys shown herein, is more available, and does not use critical materials. Since it has hysteresis loops which are wider (for comparable thicknesses) than those of the other alloys shown, magnetic amplifiers constructed of this material will have relatively poorer performance.

Figure 6 shows the hysteresis loops for 0.002-inch 65 Permalloy. Note particularly the very narrow d-c hysteresis loop, yet the dynamic loops are com-

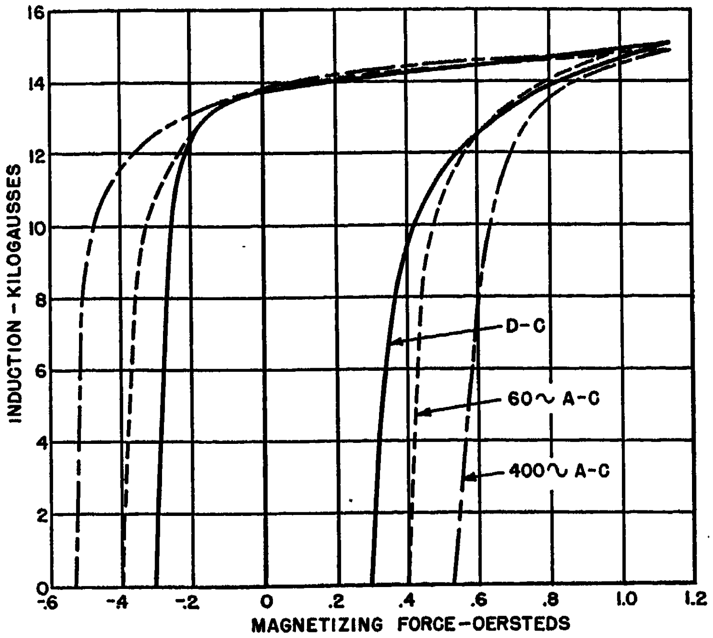

Figure 5. Hysteresis loops of 0.002-inch oriented silicon steel

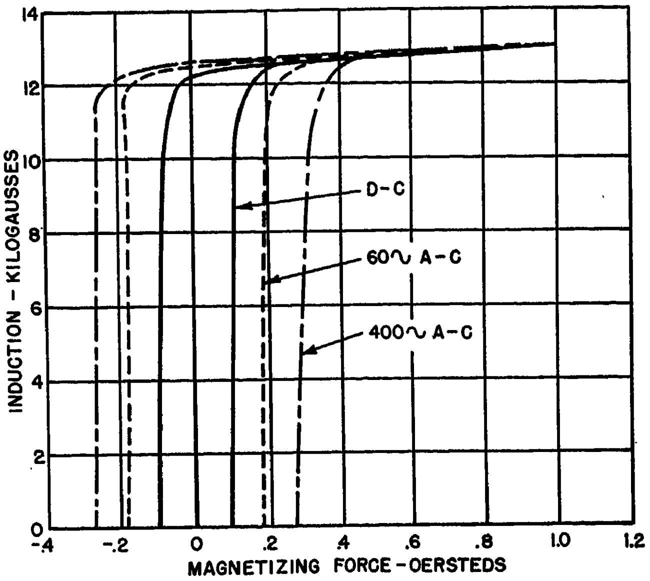

Figure 7. Hysteresis loops of 0.002-inch Deltamax

parable in width to those for Deltamax as shown by Figure 7. The so-called hourglass or wasp-waisted shape shown by the a-c loops of Figure 6 has been observed to occur with highly oriented alloys. This tendency seems to be particularly pronounced when they are domain-oriented alloys. Orientation in 65 Permalloy is obtained by a magnetic anneal so it is a domain-oriented material. At present, 65 Permalloy is not available commercially. In a magnetic amplifier it yields no better performance than that of Deltamax and its saturation density is a little lower than that of Deltamax.

Figure 7 shows the hysteresis loops for a specimen of Deltamax which has been annealed at a temperature slightly above that which produces optimum rectangularity of the d-c loop. However, the dynamic loops shown are more rectangular, so this specimen represents about the best over-all characteristic for this material for use in high-performance magnetic amplifiers.

Figure 8 shows the results obtained when the original specimen used for the Figure 7 data was given a magnetic anneal. This treatment provided a material whose d-c hysteresis loop is not only narrower but is more rectangular. However, the comparable dynamic hysteresis loops are actually wider than they were before the magnetic annealing treatment and tests in a magnetic amplifier showed a corresponding deterioration of performance.

The effect of annealing temperature upon the shape and width of the d-c hysteresis loops is shown by Figure 9. These three specimens were all from the same laboratory produced ingot. Dynamic hysteresis loops have been omitted in this comparison. The amount of widening was roughly the same for the two specimens annealed at the lower temperatures and about 40 per cent less for the one annealed at 1,200 degrees centigrade.

Figures 10 and 11 show the effect of gauge upon the dynamic hysteresis loops of Deltamax. The two specimens used for this comparison were selected on the basis that their d-c hysteresis loops were

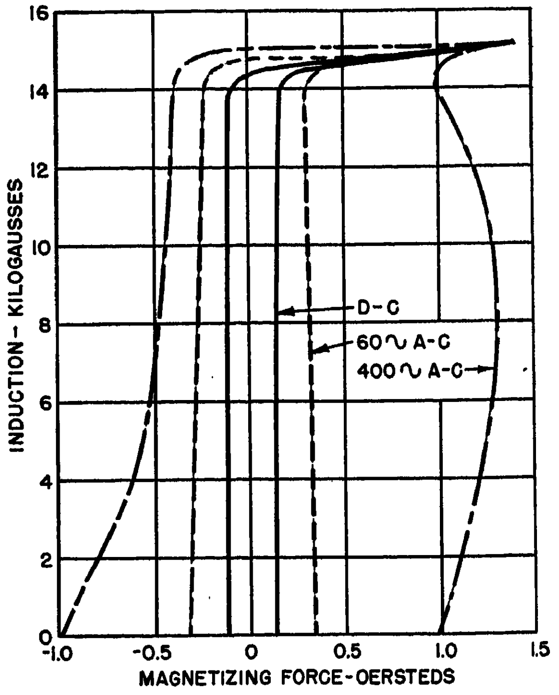

Figure 12 (right). Hysteresis loops of 0.010-inch Deltamax

practically identical. Thus any differences in their dynamic characteristics can be attributed to their difference in thickness. Note that even at 60 cycles there is some advantage in favor of the thinner material.

Figure 12 further illustrates the effect of gauge and is convincing evidence of the poor performance of 0.010-inch-thick materials of high permeability at 60 cycles when compared with thin gauge specimens of such materials. These loops illustrate why it is poor practice to use high permeability materials such as Deltamax, Monimax, Supermalloy, Mumetal, Nicaloi, and Molly-permalloy in thicknesses exceeding 0.005 inch for cores in 60-cycle magnetic amplifiers. For frequencies of 400 cycles, such thick gauge alloy cores are little or no better than comparable gauges of ordinary silicon steel materials.

The Rayleigh Method in Network Calculations

FREDERICK W. SCHOTT
ASSOCIATE MEMBER AIEE

JACK HEILFRON
NONMEMBER AIEE

Synopsis: An approximation method for determining the input impedance of a resistive circuit, or one in which the reactance-resistance ratio is the same for every branch, hence permitting treatment as a resistive circuit, is presented. The method is based on the minimum power-dissipation characteristics of such networks and provides both an upper and a lower bound to the true impedance. It is presented with the view that in certain cases, as in power-system short-circuit calculations where the resistive component may often be neglected, the necessity of evaluating high-order determinants or manipulating star-mesh transformations can be eliminated.

LORD Rayleigh seems to have been the first to use an energy method in solving for a characteristic system parameter and his method[1] for approximating the lowest resonant frequency of a mechanical system is well known. This paper presents a method for determining the input impedance of a resistive circuit, or one in which the reactance-resistance ratio is the same for every branch and hence may be treated as a resistive circuit. It is also based on the energy (or power) relationships and provides an approximate solution; hence Rayleigh's name has been applied to the procedure.

The primary contribution of this development is the use of the dual formulation of the circuit equations to provide both an upper and a lower limit to the result. Thus the true solution will not be found but the approximate result will be known, and also that it lies within a certain percentage of the true value.

For simple circuits the method does not appear to have any particular advantage, but as the complexity increases it does seem to reduce the computation needed, that is, the evaluation of high-order determinants or the equivalent star-mesh reduction procedure.

The Method

The ability to formulate circuit equations in terms of either loop currents or node voltages provides the basis of the method. If a known voltage is impressed across two nodes of a resistive network and if the voltages at all other nodes, hereafter called internal nodes, are assumed, the power dissipated in the circuit as computed from these assumed values will be greater than (or equal to, in the event of correct assumptions) the true value.

This may be demonstrated by expressing the actual loss in the system, P_o, in terms of the correct node voltages E_{io} and the branch conductances G_{ij} as

$$P_o=\frac{1}{2}\sum_i\sum_j(E_{io}-E_{jo})^2G_{ij} \tag{1}$$

and comparing this with the dissipation based on the estimated voltages. The power loss calculated from these assumed node voltages E_i may be written as

$$P=\frac{1}{2}\sum_i\sum_j(E_i-E_j)^2G_{ij} \tag{2}$$

The difference ΔP between P and P_o is given by

$$\Delta P=P-P_o=\frac{1}{2}\sum_i\sum_j[(E_i-E_j)^2-(E_{io}-E_{jo})^2]G_{ij}$$

By expanding the quantity in brackets and adding and subtracting appropriate terms, the expression may be rearranged to read

$$\Delta P=\frac{1}{2}\sum_i\sum_j[(E_i-E_{io})-(E_j-E_{jo})]^2G_{ij}+\sum_i\sum_j[(E_i-E_{io})(E_{io}-E_{jo})-(E_j-E_{jo})(E_{io}-E_{jo})]G_{ij}$$

But at each internal node, from Kirchhoff's junction law

$$\sum_j(E_{io}-E_{jo})G_{ij}=\sum_i(E_{io}-E_{jo})G_{ij}=0$$

and at the two external nodes, the voltage is known, that is

$$(E_i-E_{io})=(E_j-E_{jo})=0$$

Therefore the second portion of the summation vanishes and

$$\Delta P=\frac{1}{2}\sum_i\sum_j[(E_i-E_{io})-(E_j-E_{jo})]^2G_{ij} \tag{3}$$

By observing that the right side of equation 3 is positive-definite, it is seen that the power loss, when calculated from the assumed voltages, is always higher than, or in the limit, equal to, the actual dissipation. From this, one may write

$$P_o\leqq\frac{1}{2}\sum_i\sum_j(E_i-E_j)^2G_{ij} \tag{4}$$

or

$$P_o\leqq\sum_{i=1}^{n}\sum_{j=1}^{i}(E_i-E_j)^2G_{ij} \tag{5}$$

Now if a known current is considered to be injected into one of the external nodes in question and allowed to flow out at the other, and if only values of branch (or loop) currents satisfying Kirchhoff's junction law are assumed, the loss in the network as computed from these guessed currents, will again be more than the actual dissipation.

This fact has long been known[2] and may be shown by expressing P_o in terms of the correct branch currents I_{ijo} and the branch resistances R_{ij} as

$$P_o=\frac{1}{2}\sum_i\sum_jI_{ijo}^2R_{ij} \tag{6}$$

The power calculated from the assumed branch currents I_{ij} is, similarly

$$P=\frac{1}{2}\sum_i\sum_jI_{ij}^2R_{ij} \tag{7}$$

and the difference ΔP between P and P_o is

$$\Delta P=P-P_o=\frac{1}{2}\sum_i\sum_j(I_{ij}^2-I_{ijo}^2)R_{ij}$$

By adding and subtracting appropriate terms

$$\Delta P=\frac{1}{2}\sum_i\sum_j(I_{ij}-I_{ijo})^2R_{ij}+\sum_i\sum_j(I_{ij}-I_{ijo})I_{ijo}R_{ij}$$

But

$$I_{ijo}R_{ij}=(E_{io}-E_{jo})$$

so that the second term on the right in the equation for ΔP may be rewritten as

$$\sum_iE_{io}\sum_j(I_{ij}-I_{ijo})-\sum_jE_{jo}\sum_i(I_{ij}-I_{ijo})$$

Also, as a direct result of the satisfaction of Kirchhoff's junction law, when making the original guesses

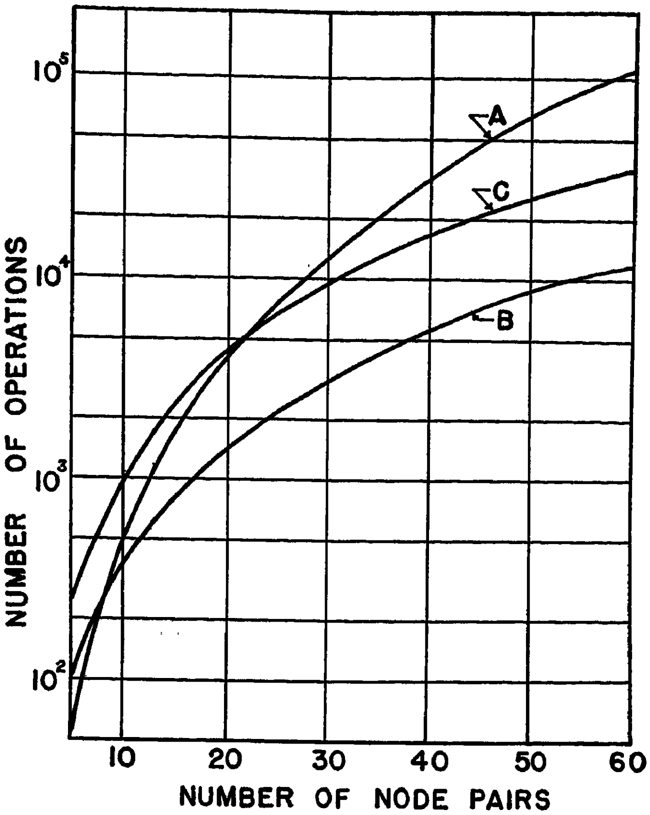

Figure 1 (left). Number of operations required to determine input resistance in the most complex circuit versus number of node pairs using

(A) Network reduction
(B) Energy method without relaxation
(C) Energy method with one relaxation step on the node voltages and a re-estimate of branch currents

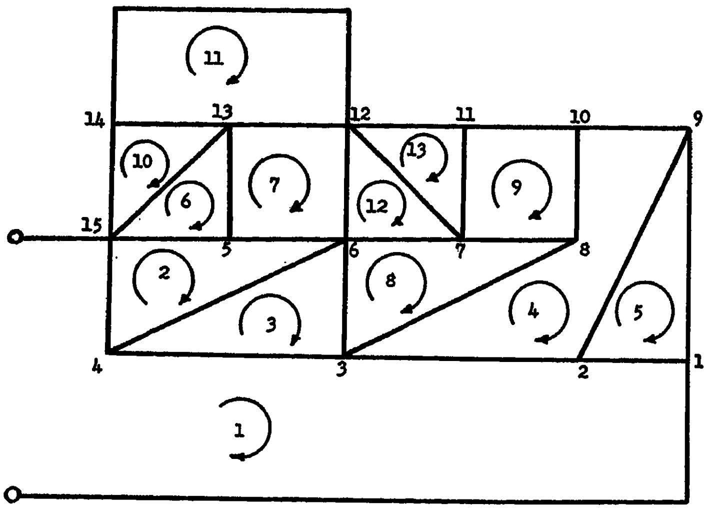

Figure 2 (above). Circuit used in the example of Rayleigh's method

$$\sum_{i \text{ or } j} I_{ij} = \sum_{i \text{ or } j} I_{ijo} = 0$$

at all internal nodes and equals the injected current at both external nodes. Therefore

$$\Delta P = \frac{1}{2} \sum_{i} \sum_{j} (I_{ij} - I_{ijo})^2 R_{ij} \tag{8}$$

or

$$\Delta P = \sum_{i=1}^{n} \sum_{j=1}^{i} (I_{ij} - I_{ijo})^2 R_{ij} \tag{9}$$

Again, observing the positive-definite nature of the right hand term in equation 9, one may write

$$P_o \leqq \sum_{i=1}^{n} \sum_{j=1}^{i} (I_{ij})^2 R_{ij} \tag{10}$$

The actual power dissipation may also be written in terms of the impressed voltage E_I or the injected current I_I and the input conductance G_I or input resistance R_I as

$$P_o = E_I^2 G_I \qquad \text{or} \qquad P_o = I_I^2 R_I$$

These reduce, in the case of unit impressed voltage and unit injected current, to

$$P_o = G_I \qquad \text{and} \qquad P_o = R_I$$

but

$$R_I = \frac{1}{G_I}$$

so, from equations 5 and 10, it follows that

$$\frac{1}{\sum_{i=1}^{n} \sum_{j=1}^{i} (E_i - E_j)^2 G_{ij}} \leqq R_I \leqq \sum_{i=1}^{n} \sum_{j=1}^{i} I_{ij}^2 R_{ij} \tag{11}$$

Therefore, by computing power loss from the assumed voltages and currents one may obtain an upper and lower bound for the desired input resistance. If the percentage difference between these two limits is less than twice the required accuracy, their average will represent an acceptable result.

On the other hand, if they differ too greatly, a form of the relaxation method developed by Southwell[3,5] may be used to obtain new voltage and current values which will confine the range of equation 11 to within acceptable limits. A modification of the general relaxation procedure by which this reiteration process may be carried out is given in the next section.

It should be mentioned here that in the case of planar networks, instead of using branch currents to obtain an upper limit, the inverse of the circuit may be found and the node voltage analysis used again.

A Relaxation Technique for Improving Results

To reduce the spread of the limits of the computed input resistance to twice the required accuracy, the original guesses may be modified so as to converge upon the correct solution. This is accomplished by the use of relaxation methods.

Relaxation methods[3] begin with an assumed solution, or set of solutions, to a problem and progress by successively correcting the assumptions. Each correction is made so as to eliminate at a point a quantity called the residual, which is determined by the values in the region of that point. Each relaxation step brings the values closer to the overall solution; thus the number of steps

3- 2	2.00	0.50
2- 1	1.00	1.00

required depends upon the correctness of the initial assumptions as well as upon the accuracy desired.

Because the complete network solution is not required, a slight modification of the general relaxation method may be used. In Southwell's procedure, applied to the computation based on the node voltages, the largest residual current at a node in the circuit is eliminated, while in the process suggested herein the residual currents at the internal nodes are eliminated in order, depending on the numbering of the nodes. This makes the determination of the greatest residual current unnecessary, a step which would require additional computation because of the special nature of the problem to be solved. However, the suggested procedure will not converge as rapidly.

The power computed from the assumed voltages may be written as

$$P=\sum_i E_i^2\sum_j G_{ij}-\sum_i E_i\sum_j E_jG_{ij} \qquad (12)$$

and the residual current I_R at node k, which is a measure of the incorrectness of the assumed voltages, may be expressed as

$$I_{Rk}=E_k\sum_j G_{kj}-\sum_j E_jG_{kj}$$

where $j\neq k$, whence

$$\frac{I_{Rk}^2}{\sum_i G_{kj}}=E_k^2\sum_j G_{kj}-2E_k\sum_j E_jG_{kj}+\frac{\left(\sum_j E_jG_{kj}\right)^2}{\sum_j G_{kj}} \qquad (13)$$

Expanding equation 12 by separating that portion of the power due to the voltage at node k results in

$$P=\left(E_k^2\sum_j G_{kj}-2E_k\sum_j E_jG_{kj}\right)+\sum_i E_i^2G_{ik}+\sum_i E_i^2\sum_i G_{ij}-\sum_i E_i\sum_j E_jG_{ij} \qquad (14)$$

where $i\neq j$, $i\neq k$, and $j\neq k$.

By substituting equation 13 into 14, P is given by

$$P=\frac{I_{Rk}^2}{\sum_j G_{kj}}-\frac{\left(\sum_j E_jG_{kj}\right)^2}{\sum_j G_{kj}}+\sum_i E_i^2\sum_j G_{ij}-\sum_i E_i\sum_j E_jG_{ij}+\sum_i E_i^2G_{ik} \qquad (15)$$

If E_k is modified in such a manner that

$$E_k'=\frac{\sum_j E_jG_{kj}}{\sum_i G_{kj}} \qquad (16)$$

then the residual current at node k will be eliminated or

$$I_{Rk}=0$$

So if the new power P' is calculated using E_k', equation 15 will be reduced by the term involving I_{Rk}. Therefore

$$P-P'=\frac{I_{Rk}^2}{\sum_j G_{kj}} \qquad (17)$$

meaning that the dissipation has been reduced by this amount.

If $P-P'=0$, then $I_{Rk}=0$, since all the branch conductances are positive. If the power does not decrease at all, for a systematic relaxation of every internal node voltage, then all of the residual currents in the circuit must have been zero. This is precisely the condition of equilibrium that must be satisfied for the power to be a true minimum, since for this case both of Kirchhoff's laws are satisfied.

A similar process may be carried out with respect to the loop currents. The power loss, as calculated on the current basis, converges to the actual loss in the network if new values of loop cur-

*2–6 indicates loop current I_2 − (loop current)I_6 = branch current I_{15-5}.

†This column arrangement is used since, without relaxation, calculations end with column 5.

rents are given by

$$I_k' = \frac{\sum_i I_j R_{kj}}{R_k}$$

where

R_k = total resistance of loop k

R_{kj} = resistance common to loop k and loop j

Some difficulty arises due to the need for branch currents to compute power and loop currents to use the iteration method presented in the preceding. Since there is no need for determining loop currents unless relaxation is found to be necessary, it is recommended that branch currents be assumed initially. Then if reiteration is needed, loop currents can be computed readily.

Comparison of the Rayleigh Method with Other Methods

The amount of computation involved will depend, in general, on the type and complexity of the network under consideration. For the most complex case, wherein every node is directly connected to every other node by one element (a circuit rarely encountered in practice), the exact method most applicable for solution of the problem is that of network reduction. This, in effect, reduces the labor of expanding high-order determinants (if the number of nodes and branches is large), but still requires considerable effort. Richardson[4] has given systematic procedures for carrying out this reduction.

If a unit operation is defined as the addition, subtraction, multiplication, or division of two numbers, it is possible in certain cases to determine the number of operations required to obtain a value for the input impedance at any point in the circuit.

Figure 1 illustrates the number of operations necessary for solution versus the number of node pairs in the system, for both the network reduction process and the method developed herein. It is seen that, for a large number of nodes, a great saving results from the use of our method providing the original guesses are accurate enough so as to require no relaxation. Figure 1 deals with the most complex case as described here and is based on the following expressions

$$O_r = \frac{7}{2}(N_p^2 + N_p) - (N_p - 1)$$

$$O_n = \frac{N_p}{2}[N_p^2 + N_p - 2]$$

$$O_v = 3N_p^2 - 4N_p + 1$$

where

O_r = operations required to compute input resistance by averaging the limits obtained from assumed voltages and currents (without relaxation)

O_v = operations required to recalculate one entire set of node voltages by relaxation procedures

O_n = operations required to find input resistance using network reduction, for the most complex case

N_p = number of node pairs in circuit

In the event iteration is necessary, for complex cases where the number of node equations is far less than the number of loop equations, it is desirable to use the relaxation process on the node voltages only, and then, on the basis of the modified potentials, re-estimate the branch currents. If this is done, no loop currents need be found at all.

In a less complicated circuit, especially if the number of loops is of the same order of magnitude as the node pairs, convergence upon the correct input resistance can best be carried out by relaxing the residuals in both sets of guessed quantities.

Example

An example is shown in Figure 2. The values of resistance and conductance of the branches have been chosen arbitrarily and are not intended to represent any specific physical problem but rather to illustrate the method; they are indicated in Table I.

The calculations have been carried out in the tabular form; see Tables II and III. For the calculation on the node voltage basis, the use of the first six columns is obvious, the sum of the values in column 6 giving the first estimate of the input conductance. Column 7 and the subtotals shown are needed for the relaxation operation to derive the modified node voltages according to equation 16. Each subgroup of column 7 is computed alternately with the corresponding element of column 8, this process being carried out in order. The new values of column 8 are then used in lieu of those of column 4 in all subsequent calculations in column 7. Columns 9 and 10 are similar to columns 5 and 6. If an additional relaxation step were performed another set of columns similar to columns 7, 8, 9, and 10 would be needed.

In computing the total power dissipated, that dissipated in each branch must be included but once; therefore, it may be noted that numerous blank spaces occur in columns 5, 6, 9, and 10.

The column arrangement used for making calculations on the current basis is similar.

From Table II it can be seen, on the basis of the voltage assumptions, that:

$R_I = 1/(0.582) = 1.72$ ohms (from original values)

$R_I = 1/(0.518) = 1.93$ ohms (after one relaxation operation)

From Table III we find that:

R_I on the basis of original guesses equals 2.64 ohms

R_I on the basis of relaxed currents equals 2.45 ohms

Results

The average value of R_I as computed from original estimates is 2.18 ohms. The maximum possible error in this result is 21.2 per cent.

The average value for R_I as computed from relaxed quantities is 2.19 ohms. The maximum possible error in this result is 11.8 per cent. Therefore, with one relaxation step, the range of possible values for input resistance has been halved, although the average, or mid-range, value has not changed appreciably.

The correct value found from a network-analyzer solution of the problem was found to be 2.22 ohms; therefore the actual error after one relaxation operation is

$$\frac{2.22-2.19}{2.22}(100) = 1.35 \text{ per cent}$$

It has been observed in applying these methods that there seems to be an equal-error tendency, that is, the upper and lower bounds tend to deviate from the correct value by roughly the same magnitude; hence the average tends to approximate the true result reasonably well.

Fluorine-Containing Gaseous Dielectrics

G. CAMILLI
FELLOW AIEE

R. E. PLUMP
NONMEMBER AIEE

Synopsis: The characteristics of gaseous chemical compounds containing fluorine are reviewed. Relative dielectric strengths, toxicities, space charge effects, electrode material, pressure effects, and so forth, are discussed. Several explanations accounting for observed differences in dielectric strength among gases are noted and shown to be inadequate for the complete understanding of all cases. A line of attack for fuller understanding is suggested in the considerations of the molecular energy systems. Some possible potentialities of gaseous fluorine compounds in electric equipment are also reviewed.

GASEOUS fluorocompounds are specifically of interest in high-voltage applications because of their generally inert character and high dielectric strength. Some of these compounds such as the Freons have already found wide use in refrigeration and air conditioning. Hydrogen fluoride is used in the petroleum industry as a catalyst for the production of high-octane gasoline.

Fluorine chemistry[1] has attained a rather unique position due to the fact that the element fluorine is the most active chemical we have, attacking nearly all other substances with the peculiar result that many of the combinations are then among the most inert substances. For example, fluorine attacks sulfur and the product is chemically, thermally, and electrically stable. Technological progress in the production and handling of fluorine and widespread study of fluorine compounds have made a separate field in general chemistry. Before the last war, fluorine was made in only gram quantities, and fluorocarbons were laboratory curiosities. Today both the variety and quantity of available fluorocompounds is large. It is of interest to review some of the gases for electrical use because of possible advantages to be gained.

The fluorogases of most interest are the Freons, sulfur hexafluoride, and the fully fluorinated compounds such as C_3F_8.

Factors which must be considered in the choice of an insulating gas for electrical use are:

1. High dielectric strength.
2. Low temperature of condensation.
3. Chemical inertness, nontoxicity, and nonflammability.
4. Good heat conductivity.
5. Availability and cost.

Other properties such as high density can

be advantageous, but in general a compromise among various properties will probably be necessary in any particular application.

Table I shows the physical variations to be found among the dielectric gases.

Dielectric Strength

VARIOUS ELECTRODE CONFIGURATIONS AND CONDITIONS OF VOLTAGE APPLICATION

In 1937 Charlton and Cooper[2] obtained five fluorocompounds among other gases and determined their relative strengths to that of nitrogen. The electrodes were curved, 2-inch radius, nickel surfaces separated 1/8-inch or 1/4-inch gap distance and the voltage applied was direct, in most cases with the gas at atmospheric pressure. The relative values when compared with nitrogen under the same conditions were: CH_2F_2, 0.69; CCl_2F_2(Freon-12), 2.4; CCl_3F(Freon-11), 3.0; $C_2Cl_3F_3$, 2.6; and $C_2Cl_2F_4$, 2.8. These authors also seem to have been the first to study known mixtures of Freon with nitrogen or hydrogen obtaining strengths proportional to the compositions of the mixtures.

Between a point and sphere in a 3-millimeter gap with a direct voltage, Pollock and Cooper[3] found with increasing pressure a certain anomalous behavior when the point was positive in Freon-12 and sulfur hexafluoride. This was similar to an effect also observed in air[4] under high pressure, and this will be discussed a little later. Nevertheless, a selection of data for the positive point at 4 atmospheres pressure gives breakdown values of 13 kv for nitrogen, 42 kv for Freon-12, and 48 kv for sulfur hexafluoride.

A comparison[5] of nitrogen and of Freon-12 with transformer oil was made in both a uniform field and between rods, 60-cycle alternating current and impulse, under different pressures.

The impulse and the 60-cycle crest breakdown strength of nitrogen were substantially the same when tested between spheres at less than radius spacing for atmospheric pressure to 200 pounds absolute; the impulse and 60-cycle crest breakdown at CCl_2F_2 were likewise the same but from atmospheric pressure to 80 pounds absolute. In order to obtain the same impulse strength as oil N_2 required a pressure of 175 pounds per square inch absolute and F-12 needed 62 pounds per square inch absolute. To obtain a 60-cycle strength equal to oil, N_2 required a pressure of 80 pounds per square inch absolute and F-12 a pressure of 25 pounds per square inch absolute. These tests were made between 6.25-centimeter spheres spaced 1 centimeter apart.

Between the ends of 1/2-inch square rods spaced 6 centimeters apart, nitrogen at about 63 pounds absolute or Freon-12 at atmospheric pressure were equal to or better than 10-C oil under 60-cycle testing. Under the same electrode arrangement with impulse testing, the strengths of the gases were less than that of oil, with N_2 up to 200 pounds absolute and Freon-12 up to 80 pounds absolute.

In comparison, with d-c uniform fields[6] in a 0.2-inch gap at 125 pounds pressure absolute, the breakdown gradient for Freon-12 was found to be 1,200 kv per inch and the pressure distance with voltage showed a small deviation from Paschen's law.

Later, Skilling and Brenner,[7] using spheres and 60-cycle alternating current found that for small spacings the strength of Freon-12 followed the relation

kilovolt breakdown $= 183PS+4$

in which P was the actual atmospheres pressure and S was the gap spacing in inches. For example in a gap of 0.1 inch at atmospheric pressure the strength of Freon was about 23 kv while that of air was 10 kv. At 30 pounds gauge (about 3 atmospheres absolute) the strength of Freon was about 60 kv in the same gap.

The impulse strength of Freon-12 and of sulfur hexafluoride in a uniform field between spheres with a positive wave under 45 pounds absolute pressure had been found to be about the same as that of transformer oil[8] and their strengths

relative to nitrogen were 1.4. The 60-cycle strength of SF_6 was about 75 per cent that of oil, and when the gas pressure was only 30 pounds absolute this factor fell to 63 per cent. Freon-12, however, at 45 pounds absolute had 90 per cent of oil strength and 77 per cent at 30 pounds absolute.

In a nonuniform field, using a pointed tungsten rod and sphere separated 1 inch, the 60-cycle a-c strength of SF_6 was, at 45 pounds absolute, 114 per cent that of oil; but the corresponding value for Freon-12 was only 40 per cent. However, when the Freon-12 was at 30 pounds then the strength was 62 per cent that of oil. This peculiar effect had already been observed by Nonken[5] whose curves showed the beneficial effect of a few pounds pressure above atmospheric but reversal and depreciation at higher pressures in nonuniform fields. In order to produce uniform fields at wider gap spacings, linked toroids were used[8] with an effective gap of 2 inches and with results summarized in Table II. The large difference in dielectric strength between air and sulfur hexafluoride in this case is evident.

Work on SF_6 continued[9] with other gap arrangements, notably with 3-inch plane disks and with a 1/2-inch sphere to 3-inch plane. Typical results as shown in Table III again exemplify the general dielectric advantage of SF_6 over air, in a 1/2-inch gap.

The highest test pressures with uniform field yet reported on SF_6 alone and in mixtures are those of Kusko, who in fact employed such high pressures that the dilution of the SF_6 became necessary in order to obtain breakdowns even with his very high voltage generator. In a 1/2-inch gap, for example, with a uniform d-c field, the following four gases had the following very informative breakdown values in kilovolts: SF_6 800; CO_2, 435; N_2, 350; He, 55, at only 215 pounds per square inch absolute pressure between stainless steel electrodes. Further effects of pressure will be discussed shortly.

Meanwhile, interesting results have been obtained on the series of fluorocarbons $C_nF_{2n} + 2$, from C_1 to C_5[10] and also with perfluoroethyl ether, furane, and bromotrifluoromethane, and others.[11] Some sample results, read from curves, are best summarized in Table IV, all with 60-cycle alternating voltage atmospheric pressure and within the gap spacings stated. The electrode configurations followed those of Camilli and Chapman.[8]

Effect of Pressure

The dielectric strength of a gas is generally raised by increasing pressure. This is most true in the uniform field, as shown by Nonken[5] with spheres, at pressure up to 200 pounds per square inch absolute and there appears to be no decrease in strength at any pressure within practical considerations. In the nonuniform field of a 6-centimeter rod gap, see Figure 1, at 60 cycles, a decrease in spark-over strength of CCl_2F_2 sets in at a pressure of little more than atmospheric. Impulse voltages generally show a rise with pressure although there are exceptions as shown in Figure 2. With direct current there appears to be no critical pressure among the gases reported in a uniform field. Also with direct current with needle-to-plane configuration, if the point is negative, there appears to be no critical pressure. However, when the point is positive, a critical pressure always seems to exist for any gas forming negative ions as similarly shown by Pollock and Cooper[3] and others. As expected, the critical pressure is different for different gases, and the simplest gases, such as oxygen, have higher pressure stability. While this phenomenon of spark-over has been observed repeatedly, the fact that prebreakdown corona voltages rise steadily with pressure under all conditions is noteworthy. The effect of

pressure on spark-over from a point electrode, by reducing the diffusion of positive space charges left by electron avalanches into the point, is a distortion and concentration of the applied field in the gap, and the gap length is thus effectively shortened by the compressed positive space charge. In other words, when a point is positive, electron avalanches into the point leave behind slow-moving heavy positive ions. When the pressure is low, these diffuse outwardly rather quickly; but when the pressure is increased, the positive ions are compressed and diffusion is reduced, and this is equivalent to a shortened gap.

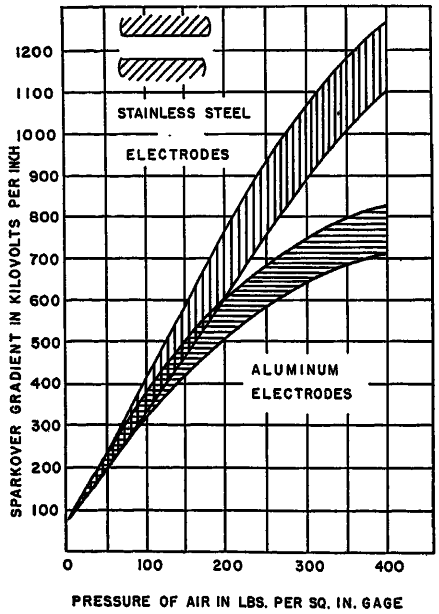

Figure 3. D-c dielectric strength of air between stainless steel or aluminum electrodes. Gap spacings of 1/4, 1/2, and 3/4 inches. From reference 6

When the point is negative, the electron avalanches travel away from the point and the remaining positive ions move slowly toward the point, in effect creating a more uniform field and one that is partially neutralized around the negative point by the positive ions, and this raises the required voltage for breakdown.

Effect of Temperature

In general there is no effect of temperature on the dielectric strength providing that the density of the gas is held constant by being in a firmly closed system. That temperature should enter into certain phenomena such as the critical pressure on positive points, just mentioned, would seem likely since the mobility of the molecules and ions always increases with temperature. This should raise the critical pressure because the rate of diffusion of space charge also increases with temperature.

Effect of Electrode Metals

The literature contains little or nothing on the effect of metals on the dielectric strength of fluorocompounds. However, the corrosion after arcing naturally is different on different metals. For example, aluminum was found more resistant than brass, and steel was even less resistant than either.[7]

While not concerned with fluorogases, it is interesting to note that other authors have found an effect of the electrode metal at subatmospheric pressures, for example, Ehrenkranz[12] and Jacobs and LaRocque.[13] Strangely, at pressures other than in the neighborhood of atmospheric, the effects of particular metals as electrodes appear more pronounced. This is still further illustrated[14] by differences between aluminum and stainless steel on carbon dioxide, nitrogen, and air, the last shown in Figure 3 at very high pressures.

Effect of Foreign Solids and Irregularities on the Electrodes

Cotton lint and dust have been shown to lower the breakdown strength.[15] The effect was most pronounced when the gas contained moisture because the dust absorbed the moisture with a probable increase in dielectric constant and conductivity. Likewise, it has been shown that surface irregularities cause a low breakdown value which rises on continued sparking due to removal of the irregularities. Howell[4] observed this effect with air.

Effect of Mixtures

Charlton and Cooper[2] in 1937 showed that mixtures of Freon-12 with N_2 and with H_2 had approximately a proportionally higher strength with increasing Freon concentration. This result was confirmed and furthermore was shown at small concentrations of F-12 to be disproportional by Skilling and Brenner[7] as shown in Figures 4 and 5. For mixtures greater than 5 per cent in uniform fields, these authors found the linear relationship $V = (88PS + 1.9)(1 + 0.8F)$ in which F is the Freon fraction by volume.

Similar results were obtained by Gossens[15] with mixtures of Freon-12 and air. For instance, 10 per cent of Freon in air at about 8 atmospheres pressure increased the air strength from 110 kv to 150 kv, or about 30 per cent in a uniform 60-cycle field. In a nonuniform field, a maximum is shown in Figure 6 in accordance with the previously discussed space charge effects.

At 27 atmospheres in a uniform d-c field, 8 per cent of SF_6 raised the strength of nitrogen from 430 kv to 680 kv, or by 58 per cent in a 1/2-inch gap. At 13.6 atmospheres the increase in strength amounted to 40 per cent.

One effect of mixtures is to change the temperature of condensation. This follows from Dalton's law of partial pressures which states that[16] in a mixture of gases the total pressure is the sum of the pressures which the separate gases would exert if each occupied the total volume of the mixture at the same temperature. For example, at atmospheric pressure Freon-12 condenses at about −29 degrees centigrade, but if a mixture by volume of 63 per cent Freon-12 and 37 per cent nitrogen at atmospheric pressure is cooled, a temperature of about −40 degrees centigrade should be attainable before condensation of the Freon-12 occurs. The presence of the nitrogen, by diluting the Freon-12, lowers the temperature for the occurrence of a "dew point." At another pressure, for example at 45 pounds absolute, the temperature of condensation of Freon-12 is found to be about 1 degree centigrade but with the 37 per cent nitrogen in a mixture the dew point drops to about −12 degrees centigrade, the temperature at which the partial pressure of the Freon-12 is the same as it would be in the pure state at 1 degree centigrade.

Summary

Considering the various factors so far discussed, and inspecting Table I, it appears that gases for indoor use might include all the Freons (excepting F-11, F-112, and F-113), the C_2F_6, C_3F_8, and C_4F_{10} fluorocarbons, and sulfur hexafluoride. Some, however, will at once be eliminated by having inferior dielectric strength. For outdoor use (−40 degrees low temperature limit) the selection of undiluted gases is reduced to SF_6, C_2F_6, and Freons 23, 22, and 13. Of these, SF_6 has the highest dielectric strength. Nevertheless, in view of the wide possibilities in fluorine chemistry, other compounds in the near future may be produced surpassing SF_6 in over-all qualities, and mixtures with lower temperatures of condensations may be useful.

Toxicity as a Major Consideration

Fluorine compounds are of great interest in the extremes which they show. On one hand they are of considerable inertness and on the other there are some of great reactivity. A property which is not well understood is the toxicity of organic fluorine compounds. Some are among the least toxic of substances, while others are among the most poisonous known. The fully fluorinated fluorocarbons as a class are probably among the least toxic of organic compounds.[17]

Much work has been done in the Freons and on sulfur hexafluoride,[18] the latter stated definitely to be physiologically inert. Referring to Table I, the toxicities of the Freons is generally low as determined by accepted methods in the Underwriters Laboratories.

However, the relative toxicity after arcing is principally dependent on the formation of reaction products. For example, Freon-12 was said to produce free chlorine and fluorine under the action of corona.[19] Results[9] on arced SF_6 showed that definite low concentrations in air produce no serious physiological effect. For example, with 7.5 per cent or less of the arced gas, there was no harmful effect on rats; with higher concentrations up to 20 per cent and exposure for 10 minutes, slight signs of irritation in the lungs on autopsy after 24 hours were noted.

To our knowledge, work on the toxicity of other fluorocompounds, especially after electrical failure is incomplete and should be done before there is industrial

application of the particular substance. It has been suggested that compounds containing only carbon and fluorine may produce less toxic products than SF_6.[11] Methods of purifying arced gases have been determined to be most practical and effective when absorption is used. Activated alumina as an absorbent was found efficient in removing the decomposition products of SF_6.[9,20]

General Outlook and Possible Applications

It appears that certain fluorogases may replace air in dry-type transformers. When a closed system is used, the advantages of greater insulation strength and cooling are obtained at little extra cost. Some fluorocarbons have already been used in high-voltage X ray apparatus and were later substituted by sulfur hexafluoride. This gas has also been used in medium voltage diagnostic apparatus in place of oil which had been used before. SF_6 has been used in experimental electrostatic generators, high-voltage cables, and capacitors.[21] An experimental transformer filled with SF_6 at 15 pounds gauge operated trouble-free for 2 years at 1.87 voltage over-load above rating.[9]

For indoor use, or in warm climates, the heavier fluorocarbons may prove advantageous after they have been more fully tested and evaluated. Continued testing of existing substances and new syntheses should be carried on of course. Specialized uses generally open the door to wider applications in many cases; and with the wide range of properties existing in fluorogases, the choice of an individual gas satisfying particular requirements might be easy.

Theoretical Aspects of Gas Dielectric Strength

The literature on dielectric phenomena has become so voluminous in the last half century that only a very small fraction of the pertinent references can be given in this paper. However, since these in turn carry additional citations, the field expands rapidly, and today it is doubtful if any one man can follow all of its divergent lines. Regarding whatever has been written on the subject, an understanding of the dielectric strength of different gases seems to remain upon an empirical basis.

Therefore, attention will be called to possible factors entering in the phenomenon of dielectric strength in a very broad way, fully realizing that some areas will thereby be neglected, but even worse, depth of presentation through detail will be sacrificed. However, there appears to be some need to clarify or define certain terms and to point out that dielectric strength is complex and always dependent on more than one property.

It would be well to find an explanation for the existing differences in the dielectric strength of various gases. Purely mechanistic theories dealing with the mean free path of the electron, limited by molecular cross sections and inelastic collisions, become inadequate when different gases are found, for example N_2O and CO_2 (both molecular weight of 44), which should have the same strength but do not.[22] The difference in acceleration of the electron by the applied voltage is therefore only one of the factors in dielectric failure.

The cumulative ionization theory of Townsend has been employed for more than 40 years to account for differences in gases; a weak dielectric gas presumably produces many ions and an exponentially increasing number of electrons, through successive collisions, while a strong gas does not produce so many. The measure of the degree of ionization α has so seldom been reported in actual numbers (usually only as the ratio α/p) that to assess its direct bearing on dielectric strength is difficult. (Necessary primary data in the literature has been in many cases regrettably withheld. Confusion regarding numerical values of α arises through the pernicious habit of reporting only α/p, E/p, and pd as ratios or products without the details of actual pressures, voltages, or gap spacings employed.) Corona, avalanches, and streamers undoubtedly depend upon ionization of gas molecules for their propagation. The work of Loeb[23] and his co-workers on these phenomena is too widely disseminated to require extensive discussion here. Cobine[24] has effectively correlated many practical applications. The inclusion of α in all discussions of gas dielectric failure has made it an indispensable number. However, Hochberg and Sandberg[25,26] offered evidence and were flatly of the opinion that at breakdown the α of one gas is practically the same as that of another, depending only on the applied field.

Space charge, which is the result of differences in the mobilities of electrons and molecular ions, is similarly necessary in the explanation of particular phenomena such as the observed differences between positive and negative point corona as previously described and the effect of pressure on "electronegative" gases. In the latter case, Pollock and Cooper[3] asserted for SF_6 and CCl_2 that an accelerated rate of positive ic formation with increasing pressure ove comes the stabilizing effect of relative fewer negative ions (when the poi electrode is positive), and breakdown ca occur from a single streamer because enhanced distortion of the field. The also indicate that factors such as th velocity of streamer propagation, stream diameter, photoionization, and electr capture (all probably dependent on th specific gas) are also important consider tions.

The chemistry of dielectric gases i relation to dielectric strength has been matter for speculation and hypothes since 1889. The almost invariable ri in dielectric strength when a given hydr carbon, for instance methane CH_4, converted to a halogen methane, such CCl_4, has long been noted. The Freo are of course examples of this clas Other fluorocarbons, such as those Wilson, Simons, and Brice[10] and Bashara are members of homologous series, an the chemical similarity of hexafluor ethane (C_2F_6), octafluoropropane (C_3F_8 and decafluorobutane (C_4F_{10}) is so gre that a simple linearity between the diele tric strength and the increasing densi of these gases was found. It is on when gases are more distinctly differe chemically that an accounting of rel tive dielectric strengths becomes mo difficult. The case of CF_4 when compar with other stronger Freons such as CCl_2 is illustrative. On the basis of symmetr bond energies, electron affinities, ar quantum mechanics, CF_4 should be strong dielectric gas but it is only slight better than nitrogen. Furthermore, su fur chloride, methyl bromide, ethyl ethe and ethyl alcohol, all distinctly differe chemically, were found by Charlton ar Cooper[2] under their conditions of testi to have the same strength as nitroge Helium, a chemically very inert gas, h the lowest strength of any [3,12,13,22] und discussion.

Another point of view, traceable either von Hipple or Frölich,[27,28] concer the energy barrier and characteristic su stance frequency which electrons mu overcome in order to cause breakdow Actual energy absorptions and dissip tion are implied, if not stated, in the authors' works, and regardless of t fact that they were concerned main with solids, we have chosen to extend t idea to the gas state. The applicabili of their concept and various speci characteristics of gases, will be discuss in the Appendix.

Meanwhile, comment on some ter

used to describe certain electrical properties of molecules is probably in order since the terminology of our subject is becoming more profuse and specialized.

Electronegativity, Electron Affinity, Ionization Potential, Appearance Potential, and Electron Trapping

"Electronegativity," the attraction of an atom for the electrons which bind it in a stable molecule,[29–31] has explained in part the high dielectric strength of some of the halocompounds. The halogen atoms have high electronegativities, see Table V, and high-strength gases produce negative ions on breakdown. In fact, any gas which does not form negative ions is unlikely to have exceptional dielectric strength, or conversely, all high-strength gases can produce negative ions. Whether this condition is causative or simply coincidental remains to be seen.

Electronegativity as the term is presently used, is rather a loose designation of an ability to consume free electrons.

"Electron affinity" is used more quantitatively to describe the process.[32]

$$M+e \rightarrow M^-$$

and indicates the energy change when an atom or molecule forms a negative ion by electron attachment. The halogen atoms in Table V have the highest values, followed by oxygen, carbon, and sulfur in diminishing order, while nitrogen and helium have negative values in line with the fact that their negative ions are extremely unstable or nonexistent. The electron affinities of high-strength gases have not been measured, but experimental methods for their determination could be used.

The "ionization potential," another property of a gas, should be an index of its dielectric strength, and is designated by the energy change in the process

$$M \rightarrow M^+ + e$$

Here, a positive ion and an electron are obtained from a neutral atom or molecule. Usually a highly energized electron is stated or assumed to be the initiator of the process and it is evident that electron avalanches can start in this way if enough molecules become involved in the action.

Practically all matter can produce positive ions and electrons, the potential of ionization varying from substance to substance. The suggestion of its value, however as an index of dielectric strength must be abandoned, at least as a single criterion since inspection (Table V) shows that the weakest dielectric gas, helium, has the highest ionization potential.

The "appearance potential" is a more recent term indicating the energy required to produce various, charged molecular fragments in the mass spectrometer. In this, a great many different ions are formed and identified. It is interesting to note[33] in passing that SF_6 going to SF_5^+ has the same appearance potential, 15.9 volts, as CF_4 going to CF_3^+ but SF_6 is the much stronger dielectric gas. These examples are different from that illustrating ionization potential, as previously defined, in that dissociation of the molecule preceded or accompanied the process, for instance

$$SF_6 \rightarrow SF_5^+ + F^- \text{ (dissociation)}$$

and this required the concept of a dissociation energy or bond energy to be discussed later.

"Electron trapping" (used only in the sense of consuming; not as in the theory of metals or ionic crystals) is closely associated with electron affinity. In the preceding equation the energized electron (not shown) causing the dissociation of the SF_6 molecule rebounded with a loss energy (that used up in the SF_6 fragmentation).[6] An alternative occurrence is the inelastic collision of the electron with attachment to the molecule, and the same process as was shown for electron affinity applies. The conditions controlling electron trapping or attachment are:

1. The pressure of the gas.
2. The velocity of the colliding electron.
3. The molecular cross section of the particular gas molecules.
4. The electron affinity.
5. Probably the temperature.

In general, only slow electrons, that is, those with energies well under 5 electron volts (ev), will attach to molecules; faster electrons may attach but can cause extensive simultaneous dissociation. Since the distribution of velocities in any electron population affecting a gas probably includes many slow ones, it is evident that to have these consumed in forming even slower heavy negative ions should raise the voltage requirement for breakdown.

In all of the foregoing discussion, a few of the factors probably related in some way with dielectric strength have been very briefly noted or defined. The work of quantitative correlation, including empiricism and induction, has been privately in progress and if successful, may be reported at some future time. Additional theoretical bearings on the nature and properties of gases will be found in the Appendix. We must conclude that no single factor can be entirely responsible for dielectric strength; the combination of physical and electrical properties in a substance without doubt produces the resultant strength or weakness.

Appendix I

Further Theoretical Considerations

It has been shown that probably no single criterion exists for the explanation of relative dielectric strength. Isolated terms, however, may possibly be pulled together by applying a unifying concept of an energy summation, more or less along the line of reasoning of Fröhlich or von Hipple.[27,28]

A volume of gas is a rather complex system of forces. These can be considered as opposing the force of the applied electrical field. But in addition to this, the volume of gas also has the property of energy absorption, and by absorbing and dissipating energy in one way or another, a higher potential must be applied to cause electrical failure. (An excellent monograph[16,34] considering all the physical properties of gases, dielectric strength omitted, has been recently published.)

A list of the strengthening forces in a volume of gas should include:

1. The cohesive forces among the molecules.
2. The cohesive forces among the atoms of the individual molecules.

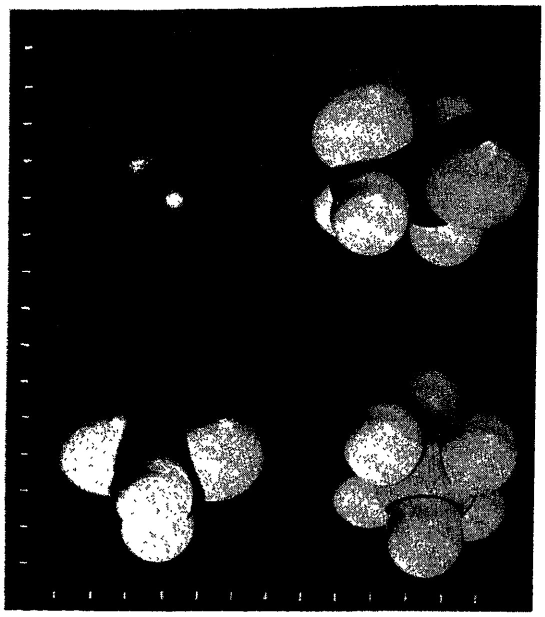

Figure 7. Molecular models of four gases. Divisions in Angstrom units

Top left, nitrogen; top right, Freon 114; bottom left, Freon 12; bottom right, SF_6

3. The cohesive forces of the electrons in the atoms.

Absorptions of energy can occur in a volume of gas through:

A. Thermal, translational, and rotational movement of the molecules, all kinetic
B. Atomic vibrations or oscillations of the atoms in the individual molecules.
C. Electron vibrations and excitation in the atoms, including structural resonance.
D. Induced, and permanent, dipole reactions to the applied field.
E. Electron attachment.
F. Chemical reaction after electron attachment or other ionization process.
G. Compression or electrostriction.

On the other hand a volume of gas also contains weakening forces and these are principally the repulsions existing among the molecules, atoms, and electrons. These should rightly be subtracted from the positive forces of cohesion. (Both forces are functions of the distance between particles, but in different degree.) Atomic and molecular inertia, if they diminish vibrational, rotational, and translational responses, should also be subtracted.

Most of the preceding general statements can be correlated with the present gases under consideration. Figure 7 shows four typical molecules illustrating differences in size, structural shapes, and chemical complexity of different dielectric molecules.

The van der Waal's equation of state provides an approximate measure of the cohesive forces among the molecules of a gas. The third column in Table VI lists the values obtained by using the original relationships of van der Waal on available critical data. A rough proportionality with dielectric strength is noted, excepting CHF_3 whose strength is out of agreement with an *a* value of 5.

Bond energies,[35] dissociation energies, and stretching force constants [36,37] provic measures of the cohesive forces betwee atoms in a molecule. Available values a shown in Table VI columns 4, 5, and That the values are for the individual bond as shown, is emphasized; they are only pa of the total energy of the molecules.

The study of the electronic cohesi forces in a molecule is one of the problen of quantum mechanics. For our purpos the ionization potential, which is the poten tial needed to remove an electron from t system, is a measure of the net cohesi force. (In this respect, the appearanc potential of the "parent" ion in the ma spectrograph corresponds to the ionizatio potential.) Values for this are also listed i Table VI. The fact that the ionizatio potential by itself cannot be a true indic tion of dielectric strength has already bee mentioned.

The aforementioned positive forces cohesion are supplemented by positive a sorptions of energy in the volume of ga It is very likely that in the stress of a applied electrical field every frequency i the energy spectrum from the far ultra violet to the far infrared can be present i some degree, depending on the manner an kind of voltage application. The tot energy which a molecule can absorb in th energy field is always considered to be th sum of items A, B, and C, previously liste independently, plus interactions of A, and C, which are of lesser magnitude. Th complete [34] expression for the availabl energy per molecule of an ideal gas wit polyatomic linear molecules is

$$G=E_0-(7/2)RT\,1nT+RT\,1n\,p+RT\Sigma\,1n \; (1-\epsilon^{-h\nu/kT})-RT\,1n\,(2\pi m)^{3/2}k^{5/2})\times (h^{-3})\cdot(8\pi^2 I_k)(h^{-2}s^{-1})\pi g_e(g_n$$

and for nonlinear molecule, such as Freon 12, the last term becomes

$$(8\pi^2(2\pi k)^{3/2}(I_AI_BI_C)^{1/2})(h^{-3}s^{-1})g_e\pi(g_n) \quad .$$

and this causes considerable trouble whe

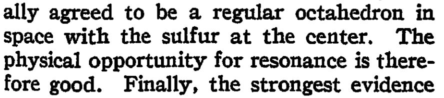
some of the quantities are not known. However, we may continue to make qualitative observations.

Thermal and translational movement of the molecules absorb energy if there is a source of heat and in actual numerical value probably is less than 0.005 electron volts per molecule. The rotational movement of a molecule is of a slightly higher order but still is probably less than 0.01 ev per molecule per degree of freedom.

Vibrational atomic oscillations absorb energy in the infrared and account for less than 0.1 ev per molecule per degree of freedom, that is, for a single vibration. If n is the number of atoms, the number of possible vibrations, that is degrees of freedom including the rotational, is given by $3n-6$ (or $3n-5$ if the molecule forms a straight line); and of these, $n-1$ are of the stretching type. The force constants of this type of vibration have been listed in Table VI and are related to the specific frequency of the vibration and to the masses of the connected atoms. In general, the greater the force constant, the greater energy absorption should be expected.

The electrons within the atoms are potentially the largest energy absorbers, ranging from about 1 ev upward to the ionization potential of the molecule. Energy calculations on the molecular electrons are difficult and uncertain except from spectrographic data. It is known that like the rotational and vibrational energies, the absorption of energy by electrons occurs in quanta. In a polyatomic molecule such as Freons, excited levels can be raised, if not directly by the external field, then by collisions. The acquired energy can be dissipated by radiation or by the vibrational excitation of the atoms which in turn can radiate at some lower frequency. This is different from another property possessed by some molecules called resonance[29] which is an electronic condition of oscillation between two or more atoms in a molecule, and is best thought of as a delocalization of particular electrons, so that several alternative electron bonds among the atoms can be visualized. Since the condition of resonance is a dynamic one, there is only a probability that the arrangement will take one particular form at any instant. The important effect of this condition is an increase in the total energy of the molecule; the molecule is more stable as a result of resonance. In SF_6 there appears to be a probability of resonance because the electron arrangements



(remaining F electrons not shown)

in terms of two covalent bonds and four semipolar singlets[38] are all possible, and it has been shown that there are no unshared electrons in the valence shells.[39] The fact that SF_6 has no permanent dipole moment does not exclude the possibility that some of the valence electrons may be in a state of resonance. The SF_6 molecule is generally agreed to be a regular octahedron in space with the sulfur at the center. The physical opportunity for resonance is therefore good. Finally, the strongest evidence is the arithmetic difference between the heat of formation,[40] 262 kilocalories per gram mole, and that obtained from Pauling's bond[35] energies, $6 \times 58.7 = 349$ kilocalories per mole. The difference, neglecting relatively small heats of fusion and vaporization, can be stated to be the resonance energy of stabilization, 87 kilocalories per mole or 3.78 ev. The Freons and fully saturated fluorocarbons have no such variation ability in their electronic arrangement.

Dipole Reactions

A molecule in an applied field becomes deformed or polarized, and this is a common property of all substances in varying degree from helium to very complex materials. Further, a certain part of the polarization is independent of the state of aggregation, that is whether the molecules are as a gas, liquid, or solid. From our point of view, the degree of polarizability is a measure of another means of energy absorption. In 1942 Hochberg and Sandberg[26] pointed out that the dielectric strength in a series of gases, including a few of the Freons, was proportional to the molecular refraction, which in turn is related to the polarizability through the Clausius-Mosotti-Debye equation. In Table VI the listed molecular refractions contain the electron refractions plus the atom refractions as given in Landolt-Börnstein tables,[41] and the proportionality with dielectric strength is evident. Helium is again found in its usual position as the weakest dielectric gas and a significant difference exists between CF_4 and CCl_2F_2. The effect of a permanent dipole, if present in a molecule, is an energy additional to the refractions shown; there is also dipole interaction which has a subtractive effect. These cannot be developed in discussion at this time; however, some known dipoles in Debyes are: $CHClF_2$, 1.4; $CClF_3$, 0.45; CCl_2F_2, 0.51; CF_4, 0.0; SF_6, 0.0 and comparisons in relative dielectric strength are interesting in this series.

"Electron attachment," since the pioneering work of Bradbury[42] on a variety of gases, has become of fundamental interest. The energy of the electrons in this process is wholly absorbed by the molecule and this fact should perhaps be emphasized. What the molecule, now an ion, does with the added energy depends on the particular molecule, and most of the energy will be dissipated in various vibrations previously described and by collisions with other particles or the wall of the vessel. Dissociation, or splitting of the molecule, however, can expend relatively more, and it is likely that all the fluorocompounds spontaneously dissociate on attaching an electron of sufficient energy as well as becoming simply negative with enhanced vibrations. Academically, a distinction can be drawn between simultaneous attachment and dissociation, and the possibility of these going on stepwise in finite time. It would seem that the stepwise process should be more acceptable on the basis of a common progenitor, the "parent" ion, even if this is very difficult to find after the reaction. For example, if Freon-14 forms the parent ion CF_4^- by attaching an electron, given sufficient energies, the following can then occur

$$CF_4^- \text{——} CF_3^\circ + F^-$$
$$CF_4^- \text{——} CF_3^+ + F^- + e$$
$$CF_4^- \text{——} CF_3^\circ + F^\circ + e$$

Of these, the first two are more likely than the last which is a higher energy reaction. These possibilities are only a few showing end products of an electron attachment. These products in turn can then enter into further electron reactions and by continuing to attach electrons the effect can be one of continuing energy absorption. Reaction possibilities of SF_6 have been briefly presented in a previous publication.[9]

The chemical, physical, and energy consideration of gases has not been exhaustively treated; much of the foregoing discussion has perhaps been presented uncritically. The fact that the problem of relative dielectric strength can be complicated has, however, been emphasized. The correlation of various factors, some applying generally and some under special conditions, is a real and challenging problem which may demand considerable time and effort.

The Nickel Base Indirectly Heated Oxide Cathode—A Review

A. M. BOUNDS
NONMEMBER AIEE

P. N. HAMBLETON
NONMEMBER AIEE

THE barium oxide indirectly heated oxide cathode came into wide use in 1927 and has since virtually dominated the field of ordinary receiving tubes and many other special types as well. The purpose of this article is to review its present status from the standpoint of the electronics engineer rather than that of the physicist. The role of the cathode alloy as well as some of the possibilities and shortcomings of such a cathode as used in the commercial production of electron tubes will be emphasized. In such a discussion it is necessary, first, to review the possible mechanisms of emission; second, to consider the performance characteristics of oxide cathodes; and third, to offer some comments upon the properties of the various cathode nickel alloys and their effect upon cathode performance.

The oxide cathode is perhaps the least-understood element in the modern electron tube, and indeed its functioning may be the least-understood phenomena in the entire science of electronics. It certainly is a credit to the electronic industry that so much has been done in the application of electron tubes without a complete understanding of exactly how the electron current is produced in the first place. Research work on oxide coated cathodes is a highly specialized and complex undertaking. The very large number of variables, the many steps necessary to construct experimental

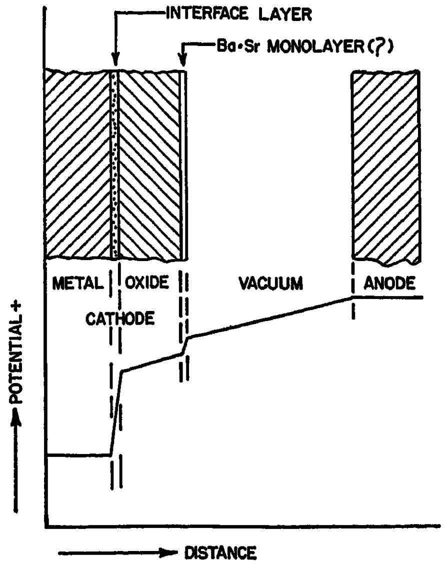

Figure 1. Schematic view through a diode tube with potential distribution approximation

tubes, and the difficulty in exact reproduction of these devices have restricted research to a very limited number of laboratories. Perhaps not more than a few dozen scientists in the entire world have directed intensive and long continued study to the oxide cathode. One of the earliest and most penetrating papers dealing with both the cathode base metal and its relation to the oxide coating was presented by Benjamin[1] in 1935. More detailed information has been developed by Sproull,[2] Eisenstein[3] and his associates in this country, and by Hermann and Wagner[4] in Germany, Loosjes and Vink[5,6] in Holland, Violet and Reithmuller[7] in France, and D. A. Wright[8] in England.

The oxide cathode has been spoken of as an "element" in the electron tube, and so it is usually considered by tube engineers. It really is a complex system composed of a metal cylinder or sleeve and a coating of alkaline-earth-metal carbonates initially held in place by a nitrocellulose binder. These carbonates of barium, strontium, and sometimes other additives must be carefully controlled as to shape, size, purity, and composition ratio. By a combination of evacuation and heating the carbonates are converted during tube processing to an adherent coating of oxide crystals, while the decomposed nitrocellulose binder and the carbon dioxide gases are withdrawn as they are generated. A carefully controlled schedule of high temperature heating, lower temperature aging, and actual cathode-current drain is required to complete activation. This process is designed to produce an optimum and stabilized electron emission from the cathode.

The precise nature of all the chemical and physical changes which occur on the coating, within the coating, and between the coating and the metal sleeve has long been the subject of speculation. An early theory held that activation was a result of electrolytic action within the mixed oxide coating, but it was not then understood that the so-called pure nickel base metal contained reducing agents which also entered into the reaction. Later, it was believed that a monolayer of free barium and strontium was formed on the outer surface of the oxide coating, and that barium impurity centers were distributed within the coating as well. Gradually the concept of the oxide coating acting as a semiconductor received considerable acceptance. More recently Loosjes and Vink[5,6] have advanced a dual-emission mechanism of pore conduction as an explanation of current passage through the coating resulting in liberation of free electrons (upon the application of a suitable positive external field). This theory is finding increasing support at the moment.

In any event, it is generally conceded that the low work-function of elemental barium and strontium in the oxide cathode provides for the release of a copious flow of electrons which are delivered to the anode when a suitable positive potential is applied. Figure 1 is a schematic view through a diode or 2-element tube showing an approximation of the potential drop when the cathode is emitting electrons to the anode.

For many reasons the oxide cathode is most widely used. It is a cheap and versatile mechanism, able to provide several hundred milliamperes of direct current for short periods, lower currents for as much as 100,000 hours, and high pulse currents (tens of amperes), depending on tube design, care, and control of manufacturing processes, coating materials and techniques and choice of metallic sleeve alloy. A comparison of typical emission current curves for oxide cathodes, tungsten, thoriated tungsten, and the "L" cathode taken from D. R. Hill[9] are shown in Figure 2.

Just as the oxide cathode is not a single element, but rather a whole system, so the characteristics of an indirectly heated oxide cathode may be separated into distinct categories, particularly with reference to the base metal alloy on which the cathode is built. These "performance characteristics" are interdependent to a degree but are sufficiently distinct to have real meaning. The following cathode performance characteristics are well worth careful attention

1. Rate of activation.
2. Emission levels, direct current and pulsed.
3. Rate of sublimation at a given operating temperature.
4. Tendency to form interface compounds of high electrical impedance.
5. Life characteristics.
    - Rate of free barium production and its influence upon grid emission.
    - Maintenance of primary emission as it contributes to maintenance of plate current and mutual conductance.
    - Maintenance of pulsed emission.
6. Heater-cathode leakage currents.

Coating and processing materials and techniques are extremely variable since each engineer in each tube plant has his own favorite materials and schedules. These are also dependent upon the equipment and tube types produced in the particular plant. Consequently, these phases, which are still a mixture of art and science, will be only touched upon, and the discussion will center on the more familiar nickel cathode alloys about which more is known with certainty.

How does the base metal affect these performance characteristics? The chemical reduction of earth-metal oxides by elements contained in the nickel sleeve has been mentioned. With one or two exceptions all cathode nickels contain controlled amounts of one or more of the elements magnesium, silicon, titanium, aluminum, carbon, and tungsten as chemical reducing agents for the alkaline earth-metal oxide coating. These may vary from as little as 0.01 per cent to as much as 4 per cent or more. When it is

considered that these alloys are melted in heats of from 700 to 20,000 pounds, the control of such small but important additives is evidently difficult and exacting. Each element and the various combinations of them affect the performance characteristics in different ways. While the effect of these elements may not be the only cause of the reduction of free barium, nevertheless the presence of various reducing agents in the nickel is easily demonstrated to have a profound effect on the performance characteristics of the cathode. Thus, the choice of proper cathode alloy for particular characteristics is more important than commonly understood.

The Reducing Elements

In such a short summary it is not necessary to review all of the major and minor effects of each of the chemical elements present in cathode nickel alloys, so only the most important and significant ones will be considered. Perhaps it should first be explained that there are a number of neutral and a few definitely poisoning elements, either unavoidably present or present for metallurgical reasons, which must be kept to reasonably low limits. The important ones are manganese, iron, copper, lead, boron, sulphur and phosphorus. These will not be considered here.

Magnesium

Magnesium is the most common and important, as well as the most active of the reducing agents. It is present in minute amounts in most of the cathode alloys and has the property of promoting rapid activation and of continuously generating free barium and strontium as they are evaporated from the surface of the oxide coating or are chemically combined to become again inactive. On the other hand, magnesium possesses a high vapor pressure and thus promotes a high sublimation rate of the metallic sleeve often resulting in electrical leakage and shifting characteristics when the magnesium in the cathode alloy exceeds about 0.07 per cent. Magnesium does not produce a high impedance interface between cathode sleeve and coating, and therefore is satisfactory as an activator for pulsed cathodes.

Silicon

Silicon is next in commercial importance. Activation is not quite so rapid as with magnesium, but d-c emission life is long and the use of silicon has therefore become popular for a number of types of cathode alloys. Silicon may be present in quantities from 0.01 to 0.25 per cent. Unfortunately, silicon seems to promote the formation of an interfacial layer between cathode alloy and coating which has been identified as barium orthosilicate and which is characterized by high electrical impedance which, in turn, results in poor performance of tubes used for pulsed or cut-off purposes. Silicon displays a lower vapor pressure than magnesium and thus does not cause deposits on insulators resulting in electrical leakage.

Titanium

Titanium is used very sparingly and primarily for its metallurgical effects rather than for its reducing action on the coating, but there are some who have advocated a more careful examination of the usefulness of this element. It is present as a scavenger in many of the cathode alloys, but rarely in the free or uncombined state so that its effect is probably minor in quantities now used. High titanium cathode alloys have been produced in the past, resulting in the formation of a black interfacial layer which has effectively reduced the operating temperature of the cathode. There seems to be disagreement as to the electrical characteristics of this interface, and it is doubtful that titanium-nickels have been used since the advent of pulse problems. Such alloys deserve more attention and they probably will be reviewed again in the near future.

Carbon

Carbon apparently may act as a reducing agent on the coatings, particularly in the absence of any other highly reducing elements, but its role in cathode activation and life has been difficult to establish. Because of its high diffusion rate and formation of gaseous compounds, any effect by carbon is probably very short lived but may be of importance in activation of the cathode.

These elements have been traditional reducing agents for both activation and constant regeneration of barium and strontium during life. Now let us review the commercial and generally used cathode alloys (as shown in Table I and II). They are classified both on the basis of their activity and according to the particular reducing agent or agents which largely determine their performance characteristics. Table I shows those in common use, while Table II shows the entire list including many which are rarely used today.

The first action of Section "A" on Cathode Alloys of the American Society for Testing Materials (ASTM) Committee B4 was to divide the alloys, ac-

Footnotes of Table I apply to this table also.

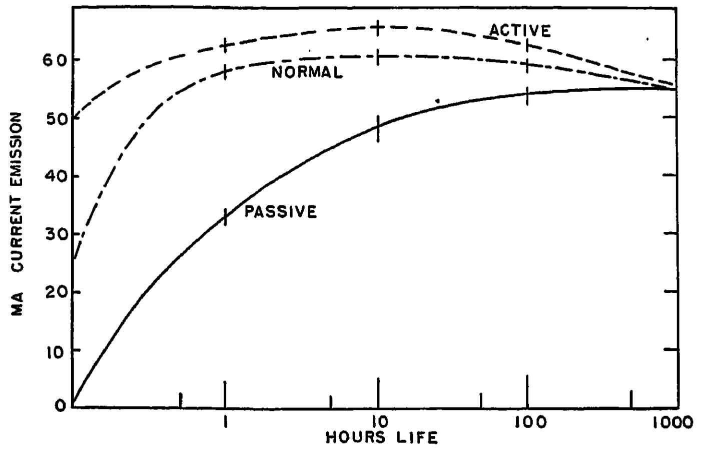

Figure 3. Rate of activation and emission levels typical of active, normal, and passive cathode base materials as tested in the standard ASTM diode

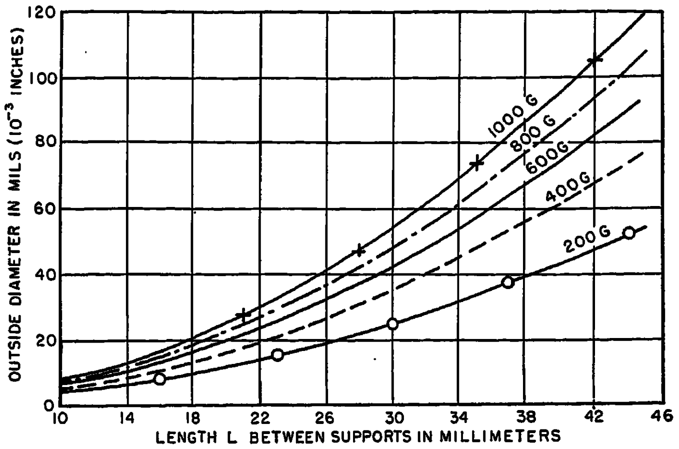

Figure 4. Relation of outside diameter and length between supports for round nickel tubing at several acceleration values and 775 degrees centigrade

cording to activity, into those which were "passive," "normal," and "active." This terminology is not exactly definitive when related to performance characteristics but does classify the alloys in a general way with respect to rapidity of activation and level of d-c emission during life. The rate of activation is of commercial importance to tube manufacturers but of little importance to the tube user.

The passive alloys show extremely slow activation, relatively low levels of emission, and extremely long life. The normal alloys show relatively rapid activation, higher levels of emission, and sometimes shorter life. The active alloys are rapid in activation, give slightly higher d-c emission and related tube characteristics, and when used under proper conditions give fairly long life. These general characteristics are shown in Figure 3. However, it is our belief that all but the passive alloys are probably outmoded by today's requirements which entail better control of sublimation characteristics, complete freedom from interface impedance, longer life, and better strength.

Newer alloys which have been recently introduced are ones containing aluminum as the activating agent in one series, tungsten as both a reducing element and a strengthening element in another series, and cobalt in still another. Now the use of these three elements is by no means new, since they are long familiar as ingredients in filamentary alloys. However, it was necessary to drastically alter the filamentary alloys, and in general to greatly reduce the content of these elements before the alloys would behave properly for indirectly heated cathodes. The new compositions are, therefore, quite distinct from the filamentary alloys.

The advantages of aluminum are evident from the characteristics of the element itself: activation is relatively rapid, d-c emission is high and long-lived, and sublimation has proved to be very low. The interfacial compounds, if present, are of low electrical impedance. In fact we may say here that in our experience only silicon has shown any effect in the creation of an interfacial layer of high impedance. Of course most of the reducing agents cause the formation of a visible interface layer, but these films do not necessarily show electrical impedance. There are indications that the absence of all reducing elements is necessary to the best pulsed performance, that is, passive cathode base metal is indicated.

In addition to doubling the hot strength of a cathode sleeve, the addition of approximately 4-per-cent tungsten seems to enhance the "reducing potential" of the cathode alloy. Tungsten-nickel alloys have shown reasonably rapid activation, long life under d-c emission conditions, relatively high emission, and complete freedom from interface impedance where the silicon content was sufficiently low. However, tungsten is a strategic element, scarce and high in price, so that tungsten-nickel alloys must be considered as premium ones for special purposes only.

Problems of reliability and shock and vibration resistance are specters which haunt tube engineers these days. Reliability is a problem not only of mechanical perfection of assembly but also one of long life with freedom from shifts in tube characteristics. The aluminum alloy for indirectly heated cathodes is expected to be a definite contribution to cathode life and stability of characteristics. On the other hand, ruggedization requires stronger cathode alloys which are, at the same time, suitable with respect to all of the cathode characteristics previously described; not a small order by any means.

Much improvement in shock resistance of cathodes can be effected with existing alloys by the application of simple and well-known laws governing the strength of shapes and materials. In considering this problem it must be understood that the heavier the cathode the less its resistance to deformation under shock loading. By the same laws it is almost elementary that the larger the diameter and the shorter the length between supports, the stronger is the cathode cylinder. And yet, these simple facts apparently are often ignored or forgotten in tube design work. In connection with this problem we have developed cathode strength curves which should enable a tube designer to predict with considerable accuracy the resistance of an indirectly heated cathode to shock loading. Figure 4 shows these curves for cathodes operating at a temperature of 775 degrees centigrade. The Bureau of Ships, Department of the Navy, has permitted publication of this small portion of recent contract development work by the Superior Tube Company in the hope that it will be an aid in the design of more rugged and reliable tubes.

In conclusion, it is desirable to emphasize a number of points which derive from the foregoing discussion. The complex oxide cathode structure is temperature dependent, not only as to electron emission but also as to chemical, metallurgical, and physical reactions. It is not an inexhaustible well of electrons; it must not be driven beyond its electron producing capacity simply by raising the temperature, raising the anode voltage, or using a positive grid bias. It cannot be expected to stand up if bombarded by positive ions which act like cannon balls in destroying the emissivity of the coating. Many of the apparent weaknesses of the oxide cathode stem from its misuse and a lack of understanding and appreciation of its characteristics.

Circuit engineers must know a great deal about the internal workings and theories of electron tubes and electron emission, in addition to knowing all about the circuits in which they are applying these tubes. When special applications of tubes are involved, it is always necessary for the circuit engineer to consult with the applications engineers of the tube manufacturer or with specialists in this field within his own organization. Relatively small differences in applied voltages and signals may be vital; they may change the tube life from 10,000 hours to a matter of hundreds of hours in a most unexpected fashion. To achieve reliability tubes should be underrated as much as is economically possible. Tubes must be processed for the application for which they are intended.

It must also be recognized that the complexity of materials and processes which are incorporated in the vacuum tube make it difficult both to substitute new alloys in old designs and to really evaluate the effects of these new materials. It is also well known that slight changes in tube characteristics, from whatever cause, greatly complicate the production of replacement tubes. Nevertheless, particularly in the design of new tubes, the electron tube industry now has an opportunity to achieve the reliability and ruggedness required by new and severe applications and specifications through an improved understanding of the indirectly heated oxide cathode and the predictable effects of the nickel alloy used as the base metal.

Application of Electric and Acoustic Impedance Measuring Techniques to Problems in Diathermy

HERMAN P. SCHWAN
ASSOCIATE MEMBER AIEE

EDWIN L. CARSTENSEN
NONMEMBER AIEE

DIATHERMY, or heating of deep tissues, must be accomplished through the absorption of radiant energy in the region to be heated. Conduction methods such as infrared or hot packing fail because of the rapid convection of heat by the flow of blood. Conventionally diathermy has come to be synonymous with high-frequency electromagnetic heating. Recently, however, ultrasonic energy has been introduced to accomplish a somewhat similar clinical purpose.

The effectiveness of these forms of radiation may be evaluated largely in terms of these physical quantities: the depth of penetration, reflection coefficient, and beaming angle, all of which can be computed from the frequency dependent electrical and acoustic impedance of the biological medium.

Rather extensive measurements of the electric impedance of tissues and blood have been carried out in the region up to 100 megacycles by Osswald[1] and by Schaefer[2] and above 1,000 megacycles recently by England[3] and by Herrick and co-workers.[4] Actually, as will be shown, the most promising region for diathermy lies between these two extremes.

For measurements in the frequency range 100–1,000 megacycles a special resonance method[5] has been adopted, which is a modification of a technique first discussed by Chipman.[6] An open-wire transmission line, see Figure 1, is loaded on one side by the sample under investigation and terminated on the other end by a movable short-circuiting plate. The line may be excited either capacitatively or inductively at a point between sample and short-circuiting end. The modulated current is picked up by a small loop protruding from the movable short-circuiting plate. This current is subsequently detected, amplified, and metered. Figure 2 shows the variation of this current as a function of the position of the short circuit for the case where the reflection coefficient of the sample is approximately one half. The points were obtained experimentally. The solid line is theoretical. The slight discrepancy between experiment and theory away from resonance arises from direct pickup

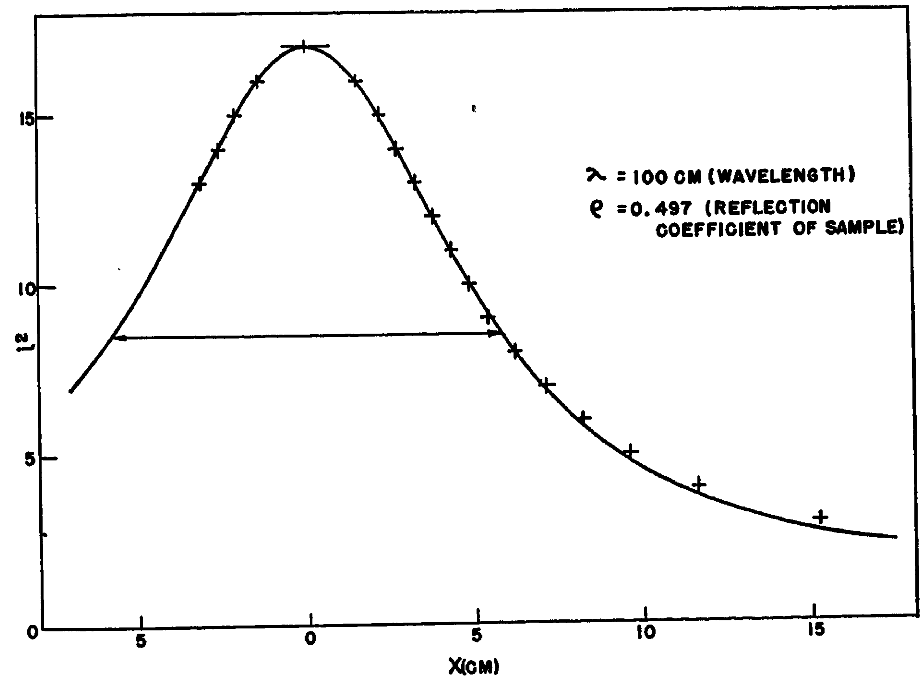

Figure 2. Resonance curve (points are experimental, curve calculated)

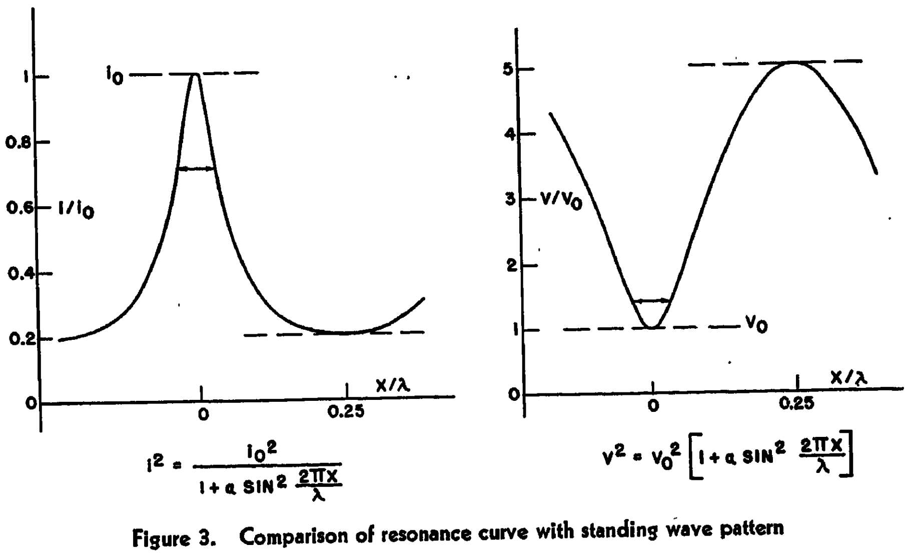

Figure 3. Comparison of resonance curve with standing wave pattern

between generator and pickup loop. In the resonance region the agreement is excellent. Actually the discrepancy serves to illustrate one of the advantages of this resonance method over conventional methods. It can be shown that, as illustrated in Figure 3, the voltage distribution along a transmission line as measured in the conventional standing wave method and the current distribution which is measured in the new resonance method are reciprocals of each other.[5] Thus, the resonance method requires the determination of the bandwidth of a maximum of current, whereas the standing wave method necessitates an investigation of a minimum of voltage.[7] Hence, the resonance method is less sensitive to stray fields and harmonic disturbances than the standing wave method. As a consequence, it is possible to measure with accuracy sample impedances which depart from the characteristic impedance of the line by factors up to 1,000.

By comparison with coaxial lines, open-wire transmission lines are flexible, accessible, and simple to construct. However, because of susceptibility to external disturbances and undesirable modes of excitation (as between system and ground), they are seldom used. The advantage of the resonance method, however, is that it makes it possible to obtain a high degree of accuracy with open systems. Measurements of the impedance of water have been conductance by the authors in the range from 36 to 200 centimeters, using an open-wire resonance system. The results are in good agreement with theoretical expectations.

Figure 4 shows measurements in this range, which have been obtained for blood, along with the results of other workers at higher and lower frequencies. The results are expressed in terms of dielectric constant and specific resistance. It can be seen that the data form a consistent pattern. The variation with frequency shown here is attributed to two different mechanisms. The existence of cell membranes in the blood causes a Maxwell-Wagner dispersion in the neighborhood of 1 megacycle.[8,9] This produces the change in the dielectric constant curve, which begins to appear, above 1 meter. The change below 30 centimeters results from Debye relaxation of the water molecules.[10] The dielectric constant between 30 and 100 centimeters is somewhat lower than that of water—54 as against 80 for water. This is explained by the presence of protein molecules.

Reflection and absorption coefficient α have been computed from these data and are presented in Table I. The absorp-

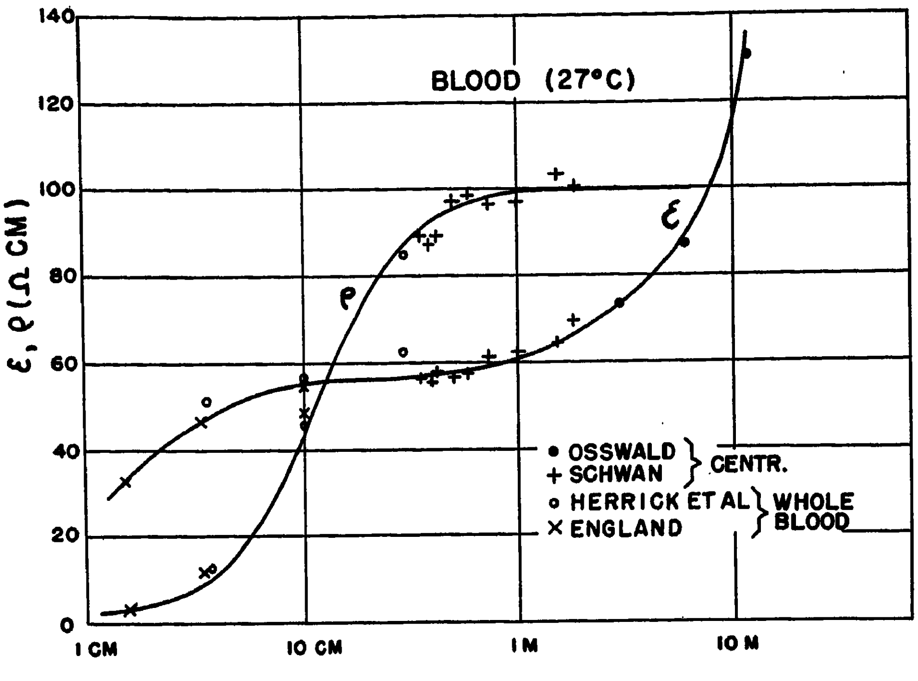

Figure 4. Dielectric constant (ε) and resistivity (ρ) of blood as function of wave length

Table I. Reflection and Absorption of Electromagnetic Radiation

Wave Length	Reflection Coefficient, Per Cent	Depth of Penetration (1/α)
10 meters	92	5 centimeters
1 meter	80	2 centimeters
10 centimeters	75	7 millimeters
1 centimeter	70	0.3 millimeter

tion is expressed in terms of depth of penetration of the intensity, that is, the depth in tissue at which intensity reaches 1/*e* of its surface value. Since cell membranes, proteins, and saline are from the electrical point of view the major constituents of all tissues of high water content, it can be said that the results for blood are characteristic of such tissue in general. The depth of penetration here decreases with decreasing wave length. For wave lengths less than 10 centimeters, the penetration is not significantly higher than could be obtained from surface heating. Use of wave lengths greater than 3 meters, on the other hand, is undesirable. If such relatively low-frequency energy is applied in form of electromagnetic radiation, any beaming is practically impossible. And, if it is supplied by high-frequency current, excessive selective heating of the subcutaneous fat layer results.[11] We therefore conclude that the optimum range for electromagnetic diathermy lies between 30 and 100 centimeters. In this range, the reflection coefficient for an air-tissue interface is rather high. It has been suggested for highest efficiency that the impedance between source and tissue be matched by filling the intervening space with a material of low loss and high dielectric constant.[12–15]

A similar approach has been taken in the investigation of the heating of tissue by high-frequency sound. Relatively little work has been reported on the acoustic impedance of tissue. However, measurements by Hueter[16] and Pohlman[17] have been sufficient to show that frequencies in the order of 1 megacycle are of interest for diathermy.

In an attempt to determine the cause of the relatively high absorption of sound observed for tissue, as compared with that for water, which is a major component of many of the tissues, the authors initiated a series of investigations on blood. Figure 5 is a diagram of the mechanical arrangement used in the measurements. The test vessel is divided into two compartments by a rubber diaphragm. One half is filled with degassed water, the other with the liquid under investigation. The transducers are mounted on a sliding assembly with the source in the water chamber and the receiver in the test liquid. The separation between the transducers is held constant and the transducer assembly moved along the axis of the test tank. Variation of receiving intensity with assembly position is used to obtain the absorption coefficient of the sample liquid. Barium titanate plates were used for transducers to cover the range 300–2,400 kilocycles. The magnitudes of the acoustic impedance for water and blood are approximately equal. Hence, there are only small reflections from the liquid interface, and refraction effects at this boundary are negligible. One of the greatest difficulties associated with conventional techniques for measuring absorption in liquids is that the output of the receiving transducer not only depends on the absorption of the liquid but is also a complicated function of transducer separation. This method avoids these difficulties simply by maintaining a constant transducer separation.

Effectively free field conditions are obtained through the use of pulsing techniques, see Figure 6. A pulse of radio frequency is applied to the source. The output of the receiver is amplified and

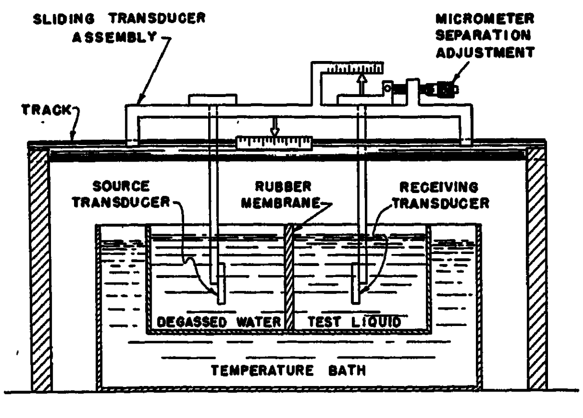

Figure 5 (left). Test cell for absorption measurements of ultrasound in blood

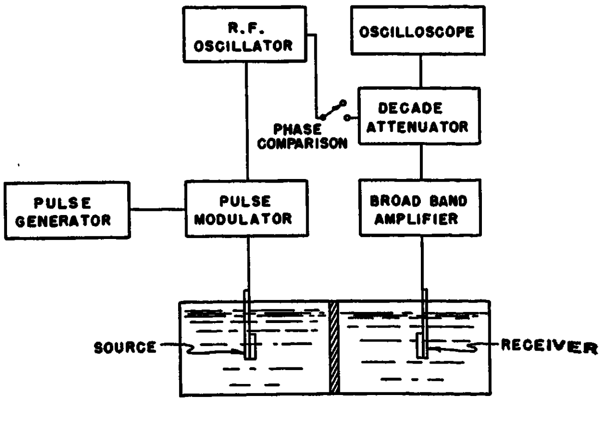

Figure 6 (right). Circuit of sound measuring equipment presented on an oscilloscope. The relative output intensity is measured by use of a decade attenuator which can be adjusted for constant signal at the oscilloscope.

For velocity of sound determinations, the wave length in the test liquid is measured by comparison of phase of the radiofrequency output of the receiver with a direct signal from the generator while the transducer separation is varied by micrometer control.

Figure 7 shows absorption as measured for the red cell residues of centrifuged human blood and for plasma.[18] The absorption is very nearly a linear function of frequency. The velocity of sound in blood is independent of frequency and approximately equal to that of water. In seeking the source of the absorption of ultrasonic energy by blood, it should be noted that the absorption in plasma which contains no cells is of the order of 25 times that for water. Further investigation as summarized in Table II[19] shows that the absorption goes in direct proportion to the protein content for blood and its components. Here the absorption, as measured at various frequencies and temperatures for concentrated red cells, plasma, and solutions of hemoglobin and albumin, is expressed in terms of absorption per unit quantity of protein present in the solution. The agreement in the results for various solutions shows that the proteins, whether in cells or in solution, are responsible for the absorption. Further, the protein content of many of the solid tissues is high enough to account for a large part of the observed absorption on this simple basis.

The actual situation in the solid tissues is somewhat more complicated. There also, however, the absorption appears to be a linear function of frequency and runs only one order of magnitude higher than that of centrifuged blood. Depths of penetration for solid tissues are of the order of 4–8 centimeters at 1 megacycle. Hence, frequencies up to approximately 2 megacycles can be useful for diathermy.

According to clinical reports, high-frequency sound can be used for many of the same applications as electromagnetic diathermy. It will be interesting to compare the two forms of radiation quantitatively on a specific problem, namely, that of the localized heating of the deep tissues. The directional properties of a piston source of either electromagnetic or acoustic energy depend upon the ratio of wave length to piston radius. The wave length of sound in its useful range is considerably smaller than that of electromagnetic radiation and thus sound

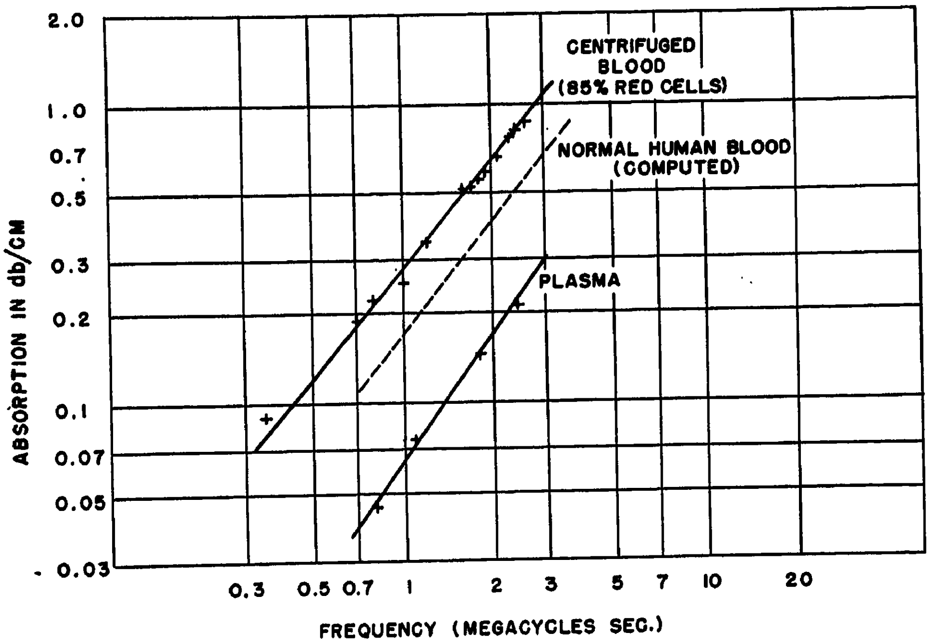

Figure 7 (above). Ultrasonic absorption of blood and plasma as function of frequency

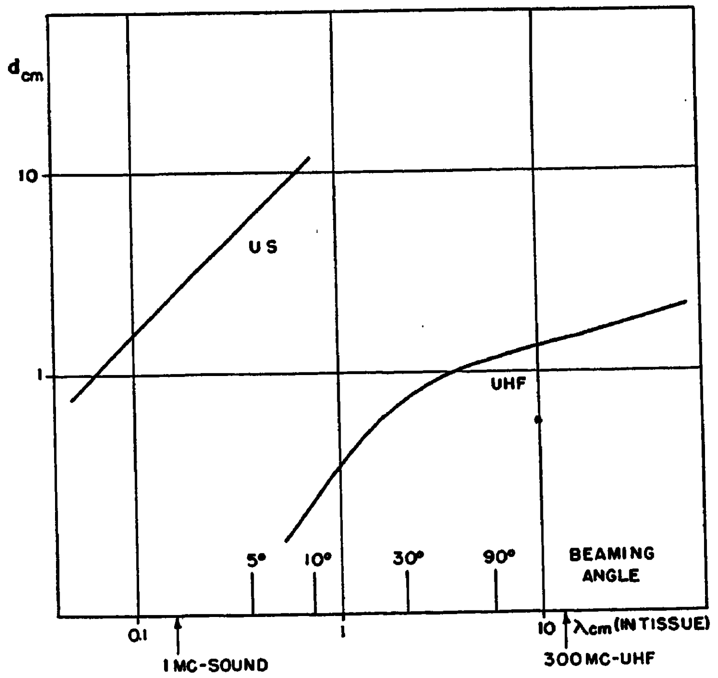

Figure 8 (left). Depth of penetration as function of beaming angle for various types of radiant energy may be more sharply beamed. This is shown graphically in Figure 8.[20] Here depths of penetration are plotted against wave length both for acoustic and electromagnetic radiation. The corresponding beam angle for a 5-centimeter radiator is also indicated along the abscissa. Over almost all of the useful range of sound the beam suffers practically no divergence. With even the shortest permissable wave lengths of electromagnetic radiation, however, the beaming is poor. From this analysis, it may be concluded that ultrasound is superior to electromagnetic radiation for the purposes of localized deep heating.

Summary

Measuring techniques are described for the dielectric constant and resistivity of biological material at ultrahigh frequencies and for the absorption of ultrasound. Electrical and acoustical data are presented for blood. The significance of these data with respect to the mechanism of absorption of the radiant energy is discussed. From a comparison using the electrical and acoustical impedance of tissue, it is possible to predict advantages of ultrasound over electromagnetic diathermy for the purpose of localized deep heating.

Maximum Impedance Transformations in Band-Pass Filters

T. J. O'DONNELL
NONMEMBER AIEE

E. M. WILLIAMS
MEMBER AIEE

Synopsis: Design of impedance transforming band-pass filters for use at radio frequencies often involves the criterion of maximum realizable impedance ratio with a minimum number of sections. A fundamental method is described for achieving this design criterion and illustrated for some simple cases.

WIDE-BAND impedance transforming elements for use at frequencies up to about 10 megacycles employ devices which are refinements of the ordinary iron core transformer. Outside this frequency range wide-band transformations commonly utilize impedance transforming wave filters. Design of such filters is derived from Norton's[1] equivalence between a dissymmetrical band-pass filter and a symmetrical section plus an ideal transformer. Various applications of Norton's equivalence have been developed by Gladwin,[2] Belevitch,[3] and Rowlands.[4] It is evident from these works that there are inherent limits to realizable band widths for any impedance ratio. Calculation of these limits, however, has been an indirect and involved procedure.

This paper is concerned with simplified direct methods for synthesis of wide-band impedance transforming filters in which the impedance ratio is maximized for a specified bandwidth.

Norton's equivalence relation is illustrated for a T-section in Figure 1. The dissymmetrical section with image transfer function θ and image impedances Z_{I_1} and Z_{I_2} is exactly equivalent to the symmetrical section with image transfer function (propagation constant) θ' and image (characteristic) impedance Z_I plus an ideal transformer of turns-ratio 1 to r provided that

$$\theta=\theta'$$

$$Z_{I_1}=Z_I$$

$$Z_{I_2}=r^2Z_I$$

It may be shown that these conditions hold if

$$\begin{aligned}Z_A&=Z_1-Z_2(r-1)\\Z_B&=r^2Z_1+r(r-1)Z_2 \qquad (1)\\Z_C&=rZ_2\end{aligned}$$

Either Z_A or Z_B will have a negative term depending on whether r is greater or less than 1. It will be assumed in what follows that $r > 1$ (increasing impedance from input to output).

Consider a cascade of n identical symmetrical sections each with image parameters Z_I and θ'. Suppose that it is desired to transform each section according to Figure 1 with turns-ratios $r_1, r_2, r_3, \ldots r_n$, and that the resulting network is to be equivalent to the symmetrical network plus an ideal transformer of turns ratio $r_1 r_2 r_3 \ldots r_n$. This may be accomplished by multiplying the impedance of each branch of the second section by r_1^2, each branch of the third section by $r_1^2 r_2^2$, and so on. The resulting sections have their

---

Paper 53-143, recommended by the AIEE Special Communications Applications Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted July 7, 1952; made available for printing December 10, 1952.

T. J. O'DONNELL is with the Gulf Research and Development Company, Pittsburgh, Pa., and E. M. WILLIAMS is with the Carnegie Institute of Technology, Pittsburgh, Pa.

This paper is part of a dissertation submitted by T. J. O'Donnell in partial fulfillment of the requirements for the Degree of Doctor of Science at Carnegie Institute of Technology. This work was supported in part by the Office of Naval Research under Contract *NR-200(00)*.

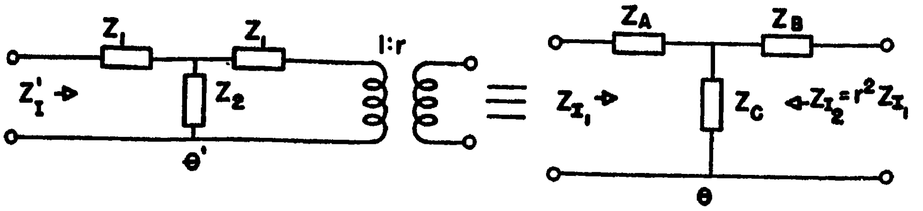

Figure 1. Norton's equivalence between a symmetrical T-section transformer combination and a dissymmetrical T-section

image impedances multiplied by the corresponding multiplier. Their image transfer functions remain unchanged. They may then be transformed by use of equation 1 and the transformed sections may be cascaded on the "image basis." The cascaded network will have image parameters Z_{I_1}, Z_{I_2}, and θ given by

$$Z_{I_1}=Z_I$$

$$Z_{I_2}=r_1^2r_2^2\ldots r_n^2Z_I$$

$$\theta=n\theta'$$

and the desired result has been achieved.

In the general case, the transformed network is not physically realizable because the transformation given by equation 1 leads to negative inductance or capacitance elements in some of the branches. There are, however, certain types of band-pass filter sections which may be transformed into sections with realizable elements for values of the transformation ratio not greater than a certain maximum. Furthermore in cascading sections it is sometimes possible to cancel negative elements in one section with positive elements in the mating section.

Two cases will be given as examples:

1. Case *a*. The transformation ratio varies from section to section. No negative circuit elements appear in the network.
2. Case *b*. The transformation ratio is the same for each section. No negative circuit elements appear in any interior branch of network.

Case a

Consider a network based on transformations of the symmetrical section of Figure 2. A special class of sections will be defined by the requirement that the reactances N_1 and N_2 may be physically subtracted from each other; that is a real constant $K>1$, independent of frequency, can be found such that

$$N_1-KN_2=0$$

Many standard sections, usually given in a different form, can be converted to the configuration of Figure 2 by the use of well-known circuit equivalences.

The first transformed section is also shown in Figure 2. From equation 1 its branches are given by:

$$Z_{A_1}=M_1+N_1-(r_1-1)N_2$$

$$Z_{B_1}=r_1^2(M_1+N_1)+r_1(r_1-1)N_2$$

$$Z_{C_1}=r_1N_2 \tag{2}$$

The maximum possible value of r_1 which will require no negative elements in the transformed section is, from the first of these equations

$$r_1=1+\frac{N_1}{N_2} \tag{3}$$

The branches of the second transformed section are

$$Z_{A_2}=r_1^2(M_1+N_1)-r_1^2(r_2-1)N_2$$

$$Z_{B_1}=r_1^2r_2^2(M_1+N_1)+r_1^2r_2(r_2-1)N_2$$

$$Z_{C_2}=r_1^2r_2N_2$$

When the two sections are cascaded, the second series branch of the network will have the impedance

$$Z_{B_1}+Z_{A_2}=2r_1^2(M_1+N_1)+2r_1^2N_2-r_1N_2-r_1^2r_2N_2$$

For a given r_1 the maximum value of r_2 which requires no negative element is that which reduces the sum of N-type impedances to zero, or

$$2r_1^2N_1+2r_1^2N_2-r_1N_2-r_1^2r_2N_2=0$$

$$r_2=2\left(\frac{N_1}{N_2}+1\right)-\frac{1}{r_1} \tag{4}$$

Similarly for the third section, the maximum transformation ratio r_3 is given by

$$r_3=2\left(\frac{N_1}{N_2}+1\right)-\frac{1}{r_2}$$

and in general for the Kth section

$$r_k=2\left(\frac{N_1}{N_2}+1\right)-\frac{1}{r_{k-1}} \tag{5}$$

Let

$$x=\frac{N_1}{N_2}+1=r_1$$

Then

$$r_1=x$$

$$r_2=2x-\frac{1}{x}=\frac{2x^2-1}{x}$$

$$r_3=2x-\frac{x}{2x^2-1}=\frac{4x^3-3x}{2x^2-1}$$

Introduction of the Tschebyscheff polynomials[5] is convenient at this point. These are given by

$$T_1(x)=x$$

$$T_2(x)=2x^2-1$$

$$T_3(x)=4x^3-3x$$

The recurrence formula is

$$T_n(x)=2xT_{n-1}(x)-T_{n-2}(x)$$

From equation 5 it is seen that

$$r_1=T_1(x)$$

$$r_2=T_2(x)/T_1(x) \tag{6}$$

$$r_3=T_3(x)/T_2(x)$$

The extension to the general case

$$r_n=\frac{T_n(x)}{T_{n-1}(x)} \tag{7}$$

is obvious.

The over-all transformation ratio r of the network is the product of the transformation ratios of the individual sections

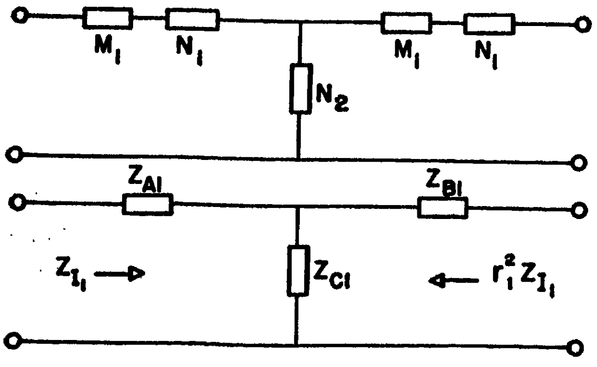

Figure 2 (left). Symmetrical section. N₁ of the series branch and N₂ of the shunt branch are understood to be the same type

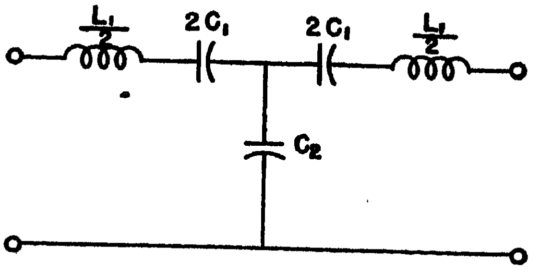

Figure 3 (right). Type III, section of Shea[6]

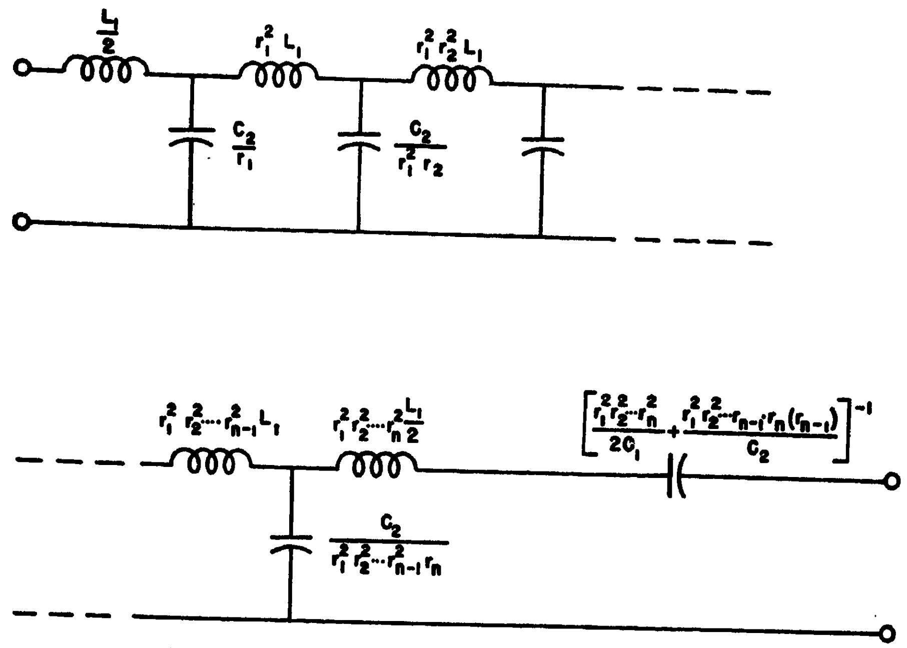

$\frac{L_1}{2}$
$r_1^2 L_1$
$r_1^2 r_2^2 L_1$
$\frac{C_2}{r_1}$
$\frac{C_2}{r_1^2 r_2}$
$r_1^2 r_2^2 \cdots r_{n-1}^2 L_1$
$r_1^2 r_2^2 \cdots r_n^2 \frac{L_1}{2}$
$\left[\frac{r_1^2 r_2^2 \cdots r_n^2}{2C_1} + \frac{r_1^2 r_2^2 \cdots r_{n-1}^2 r_n (r_n - 1)}{C_2}\right]^{-1}$
$\frac{C_2}{r_1^2 r_2^2 \cdots r_{n-1}^2 r_n}$

Figure 4. Result of "Tschebyscheff" transformation of case a

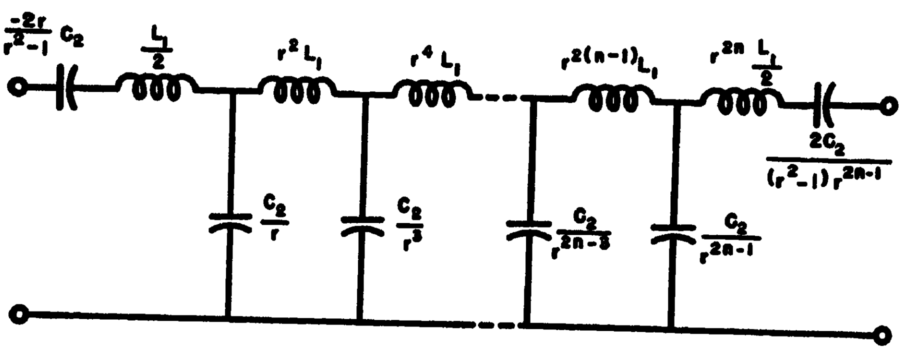

Figure 5. Result of transformation of case b type to section of Figure 3

$$r = r_1 r_2 r_3 \ldots r_r = T_1 \frac{T_2}{T_1} \frac{T_3}{T_2} \cdots \frac{T_n}{T_{n-1}} \tag{8}$$

or

$$r = T_n(x) = T_n\left(1 + \frac{N_1}{N_2}\right)$$

The argument $x = (N_1/N_2) + 1$ is a constant depending on the parameters of the symmetrical section on which the network is based. It can usually be expressed in terms of the cutoff frequencies.

It will be noticed that the resulting network is economical, that is, the N-type elements have been made to disappear from the interior series branches so that all the series branches except the last (Z_{B_n}) contain only M-type reactances.

Case b

Starting with the basic symmetrical section of Figure 2, a cascade of such sections may be transformed so that the transformation ratio r is the same for each section and has the maximum value consistent with requiring no negative reactance elements in interior branches of the network. From equation 1 the branches of the first transformed section are given by

$$Z_{A_1} = M_1 + N_1 - (r-1)N_2$$

$$Z_{B_1} = r^2(M_1 + N_1) + r(r-1)N_2$$

$$Z_{C_1} = rN_2$$

The branches of the succeeding sections are, since r is constant,

$$Z_{A_2} = r^2 Z_{A_1} \qquad Z_{A_3} = r^4 Z_{A_1}$$

$$Z_{B_2} = r^2 Z_{B_1} \qquad Z_{B_3} = r^4 Z_{B_1}$$

$$Z_{C_2} = r^2 Z_{C_1} \qquad Z_{C_3} = r^4 Z_{C_1}$$

When the first two transformed sections are joined, the impedance of the interior series branch is

$$Z_{B_1} + Z_{A_2} = 2r^2(M_1 + N_1) + 2r^2 N_2 - rN_2 - r^3 N_2$$

The maximum value of r for which this branch contains no negative elements is given by

$$2r^2 N_1 + 2r^2 N_2 - rN_2 - r^3 N_2 = 0$$

$$r^2 - 2r\left(\frac{N_1}{N_2} + 1\right) + 1 = 0$$

Again letting

$$x = \frac{N_1}{N_2} + 1$$

we have

$$r = x + \sqrt{x^2 - 1} \tag{9}$$

where the positive root has been chosen because we are looking for the maximum value of r. Similarly the conditions that no negative elements appear in the succeeding series branches of the transformed network lead in each case to equation 9.

It will be noted that the input series branch Z_{A_1} now contains a negative N-type reactance element, the interior series branches contain only positive M-type elements, and the output series branch contains a positive M-type and a positive N-type element. The negative element, being in an exterior branch, can under certain conditions be eliminated by adding a properly designed terminating section to the network.

Examples

Consider the type III$_1$ section of Shea[6] shown in Figure 3. This is a simple type of derived band-pass section with a peak of infinite attenuation at infinite frequency and with constant-K image impedance. The values of the reactance elements are

$$L_1/2 = R/(\omega_2 - \omega_1)$$
$$2C_1 = (\omega_2 - \omega_1)/\omega_1^2 R$$
$$C_2 = 2/(\omega_1 + \omega_2)R \tag{10}$$

where ω_1 and ω_2 are the lower and upper cutoff (angular) frequencies and R is the mid-band image impedance. It will be seen that this section belongs to our special class with

$$M_1 = j\omega L_1/2$$

$$N_1 = 1/2j\omega C_1$$

$$N_2 = 1/j\omega C_2$$

The parameter

$$x = \frac{N_1}{N_2} + 1 = \frac{C_2}{2C_1} + 1 = \frac{\left(\frac{\omega_2}{\omega_1}\right)^2 + 1}{\left(\frac{\omega_2}{\omega_1}\right)^2 - 1} \tag{11}$$

is a function of the bandwidth ratio.

The "Tschebyscheff" transformation of case a leads to the network of Figure 4. It will be seen that the interior of the network has the configuration of a lumped circuit analogue of a transmission line with special taper.

From equation 9 the transformation of

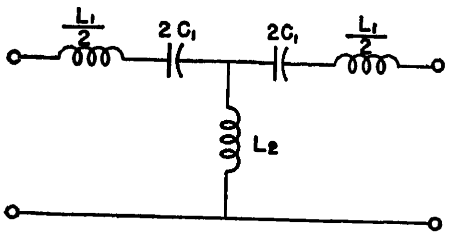

Figure 6. Compensating network for low impedance end of impedance transforming network

case b, again applied to the type III_1 section, leads to a transformation ratio

$$r=x+\sqrt{x^2-1}=\frac{\left(\frac{\omega_2}{\omega_1}\right)+1}{\left(\frac{\omega_2}{\omega_1}\right)-1} \qquad (12)$$

The resulting network is shown in Figure 5. Its properties are easily studied since it is matched on an image basis. It has image parameters Z_I, $r^{2n}Z_I$ and $n\theta$ where Z_I and θ are the image parameters of the basic 3-element symmetrical section.

One method of eliminating the negative capacitance is to add a section to the input (low-impedance) end of the network which contains in its series branch a series positive capacitance equal to or less than the magnitude of the negative capacitance. One such section, which has the same image impedance as the first section of the network, is the type III_2 section, shown in Figure 6. Its elements are

$$\frac{L_1}{2}=\omega_1 R/\omega_2(\omega_2-\omega_1)$$

$$2C_1=(\omega_2-\omega_1)/\omega_1\omega_2 R$$

$$L_2=(\omega_1+\omega_2)R/2\omega_1\omega_2$$

The capacitance $2C_1$ can be shown to be exactly equal to the magnitude of the negative capacitance of Figure 5.

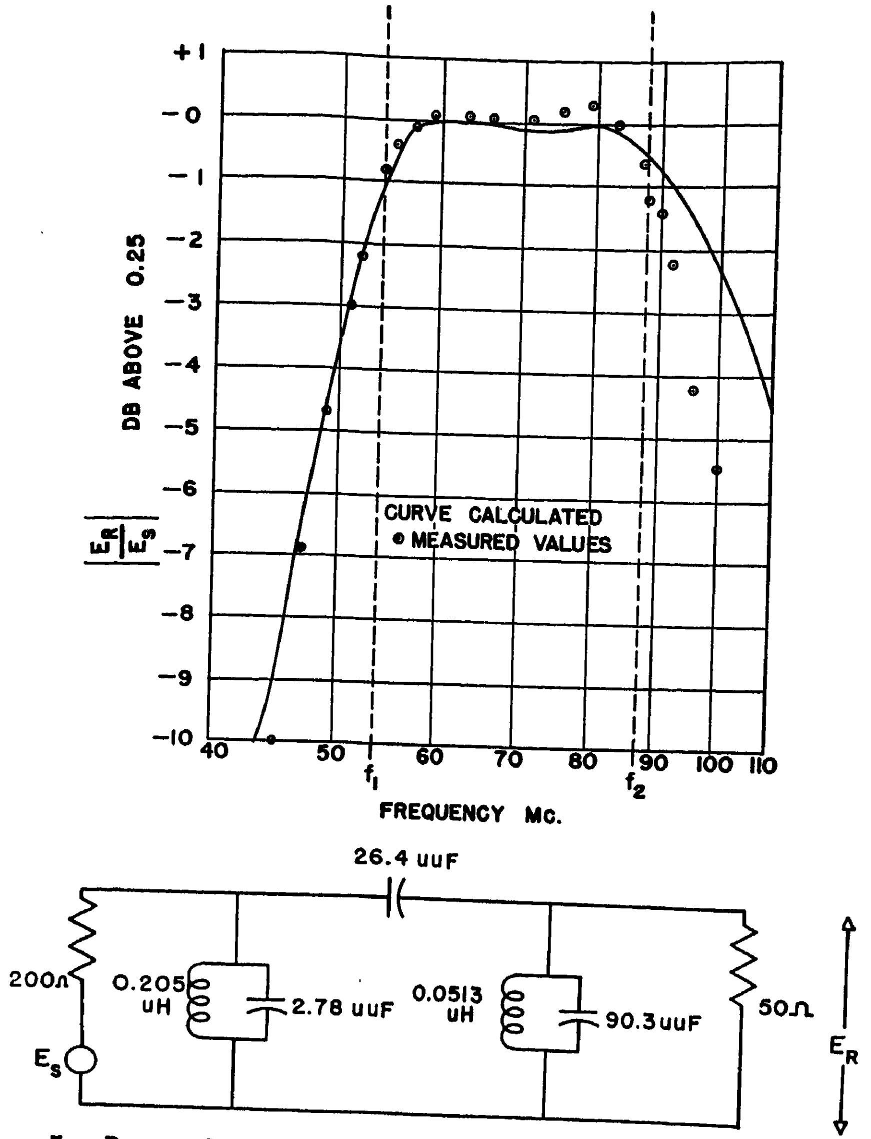

Figure 7. Bottom: Constants of a single-section type-a filter designed for 200-to 50-ohm transformations for the frequency range of television channels two through six. Top: Calculated and measured values of voltage transfer ratio for the filter below in the circuit shown

The analysis can be carried out for Pi sections with similar results. Maximum transformations of transformable band-pass sections other than the 3-element sections also lead to economical structures. It is evident that the gain for a given bandwidth is greater per section with a case b structure than with a case a. Since an extra terminating section is always required to eliminate the negative capacitance at the end of a cascade of case b sections, case a sections are actually more economical when few sections are required while case b are more economical for a filter of many sections.

As an example of a simple single-section impedance transforming filter the case a Pi unit of Figure 7 was constructed and tested. Characteristics are shown in Figure 8. It may be seen that predicted properties are realizable to an excellent degree of approximation.

Wheatstone Bridge for Admittance Determinations of Highly Conducting Materials at Low Frequencies

HERMAN P. SCHWAN
ASSOCIATE MEMBER AIEE

KARL SITTEL
NONMEMBER AIEE

Synopsis: The determination of reactive properties requires the use of sensitive bridge techniques, whenever the reactance is very small compared with the resistance. The following article describes an accurate Wheatstone bridge which permits resistance and reactance determinations within the frequency range from 10 to 200,000 cycles per second. The maximum accuracy for resistance determinations is one part in 10^{-7}; the accuracy for reactance depends on frequency and power factor. The various inductance values of the resistance coils cause negative capacities, which are especially high when the resistance values are smaller than 100 ohms. A simple and accurate technique for determination of these capacities is described.

HIGH precision bridges have been built by many investigators. Contributions up to 1926 have been summarized by Morgan and Lammert.[1] Jones *et al* published a series of papers in which more advanced bridge techniques are described and special questions, which concern conductivity determinations of electrolytes, are discussed.[2–8] Jones and Josephs achieved a maximum sensitivity of about one part in 10^{-6}. Their design proved to be very successful and further work in this field has been done with bridges of similar design. Another important contribution is Shedlovsky's investigation concerning proper shielding of the various bridge components.[9] More recently Luder[10] described an accurate conductivity bridge with very wide range, and Cole and Gross[11] constructed a wide-range capacitance-conductance bridge, which is useful up to 10 megacycles. Its main features are a special shifter network for balancing a hybrid-coil transformer arrangement, instead of an equal-ratio arm as introduced by Jones and Josephs and perfected by Campbell and Shakleton and Behr and Williams.[12] This 1 to 1 transformer automatically eliminates all undesirable unbalancing effects as caused by the generator or guard-electrodes; otherwise an additional Wagner ground arrangement[13] is necessary.

All these publications concern either the problem of measuring electrolytic conductance values with very high accuracy, or[11] capacitance and conductance determinations with somewhat reduced accuracy but at higher frequencies. Little work has been done to achieve capacitance and conductance determinations of highest possible accuracy at low frequencies. Attempts in this direction have been made by biphysicists who were interested in the electrical properties of various biological materials. Biological materials have very high dielectric constants at low frequencies, and their reactance is therefore not too small compared with their resistance to be detected with sufficiently sensitive bridges.

A major difficulty in performing reactance determinations of materials with relatively high conductivity is due to the existence of inductances in the variable resistors as used in bridges. Such variable units have been used most by authors and are essential for accurate tuning. Their inductance values simulate negative capacities $C=-L/R^2$ where $-C$ reaches values of more than 1,000 micromicrofarads in most resistance boxes when resistance R becomes smaller than 100 ohms. This high capacity depends strongly on the resistance box setting and directly influences the capacity determination. Knowledge of its value for each dial setting of the conductance box is therefore a necessity, and the accuracy with which these capacitances can be calibrated determines the accuracy of the capacitance measurements.

The determination of the reactive behavior of conductance and resistance boxes is a cumbersome task. Some biophysicists avoided this difficulty by use of a substitution method.[14,15] They replaced the biological material by an electrolytic solution whose total resistance was made equal to that of the biological material, either by a change of concentration or electrode distance. The resulting unbalance in capacity is eliminated by use of an additional variable capacitor parallel to the electrolytic solution. This substitution method is based on the assumption that electrode polarization either can be neglected or is the same in the biological sample and the electrolytic substitution solution. These assumptions are not always justified and special care has to be taken to assure that polarization does not affect the results.[16] Another disadvantage of the method is the difficulty of setting the resistance accurately. It is practically impossible to increase this accuracy beyond one part in 10^{-4} (0.01 millimeter for 10-centimeter electrode distance), which is insufficient for many investigations. Another arrangement is described by Schwan.[17] Here the determination of the electrical properties is achieved by use of a special direct reading bridge. The use of a simple slide-wire eliminates problems inherent in the use of a conductance box and effectively diminishes disturbing influences from the generator. However, the accuracy of this bridge is limited and reactance determinations under 1 kc are difficult even for biological materials with very high capacitance.

The bridge described in this article presents another solution to this problem. Its design is conventional and rather a simplification of the Jones and Joseph type bridge. However, amplification and tuned circuits have been used extensively to achieve as high a sensitivity as possible.

Description of Bridge

Figure 1 shows the wiring diagram of the bridge. The switches A and C permit throwing into each of the two grounded arms the unknown quantity X alone or in parallel to the resistance box 7 or the conductance box 6. The use of two resistance boxes would result in difficulties in adjusting to low resistance values accurately and for similar reasons two conductance boxes do not permit accurate tuning of high resistances. The use of a resistance box in one arm, together with that of a conductance box in the other arm has the advantage that it is possible to tune the resistive component of the bridge over the total range from 10 to 100,000 ohms with very high accuracy. This, together with the possibility of

connecting the various capacitance boxes 3, 4, and 5 at will, makes the arrangement flexible. It can be used either for direct measurements or substitution determinations. For highest accuracy the following substitution method is used: At first, the unknown, *X*, is switched in parallel with the conductance box 6, the latter being set at its lowest conductivity. Balance is achieved by varying the resistance box setting with additional slight variations of the conductance box of necessary and by varying the capacitance boxes 3, 4, and 5. Then the unknown is disconnected and conductance 6 and capacitance 3 are increased by an amount equal to the unknown quantity to re-establish balance. The advantage of this method is that all static capacitances cancel out. One must take into account, however, the change of the capacitance of the conductance box, because of its different dial setting and the reactive properties of the connections to the unknown (inductance, stray field).

The bridge does not utilize a Wagner arm arrangement, since this would only complicate the procedure of measuring. The use of good electrostatically shielded transformers between oscillator and bridge prevents any disturbing influences from the oscillators. The substitution method already described is another safety factor, since each possible oscillator effect appears equally in the measurement of the unknown and the substituted impedance; therefore they cancel out. The electrostatically shielded input transformer of the bridge is part of the equal ratio arm and reduced the oscillatory effects very successfully. Grounding either one of the balanced terminals of the generator did not affect at all the balance of the bridge.

The transformer is small in size. Low resistances under 100 ohms draw enough current to reduce the output voltage of the transformer considerably. This was considered to be a minor disadvantage considering that sufficient magnetic shielding is more difficult to achieve with a larger transformer.

A Hewlett-Packard oscillator, type *205AG*, supplies the energy up to 20,000 cycles per second, and a General Radio oscillator, type *700A*, the higher frequencies. The output of the bridge is fed into a General Radio transformer, type *941A*, and stepped up 1 to 4 before it is applied to the input terminals of a Ballantine voltmeter, model *300*. This voltmeter serves as a preamplifier. Its output voltage finally is measured by a General Radio wave analyzer, model *736-A*, for frequencies under 16 kc, and by a Radio Corporation of America *RAK-5* receiver for frequencies above 15 kc (by production of an audible beat signal by means of regeneration). The wave analyzer and the tuned radio-frequency receiver suppress harmonics and noise effectively. The *736-A* wave analyzer only has a bandwidth of 4 cycles per second. The *RAK-5* receiver, in addition to its high frequency circuits, utilizes a special audio-frequency filter which helps considerably in suppressing noise. The total gain of this arrangement is so high that noise occurs when full gain is used in spite of the presence of tuned circuits. The noise level corresponds to a voltage of about 0.03 microvolt, referred to the input of the preamplifier, and the smallest detectable bridge output voltage is about 0.01 microvolt. The maximum sensitivity of the bridge, referred to an input voltage of 1 volt, is therefore given by a ratio of better than 1 to 10^{-7}. All the various resistances, capacitors, and transformers are shielded, and the total bridge is itself built into a metal enclosure. The generators and receivers are also shielded and mounted on a relay rack. This, together with proper grounding by low inductive copper bands, reduces the direct influence from the generator to the receiver to an unnoticeable amount.

Figure 1. Bridge circuit

Sensitivity of Bridge

The absolute accuracy of a bridge depends upon the interaction of a number of factors. More or less constant errors result from the mechanical limits inherent in setting the dials; variable errors result from the variation in the accuracy of calibration of the electrical components at different dial settings. The balance sensitivity is limited, furthermore, by the function of the bridge components, by the amplifiers applied to the bridge output, by the applied generator voltage, and by the inherent noise level. Frequency precision is another factor requiring meticulous control in many instances. It is achieved at lower frequencies by comparison of the power-line frequency with an oscillograph and at higher frequencies by use of harmonics, as produced by a square-wave generator whose fundamental has been compared with the tenth harmonic of the power frequency.

The upper limit of bridge sensitivity depends on the mechanical limitation of dial settings, and is equal to the ratio of the smallest possible dial change to the total quantity to be measured. The resistance box has a total maximum resistance of 11,11.11 ohms with the smallest possible change being equal to 0.01 ohm. The conductance box incorporates a slide-wire which permits conductance changes of less than 0.01 micromho and has a maximum conductance of 111,111.11 micromhos. The common use of both boxes in different bridge arms permits the tuning of resist-

Figure 1. Bridge circuit

Sensitivity of Bridge

The absolute accuracy of a bridge depends upon the interaction of a number of factors. More or less constant errors result from the mechanical limits inherent in setting the dials; variable errors result from the variation in the accuracy of calibration of the electrical components at different dial settings. The balance sensitivity is limited, furthermore, by the function of the bridge components, by the amplifiers applied to the bridge output, by the applied generator voltage, and by the inherent noise level. Frequency precision is another factor requiring meticulous control in many instances. It is achieved at lower frequencies by comparison of the power-line frequency with an oscillograph and at higher frequencies by use of harmonics, as produced by a square-wave generator whose fundamental has been compared with the tenth harmonic of the power frequency.

The upper limit of bridge sensitivity depends on the mechanical limitation of dial settings, and is equal to the ratio of the smallest possible dial change to the total quantity to be measured. The resistance box has a total maximum resistance of 11,11.11 ohms with the smallest possible change being equal to 0.01 ohm. The conductance box incorporates a slide-wire which permits conductance changes of less than 0.01 micromho and has a maximum conductance of 111,111.11 micromhos. The common use of both boxes in different bridge arms permits the tuning of resist-

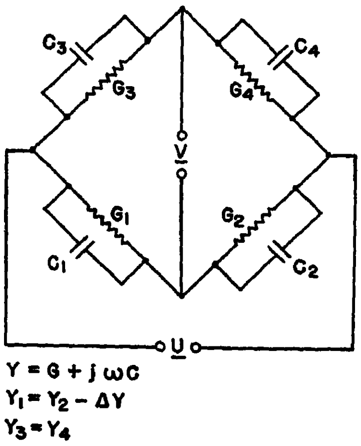

Figure 2. Definition of terminology

ances to exactly 10^{-6} ohm for high resistance values and better than 10^{-7} ohm for low values. The variable capacitors are calibrated within 0.1 micromicrofarad in their 25 to 110-micromicrofarad range and exactly within 0.1 micromicrofarad up to 1,100 micromicrofarads. They can be set with the same precision.

The absolute electrical accuracy of the resistance and conductance box is 0.1 per cent. It should be pointed out that the use of a bridge, which permits, let us say, a sensitivity of one part in a million does not mean that determinations with this accuracy can be carried out. It permits, however, detection of changes of this order of magnitude.

If an equal ratio arm bridge has admittances Y_3 and Y_4 equal (see Figure 2) and if further the output voltage V is measured with a voltmeter of high impedance as compared to the bridge impedances, then the following relationship holds

$$\frac{V}{U}=\frac{1}{4}\frac{\Delta Y/Y}{1-\frac{1}{2}(\Delta Y/Y)} \qquad (1)$$

or

$$\frac{V}{U}=\frac{1}{4}\frac{\Delta Y}{Y} \qquad (2)$$

when only small deviations ΔY from the correct bridge balance $\Delta Y=0$ are considered. Measuring the output with an amplifier, which registers only amplitude, but not phase, yields

$$V=\frac{U}{4}\sqrt{\frac{(\Delta G)^2+(\omega\Delta C)^2}{G^2+(\omega C)^2}} \qquad (3)$$

where

U and V are amplitudes of voltages V and U
ΔG and ΔC are conductance and capacitance deviations from point of balance as defined by $\Delta Y=\Delta G+j\omega C$, $Y=G+j\omega C$
ω is angular frequency

Two special cases require further consideration: One is where the capacitances C_1 and C_2 are equal, for example, when the capacitances are correctly balanced but the conductances are slightly out of balance. The second case assumes correct balance of the conductance values but slight unbalance of the capacitances. In the first case where $\Delta C=0$, the condition for perfect capacitive balance is

$$V_G=\frac{U}{4}\frac{\Delta G}{\sqrt{G^2+\omega^2C^2}} \qquad (4)$$

In the second case, where $G=0$, for example, the case of perfect conductive balance

$$V_C=\frac{U}{4}\frac{\omega\Delta C}{\sqrt{G^2+\omega^2C^2}} \qquad (5)$$

The comparison of both results shows that the smallest noticeable conductance change ΔG_0 is equal to the smallest noticeable admittance change $\omega\Delta C_0$. This can be expressed as follows

$$\frac{\Delta G_0/G}{\Delta C_0/C}=\frac{\omega C}{G} \qquad (6)$$

which means that the ratio of the smallest noticeable relative changes of capacitance and conductance equals the loss tangent of the material to be investigated. This value is very high at low frequencies for all substances which are good conductors. Consequently, the smallest noticeable conductance change is much smaller in all such cases than the smallest noticeable relative capacity change. This necessitates a very high sensitivity for the conductance, in order to be able to determine the susceptance with some reasonable degree of accuracy.

To characterize the high sensitivity of the bridge by high values, we define as conductive and capacitive sensitivity the following quantities for a bridge input voltage $U=1$ volt

$$\epsilon_G=\frac{G}{\Delta G_0};\ \epsilon_C=\frac{C}{\Delta C_0} \qquad (7)$$

where ΔG_0 and ΔC_0 are the smallest measurable conductance and capacitance changes. Introducing this into equations 4 and 5, it is possible to express the sensitivities in terms of the smallest detectable voltage V_0 as follows

$$\frac{1}{\epsilon_G}=4V_0\sqrt{1+\left(\frac{\omega C}{G}\right)^2};$$
$$\frac{1}{\epsilon_C}=4V_0\sqrt{1+\left(\frac{G}{\omega C}\right)^2} \qquad (8)$$

The conductive sensitivity obviously is independent of the frequency, as long as $(\omega C/G)<0.1$ and equal to $1/(4V_0)$. Under the same assumption, the capacitive sensitivity increases in proportion with ω to a maximum value of $1/(4V_0)$ at higher frequencies.

Determinations of the smallest voltage detectable by the amplifier section have been carried out over the frequency range of 20 to 200,000 cycles per second. It was found that this voltage is relatively independent of the frequency between 100 and 200,000 cycles per second and has a value of about 0.02 microvolt. Introducing these figures in equation 8 shows that these threshold voltage values permit the detection of resistance changes of the order of 10^{-7} ($U=1$ volt).

Calibration of Conductance Box

The most practical method of expressing the reactive behavior of a resistance

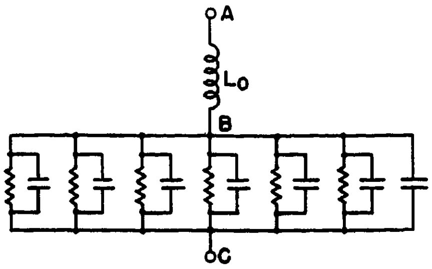

Figure 5 (right). Equivalent circuit of conductance box

box, which has all its variable decade resistors in series, is to transform the reactive properties of each resistor into an inductance in series with the resistor. Reactive properties of a conductance box, however, with all its decade units in parallel are conveniently expressed by capacitances in parallel with the conductance. If this is done, the total reactance is, in both cases, given by the sum of the inductances or capacitances of all the dials in series or in parallel respectively.

For capacitive measurements, where the reactive component is tuned by capacitors in parallel with the variable resistor units, it is more convenient to have the reactive properties of the variable box expressed in terms of capacitance. This is one of the reasons for choosing a conductance box as a substitute for the unknown. Another reason is the small influence of contact resistances on the tuning while varying the relatively high resistance dials which are used for the fine tuning. It is only necessary to calibrate the reactive properties of the conductance box when the conductance box is used as a substitute as described in the foregoing.

The conductance box which has been incorporated in the bridge has six variable resistance units in parallel, which permit variation of the conductance from 0 to 1. 0 to 10. 0 to 1,000. 0 to 10,000, and 0 to 100,000 micromhos. The first unit up to 1 micromho uses a continuous variable slide-wire. All the other units for the higher conductance values are decade units. The conductance box has an initial conductance of 100 micromhos when all its dials are set to their zero position. This initial value has to be added to the value given by the dial setting. The box permits, therefore, an absolute variation from 100 to 111,211 micromhos. Its usable range, however, is much greater with the aforementioned substitution method, where the initial 100-micromho value is also present across the unknown and cancels out.

The principle of the calibration of the reactive properties of the conductance box can be described as follows: Suppose the capacitance of the slide-wire dial for its highest setting, 1 micromho is known to be x with reference to its zero setting. The bridge may be balanced for this 1-microhmo setting. By setting this dial back to zero and setting the next dial (range 0 to 10 micromhos) to its first position of 1 micromho no disturbance occurs in the resistive part of the bridge balance. However, the capacitive balance has to be re-established, because the 1-micromho setting of the 1 to 10-micromho dial has a different capacity than the slide-wire. The change in capacitance, which is required for re-establishing balance as added to x, gives the capacitance value for the 1-micromho setting of the new dial. The total capacity of the conductance box, for a setting of 2 micromhos, as achieved by setting the slide-wire and the 1 to 10-micromho dial to their 1-micromho reading is then known. By exchange of this setting against the 2-micromho setting of the 1 to 10-micromho dial the 2-micromho setting can be calibrated in terms of x. Thus it will be possible to calibrate by successive steps the total 1 to 10-micromho dial. By application of these same procedures to the other dials, the calibration of the whole box in terms of x is achieved. All the various capacitance values thus obtained are differences between the total box capacity and the box capacity with all dials set to zero. However, only these differences are of interest in the substitution procedure. The determination of x requires one standard of known resistance and reactance which can be exchanged with the conductance box. This standard should have a relatively high conductance. If its value is low, the continuous repetition of the step-up procedure will apply an initially small error in the determination of x always in the same direction. This would lead to considerable errors in the capacitance values for the high conductance settings of the box.

Various distributed inductances effect the step-up procedure, in spite of their low values, and require a closer analysis. Figure 3 shows the total circuit of the conductance box. The slide-wire dial and the other five decade dials, x, y, z, u, and v are connected with wires and copper bands of low resistance and inductance. All resistors are assumed to be R-L series circuits. They are mutually connected to the bridge by the connection R_0-L_0. Distributed capacitances between the various connections are omitted since they cancel out in the substitution procedure. To better understand the effect of the various elements, the following basic circuits as illustrated in Figure 4 should be discussed. Figure 4(A) shows an inductance L in series with an $R-C$ parallel combination and its equivalent parallel combination with the same impedance. The inductance, L, in the case of the conductance box, is caused by the lead L_0 which connects the box with the bridge. The products ωCR are in this case so small that they can be neglected as compared to 1. Then the effect of L can be described by a frequency-independent negative capacity $-L/R^2$. For the same reason, the deviation between R and R'' can be neglected. Figure 4(B) is somewhat more complicated. It shows two inductive resistors in parallel and in series with an inductance L_0. The equation which describes how the total capacitance C of this system can be expressed is obtained under the assumption that the susceptance ωC is small compared to the resistive conductances, G.

The application of the aforementioned circuits permits analysis of the total circuit of the conductance box. The inductance values L_2 and L_3 appear only in line with the variable resistors R_1, R_x, and R_y and their inductance values L_1, L_x, and L_y. All these resistors are higher than 600 ohms and the inductance values L_2 and L_3, represented by relatively short connections smaller than 0.1 microhenry.

Table I. Box Capacitances for Dial u

Dial	Dial Setting	Box Capacitance	Conductance
$u-1$	10	$C_{(u-1),10}{}^{B}=a$	$G_{(u-1),10}\approx G_{u,1}$
u	1	$C_{u,1}{}^{B}=a+\Delta C_{u,1}{}^{B}$	$G_{u,1}$
u	1	$C_{u,1}{}^{B'}=2a+\Delta C_{u,1}{}^{B}-2L_0G_{u,1}G_{u,1}$	$G_{u,1}+G_{u,1}\approx G_{u,2}$
$u-1$	10		
u	2	$C_{u,2}{}^{B}=2a+\Delta C_{u,1}{}^{B}+\Delta C_{u,2}{}^{B}-2L_0G_{u,1}G_{u,1}$	$G_{u,2}$
u	2	$C_{,u2}{}^{B'}=3a+\Delta C_{u,1}{}^{B}+\Delta C_{u,2}{}^{B}-2L_0G_{u,1}(G_{u,1}+G_{u,2})$	$G_{u,2}+G_{u,1}\approx G_{,u3}$
$u-1$	10		
u	3	$C_{u,3}{}^{B}=3a+\Delta C_{u,1}{}^{B}+\Delta C_{u,2}{}^{B}+\Delta C_{u,2}{}^{B}$	$G_{u,3}$
⋮			⋮
u	n	$C_{u,n}{}^{B}=na+\sum_{\nu=1}^{\nu=n}\Delta C_{u,\nu}-2L_0G_{u,1}\sum_{\nu=1}^{\nu=n-1}G_{u,\nu}$	$G_{u,n}$
⋮			⋮
u	10	$C_{u,10}{}^{B}=10a+\sum_{\nu=1}^{\nu=10}\Delta C_{u,\nu}-2L_0G_{u,1}\sum_{\nu=1}^{\nu=9}G_{u,\nu}$	$G_{u,10}$

$a=x, y, z, u, v$ according to $u=2, 3, 4, 5, 6$

The capacitive effect of these inductances is smaller than 0.3 micromicrofarad and in the majority of cases even smaller than 0.1 micromicrofarad. It will be neglected, therefore. On the other hand, the inductance L_0 may be in series with resistors as small as 10 ohms and has been found to be 0.17 microhenry. It can cause a negative capacity of the order of 1,000 micromicrofarads and definitely must be considered.

All connections within the box are relatively short and their resistances are so small, compared with the resistance of the variable units, that they can be neglected. The same holds true for the resistance R_0 of the leads which connect the box with the bridge. However, R', R_x', and R_y' are resistors in series with the lead wires. The inductances L_1, L_x, and L_y can be lumped together with the inductance values of the variable units and may always be expressed as capacities in accordance with the equations as given in Figure 4. Thus, it has been shown that the total conductance box circuit can be replaced by the circuit which is shown in Figure 5.

The terminology used to express all quantities is as follows: More than one dial set different from zero is called total gross-box capacitance. Only one dial set different from its zero setting is called gross-box capacitance. These two quantities correspond to certain capacitances between points B and C, which are called total-gross-dial-capacitance and gross-dial-capacitance. All dials set at zero result in the residual box capacitance across AC and the corresponding residual dial capacitance across BC. When these residual values are subtracted from the first defined quantities, the differences are called box capacitances or total box capacitances respectively. The symbols which will be used for the different quantities are as follows:

Capacitance as appearing across dial resistors BC:	Symbol
Gross dial capacitance	$c_{u,\nu}$
Total gross dial capacitance	c
Dial capacitance	$C_{u,\nu}$
Total dial capacitance	C
Residual dial capacitance	C_0
Capacitance as measured across box terminals AC:	
Gross box capacitance	$c_{u,\nu}{}^{B}$
Total gross box capacitance	c^{B}
Box capacitance	$C_{u,\nu}{}^{B}$
Total box capacitance	C^{B}
Residual box capacitance	$C_0{}^{B}$
Conductance	$G_{u,\nu}$
Total conductance resulting from a specified setting of all six dials less the residual conductance	G
Residual conductance (sum of the residual) values of the different dials in zero position	G_0

Index u stands for the dial number ν for the dial setting

It has been mentioned that the dial capacitance C_u is defined as the difference $c_{u,\nu}-C_0$ and the total box capacitance C^B as $c^B-C_0{}^B$. The total gross box capacitance is given, therefore, as follows:

$$c^B=-L_0(G+G_0)^2+c \tag{9}$$

where

$$c=\Sigma c_{u,\nu}=C+C_0 \tag{10}$$

This equation is a direct consequence of the equations depicted in Figure 4(B), when it is assumed that the products ωRC can be neglected. The residual box capacitance is obtained when all dial settings are zero

$$C_0{}^B=-L_0G_0{}^2+C_0 \tag{11}$$

The difference between the total gross box capacitance, for any arbitrary dial setting, and the residual value $C_0{}^B$ gives the total box capacitance C^B. Applying the previously described substitution method

$$c^B-C_0{}^B=C^B=C-L_0G^2-2L_0GG_0 \tag{12}$$

By this equation the capacitance changes are determined when the conductivity is increased by an amount ΔG

$$C^{B'}-C^B=\Delta C-L_0\Delta G^2-2L_0\Delta G(G+G_0) \tag{13}$$

ΔC is the change in total dial capacitance due to the conductance change ΔG. The conductance ΔG alone, as applied to the box when its initial setting is zero, would cause a total box capacitance

$$\Delta C^B=\Delta C-L_0\Delta G^2-2L_0\Delta GG_0 \tag{14}$$

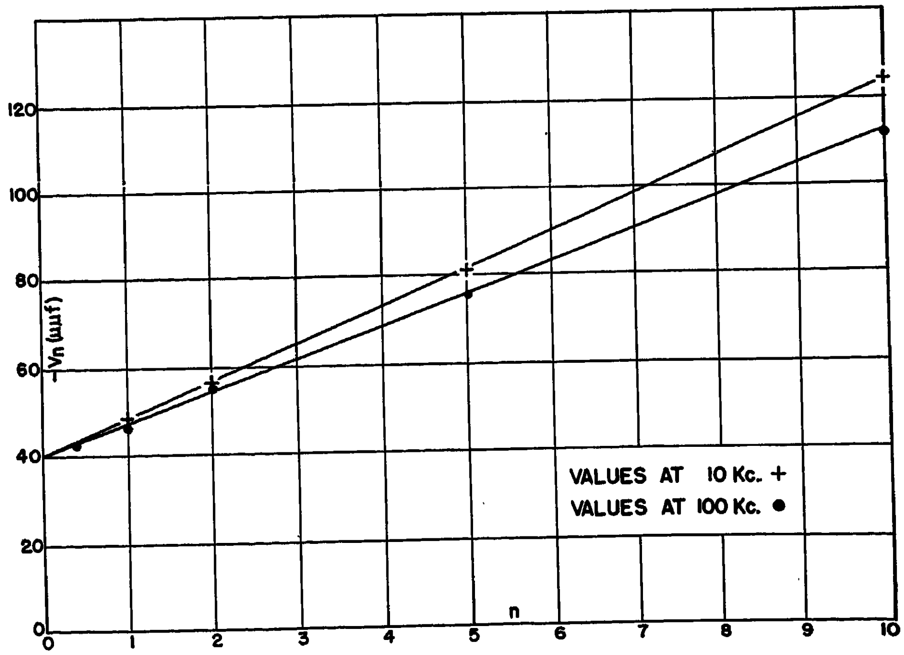

Figure 6. Capacitance V as function of conductance

Equation 13 can be rewritten

$$C^{B'}-C^{B}=\Delta C^{B}-2L_0\Delta GG \qquad (15)$$

The total box capacitance change due to a change of the conductance G is, therefore, identical with the total box capacitance due to a change of the dial setting from zero to ΔG when corrected for $-2L_0G\Delta G$, and is independent of the residual conductance value G_0.

These results will now be used to discuss the corrections which have to be applied to the step-up procedure. Only box capacitances, as measured between the terminals of the conductance box, can be observed while performing the calibration of the box. The box capacitances for the $\nu=10$ settings are used as build-up units in the step-up procedure. For abbreviation these values shall be called x, y, z, u, v with u being 2, 3, 4, 5, 6 respectively. Table I shows for one dial how the box capacitances can be related to the initial build-up value $a=C^{B}_{u-1,10}$. Its values are derived by successive use of the step-up principle and corrections in accordance with equation 15. The $\Delta C_{u,\nu}{}^{B}$ values are the observed changes of the box capacitance which are required for re-establishing bridge balance while exchanging the setting $G_{u-1,10}=G_{u,\nu}$ against the settings $G_{u,\nu+1}$.

If the effect of L_0 did not exist, the following relationship for the capacitance associated with the conductance setting $G_{u,\nu}$ would be valid for $\nu=n$

$$C_{u,n}{}^{B}=na+\sum_{\nu=1}^{n}\Delta C_{u,\nu}{}^{B} \qquad (16)$$

Including effects caused by L_0, we obtain, however

$$C_{u,n}{}^{B}=na+\sum_{\nu=1}^{n}\Delta C_{u,\nu}{}^{B}-2L_0G_{u,1}\sum_{\nu=1}^{n}G_{u,\nu} \qquad (17)$$

The simple-step-up procedure as expressed by equation 16, therefore, has to be corrected for $-2L_0G_{u,1}$. Equation 16 simplified, includes L_0 values different from zero when we replace the build-up value by a value a_n which is defined by

$$n(a_n-a)=-2L_0G_{u,1}\sum_{\nu=1}^{n-1}G_{u,\nu} \qquad (18)$$

and which is dependent on the dial setting as indicated by the indices n. If $G_{u,n}=nG_{u,1}$ we can replace $\sum_{\nu=1}^{n-1}G_{u,\nu}$ by $\frac{n}{2}(n-1)G_{u,1}$ and obtain

$$a_n=a-(n-1)L_0G_{u,1}{}^{2} \qquad (19)$$

This equation has been used for a determination of L_0 as described later on.

The dial capacitance A equivalent to the box capacitance a can be determined with equation 12

$$a=A-L_0G_{u,1}{}^{2}-2L_0G_{u,1}G_0 \qquad (20)$$

The equivalent dial capacitance $C_{u,n}$ to the box capacitance $C_{u,n}{}^{B}$ is

$$C_{u,n}{}^{B}=C_{u,n}-L_0G_{u,n}{}^{2}-2L_0G_{u,n}G_0 \qquad (21)$$

Introducing A and $C_{u,n}$ in equation 17

$$C_{u,n}=nA+\sum_{\nu=1}^{n}\Delta C_{u,\nu}{}^{B} \qquad (22)$$

This result shows that the simple step-up equation 16 remains correct when applied to the dial capacitance values regardless how big L_0 and G_0 are. The validity of equation 22 is evident when we return to a brief discussion of the circuit in Figure 5 (A). It is obvious that the simple step-up method is correct when applied to the dial capacitances as measured between points B and C. The differences ΔC which are required for rebalancing the bridge while exchanging $G_{u-1,10}+G_{u,\nu}$ against $G_{u,\nu+1}$ are here, of course, referred to the points B and C. However, the difference between box capacitance and dial capacitance is only dependent on L_0 and $G+G_0$ and independent of the dial combination by which the total conductivity is achieved. Therefore this difference cancels out when we determine the differences in C while exchanging the position $u+1,10+u,\nu$ against $u,\nu+1$. This makes it possible to replace the sum $\Sigma\Delta C_{u,\nu}$ by $\Sigma\Delta C_{u,\nu}{}^{B}$ and yields equation 22. The final result of the calculations, as presented in equation 22, is evident. The calculations, however, are still of value, since they provide methods for the determination of the fundamental constants A and L_0.

Several standards have been used for the calibration of the reactive behavior of the conductance box. Four standard resistors, type *663*, were purchased from General Radio Company. These are small wire-wound resistors with a special construction which minimizes magnetic fields and reduces their inductance to a very small value, determined by the manufacturer. Two additional standard resistors were built in our laboratory and consist of thin manganin wire, which is stretched in the center of a brass cylinder. The inductance of this arrangement has been determined by calculation. The distributed inductance values of various leads which connect the variable units and terminals with the bridge points A and C have been determined with the greatest possible accuracy. This was done by a determination of the capacity $C=-L/R^2$ which is necessary to rebalance the bridge when a resistor R is connected between ground and first one, then the other end of the inductive lead under investigation. The accuracy in the L determinations was found to be about ±0.0001 microhenry as proved by repeated L determinations with different resistors R. All standards had different resistance values. The General Radio resistors had 10, 20, 50 and 100 ohms and our standards 25.5 and 250 ohms.

The following procedure has been chosen for calibration. The standards were at first in parallel with the conductance box, the latter with all dials at zero. When the standard was removed, the conductance of the box increased to the value of the standard and the capacitance determined which was necessary to re-establish balance. From this capacitance the expression L/R^2 was subtracted, where L is the combined inductance of the standard and the leads which connect it to the conductance box terminal of the bridge. The difference is then due to the conductance box and its L_0 up to the point where the conductance box and the standard are linked together. The result has been expressed in terms of a_n by utilizing the equations for the simple step-up procedure and all values which had been determined before. Figure 6 shows the results of these determinations. It is obvious that $a_n=\nu_n$ changes linearly with the conductance which was present during the calibration. This is in agreement with equation 19 and makes it possible to determine L_0. Its value, as given by the slope of the curve, is equal to 0.084 microhenry at 10 kc and 0.071 microhenry at 100 kc. Subsequent use of equations 19 and 20 for the case $n=10$ made it possible to determine all quantities a:(x, y, z, u, and v) and corresponding dial values A:(X, Y, Z, U, V). After that equation 22 was used for determination of all other dial values $C_{u,\nu}$. There is no value in calculating all corresponding box capacitances, since the total box capacitance for any arbitrary dial setting is not equal to the sum of all the single box capacitances of the various dials. However, the sum of all the single dial capacitances is equal to the total dial capacitance. It is therefore more practical to add up all dial values and to apply the correction $-L_0G^2-2L_0GG_0$, equation 12, afterwards for each measurement performed with the bridge. It will be found that the correction, especially its first term, can be very often neglected in cases where either relatively high capacitances are observed or when the conduc-

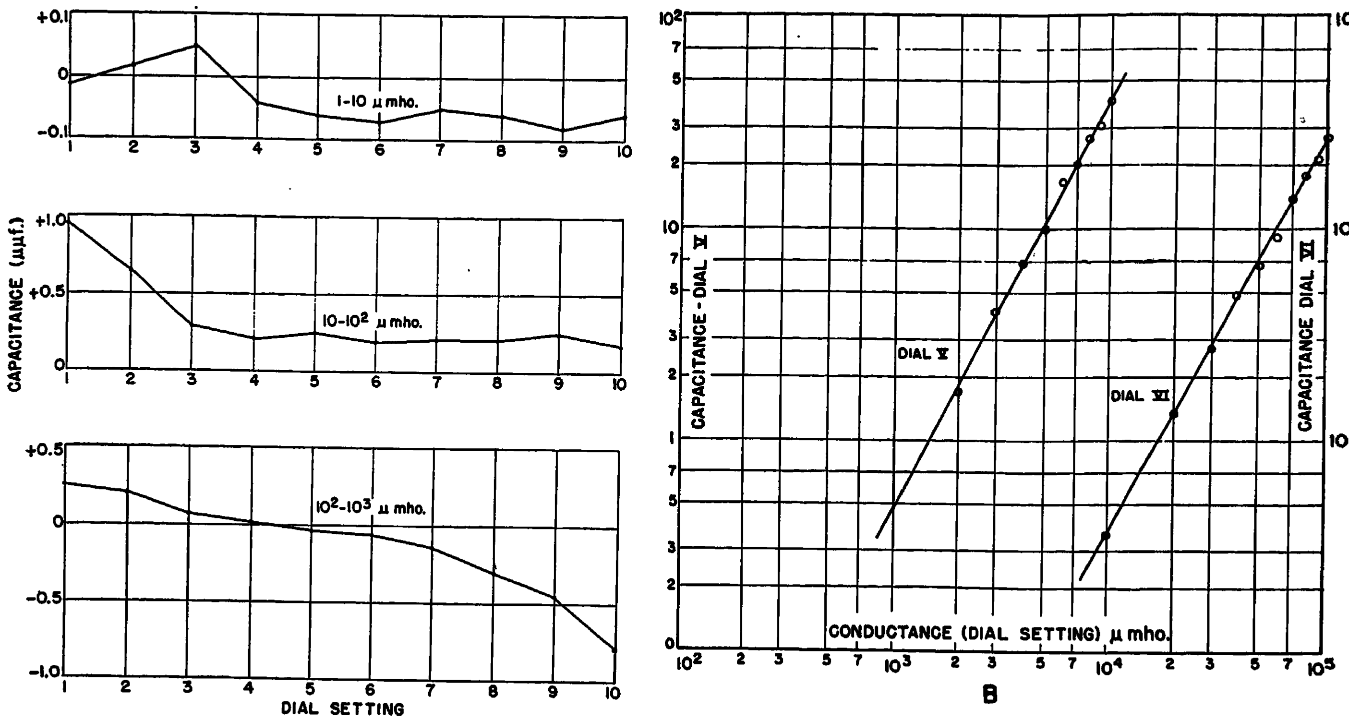

Figure 7. Calibration of conductance box

tivity of the sample is low.

Figure 7 shows the results of the calibration. Calibrations have been performed at 3, 10, 30, and 100 kc. The results agree within the accuracy of the measurements for all dials except the last one. In this case, the results as given in Table II are obtained. The fact that the capacitance changes with the square of the dial setting for the dials V and VI is explained when we assume that the low resistance coils of these dials do not add materially to the inductance of the various leads which connect these resistors separately with the box terminals. It is apparent further that this is no longer the case for the dials II, III, and IV.

If the inductance were completely concentrated in the resistor and proportional to R, equation $C=L/R^2$ would result in a capacitance proportional to the first power of the conductance. Curve IV represents a case where a nearly constant value, C, as given by dial III, changes at first to a linear behavior and then approaches a square behavior as a function of the conductance. This total C has superimposed on it fluctuations due to small irregular changes of both static capacity and conductance.

It was suspected that the change of the dial capacitances of dial VI was due to skin effect in the leads to the resistive elements. If this is true, all capacitance changes for the various dial settings, as observed between two of the various frequencies, must be explained by the same inductance change. Table III gives the change of L due to skin effect and as calculated by the equation $\Delta C=-\Delta L/R^2$. The ΔC values are the differences between the dial capacitances as determined at 3, 10, and 30 kc and the dial values at 100 kc. The ΔL values are indeed constant for each frequency within the accuracy of determination. Further proof was obtained by analytical study of the inductance of a copper bar of equal dimensions as those used as connecting leads inside the conductance box. This led to a predicted change of 0.005 microhenry between 10 and 100 kc which is considered in good agreement with the experimental result of 0.007 microhenry. The calculation further predicted that the frequency range of the L change due to skin effect should be about 0.003 microhenry between 3 kc and 100 kc, approximating the ultimate values at very low and high frequency within 1 per cent. Thus it was possible to say that the calibration of the box has been performed for the total frequency range of the bridge.

The conductance box calibration becomes more and more frequency-dependent when values ωL can no longer be neglected compared to the various resistors, R. Introducing R equal to 10 ohms, its L of about 0.3 microhenry yields a frequency of about 600 kc for a 1-per-cent deviation in C.

The only dial which could not be calibrated with the step-up method was the slide-wire dial I. However, its final capacitance for its highest setting of 1 micromho is known from the step-up calibration to be equal to +0.20 micromicrofarad. It was found experimentally that the capacitance change which is necessary to rebalance the bridge, when the dial setting is decreased from 1 to 0 micromhos, is identical with this value within 0.02 micromicrofarad. The change

in the resistance box setting, which is required for re-establishing bridge balance, does not affect the capacitance setting. (A study of the resistance box showed that its contribution to the total bridge reactance was small compared to that of the conductance box as long as its resistance remained high. It becomes stronger, however, than the conductance box effects for lower resistance values.) This fact made it possible to determine capacitances of the slide-wire dial over its range by slight variations of the resistance box and the slide-wire dial I at the same time. The result of this calibration shows that the slide-wire capacity increases continuously from 0 to 0.18 micromicrofarad.

High-Power Industrial Vacuum Tubes Having Thoriated-Tungsten Filaments

R. B. AYER
NONMEMBER AIEE

Synopsis: Contrary to a long-standing belief, thoriated-tungsten filaments can be used as electron emitters in high-power vacuum tubes with a reliability equal to that established by low-power types. High-power types may be defined as those having unmodulated class *C* plate voltage ratings of greater than 5,000 volts. The use of thoriated-tungsten filaments in high-power types has been made possible by the use of new and improved materials and processing techniques. In the radio broadcast field, performance of these high-power tubes has been excellent. In the industrial field, tubes having thoriated-tungsten filaments are continuing to set new records after as much as 22 months of uninterrupted full-load service at plate voltages as high as 17,000 volts. Such performance, in addition to the lower cost of equipment components and lower cost of operation due to reduced filament-power requirements, makes these tubes very attractive for industrial applications.

THE USE of thoriated tungsten instead of pure tungsten for vacuum-tube filaments is desirable for two main reasons. First, the theoretical emission efficiency of thoriated tungsten, which is approximately 100 milliamperes per watt of heating power, is 10 to 15 times that of pure tungsten. Second, the normal range of operating temperatures of thoriated-tungsten filaments is on the order of 1,950 to 2,000 degrees Kelvin, which is 500 to 600 degrees lower than that of pure-tungsten filaments. These features provide definite advantages in the design and application of high-power industrial tubes.

Basic Process

Thoriated-tungsten filament wire is made by adding a small percentage of thoria (thorium oxide) to pure tungsten during manufacture. The thoria content of wire in general use today ranges between 1 and 2 per cent by weight. The procedure required to achieve the high electron-emission capabilities of thoriated tungsten was described by Langmuir[1] in 1923 and has remained substantially unchanged ever since. The filament is flashed at approximately 2,800 degrees Kelvin for a short period (less than 1 minute) to reduce some of the thoria to thorium, and then is operated at a temperature of 2,200 degrees Kelvin or less for a longer period (10 to 15 minutes) to permit diffusion of sufficient thorium to form a monatomic layer on the surface of the wire. Subsequent operating temperatures must be suitably chosen so that a balance is maintained between the production of thorium atoms and their loss from the surface due to evaporation and to positive-ion bombardment.

Early Use

Thoriated-tungsten wire was developed originally for use in the lamp industry to prevent off-setting of filaments operating on alternating current. Its electron-emission history dates back to 1913, when it was observed that after suitable heat treatment the emission from thoriated tungsten was considerably higher than that from pure tungsten. Warner and Pike[2] described the use of thoriated-tungsten filaments in low-power transmitting tubes in 1925. Since then, many

Figure 2 (above). Thoriated-tungsten filament life curves

other low-power tube types using these filaments have been introduced for radio and industrial use, and a long history of reliable performance has been established. From 1925 to 1945, many attempts were made to use thoriated-tungsten filaments in high-power tubes (those having unmodulated class *C* plate voltage ratings of greater than 5,000 volts), but no success was reported until about 1945.[3] As a result, the general belief developed that these filaments could not be used in tubes operating above 5,000 volts because of rapid deactivation due mainly to high-speed ion bombardment. Statements throughout the literature and in recent books on vacuum tubes[4,5] indicate that this mistaken belief is still widely accepted.

During World War II, however, many radar types were made with thoriated-tungsten filaments. These tubes operated at plate voltages as high as 30 kilovolts and gave very creditable performance.[6–10] Applications in the X-ray field where tubes operated at 100 to 125 kv have also been described recently.[11,12]

Use in High-Power Tubes

Early in 1940, a critical review of the theory and design of thoriated-tungsten filaments was made. At that time, it was concluded that there was no fundamental reason why these filaments could not be used in high-power tubes, provided the mechanical strength and processing factors were given appropriate consideration. Exploratory test models were made of a 20-kw tube type, the *RCA-207*, in which the only deviations from the original structure were the substitution of thoriated tungsten in the filament and the addition of some batalum-type getters. Two of these experimental tubes operated at a plate voltage of 10 kv for 7,953 hours in a 10- to 18-megacycle telegraph transmitter before failure of one tube due to low emission. The grid currents of these tubes, however, were very sensitive to filament input because no precautions had been taken to prevent grid emission. Best performance was obtained with the heating power reduced to 45 per cent of the power required for a corresponding tungsten filament.

Because of the success of the 20-kw type, plans were made to build a 100-kw tube having thoriated-tungsten filaments. Proven mechanical structures were incorporated in this tube, and attention was given to experience gained with low-power thoriated-filament tubes and to the results of numerous filament-emission life tests made at various temperatures on 50-watt types having filaments 8.5 mils in diameter.

Filament Processing

It is customary to carburize a thoriated-tungsten filament to reduce the rate of thorium evaporation from the surface and the susceptibility to deactivation by ion bombardment,[13,14] and thus to achieve longer life. This carburization is accomplished during manufacture by heating the filament to a high temperature in an atmosphere containing a hydrocarbon gas or vapor, as described by Horsting.[15] The result of this process is the formation of a shell of tungsten carbide around the wire as shown in Figure 1. The percentage of the cross section of the wire converted to tungsten carbide is called the "per cent carbide." During life, the filament is gradually decarburized as a result of chemical and thermal processes. Experience has indicated that when substantially all of the carbide is lost, the monatomic layer of thorium can no longer be maintained and the emission decreases. However, the use of a high percentage of carbide, although desirable to assure long life, makes the filament very brittle. A compromise must be made, therefore, between wire size and per cent carbide. Recently, the author presented some curves for use in predicting the emission life of thoriated-tungsten filaments containing various percentages of carbide.[16] Data for these curves were obtained from the life tests referred to previously and from other experience. These curves are shown in Figure 2 in a somewhat more convenient form than in the original presentation. Surprisingly good results have been obtained with these filaments on a wide range of tube types and sizes in spite of differences in construction, processing, and operation. These results represent a useful addition to the available design information on this type of filament.[17–19]

Filament Design

Final designs of a 100-kw tube having a thoriated-tungsten filament showed a reduction in filament heating power of 60 to 70 per cent over pure-tungsten types having equivalent electrical ratings. An example of a water-cooled tube of the 100-kw size is shown in Figure 3. This tube, the *RCA-5770*, can deliver a power output of over 100 kw at frequencies as high as 20 megacycles when used in unmodulated class *C* service with a plate current of 8.5 amperes at 17 kv and a driving power of approximately 2,300 watts. The *RCA-5770* incorporates a self-supported filament structure which requires only 3.1 kw of heating power instead of the 8.1 kw required for its pure-tungsten equivalent. This filament structure, shown in the left portion of Figure 4, was chosen because of its simplicity and its reliable performance in tubes manufactured both here and abroad.[20] The filament consists of a multiplicity of wires connected in series parallel so that the heating current flows in opposite directions in adjacent wires. This arrangement effects the best balance of the magnetic forces and also permits the use of wire crossties to hold alternate filament wires in proper mechanical alignment. These crossties are visible in the assemblies shown in Figure 4. No insulators, springs, or sliding members are required.

Tube Design and Processing

Other design features and processing techniques have contributed to the successful performance of high-power tubes having thoriated-tungsten filaments. Grid emission, which was a problem in the initial 20-kw tubes, has been minimized by the use of platinum-clad molybdenum wire for the grid winding. Oxygen-free high-conductivity copper anodes, widely used in the vacuum-tube industry today, have aided materially in maintaining cleanliness and in minimizing the sources of contaminants. Anodes 1/4 inch thick are used to provide greater mechanical strength and better heat distribution. In addition, although similar tubes built without a getter are still in operation after 20,000 to 30,000 hours, a getter consisting of a small sheet of zirconium is incorporated in such tubes as the *RCA-5770*. The zirconium, heated mainly by radiation, assures a high degree of vacuum over a long period of time. The gettering properties of zirconium at elevated temperatures have been described by Raynor.[21]

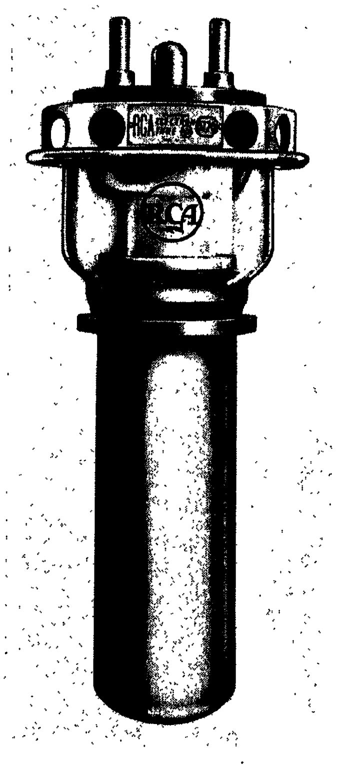

Figure 3. The RCA-5770

A grid support which totally encloses the internal filament-support structure is used in the *RCA-5770* to provide a very-low-inductance grid connection and excellent radio-frequency shielding. This grid support, shown in the center section of Figure 4 also provides good thermal shielding of the glass and minimizes bulb-bombardment effects, thereby reducing the operating temperature of the glass.

A prime requisite in the manufacture of vacuum tubes is cleanliness. In these high-power thoriated-filament tubes, cleanliness is assured by the complete removal of all greases and contaminants resulting from mechanical operations and by a thorough washing and rinsing after chemical or electrochemical cleaning. Oxidation is kept to a minimum during the welding of the final assemblies. The tube elements are outgassed by means of filament radiation and electron bombardment. Gas pressures are measured with an ionization gauge. Pressures are kept low during the initial stages, and processing is continued until a final pressure of 10^{-5} to 10^{-6} millimeter of mercury is reached with the tube hot. Final seal-off is accomplished by squeezing the metal exhaust tube between round, hardened-steel jaws until the tube is severed from the exhaust system.

Final tests made on the *RCA-5770* include measurement of residual gas, of electrical characteristics, and of peak emission. In addition, tubes are operated under dynamic conditions in excess of their ratings. Oscillator tests at 1.5 megacycles have been made at a plate input of 193 kw at 19 kv, which is approximately 24 per cent above its rating. Oscillator tests at 22 megacycles have been made with an input of 153 kw at 17 kv, which is about 25 per cent above the rating of the pure-tungsten-filament type at this frequency. The limiting factor in these oscillator tests was either available rectifier power or failure of circuit components.

Many of the design features and processing techniques used in the 100-kw tubes also were incorporated in tubes of the 50-kw size. A typical water-cooled 50-kw tube is shown in Figure 5. This tube, the *RCA-5771*, can deliver a power output of over 50 kw at frequencies as high as 25 megacycles when used in unmodulated class *C* service with a plate current of 4.5 amperes at 15 kv and a driving power of approximately 1,160 watts. The *RCA-5771* also uses a self-supported thoriated tungsten filament as shown in the right portion of Figure 4. Standard tests on this tube are similar to those made on the *RCA-5770*; special tests have been made at 1.5 megacycles with an input of 90 kw at 15 kv.

A radical departure from conventional high-power tube design was made in constructing a water-cooled super-power tube of the 500-kw size, the *RCA-5831*. This tube, shown in Figure 6, can deliver a power output of approximately 500 kw at frequencies up through the standard broadcast band when used in unmodulated class *C* service with a plate current of 39 amperes at 16 kv and a driving power of approximately 900 watts. The *RCA-5831* utilizes electron-optical principles, thereby improving the power gain by a factor of ten or more. The emitter consists of 48 thoriated-tungsten filaments of trapezoidal cross section held in accurate alignment within the beam-former slots by means of tension provided by a spring-loaded pantograph. Grid rods of similar cross section are held in position over the beam-former in a similar manner. The plate has external spiral slots and is jacketed to improve the cooling efficiency. Normal tests on this type include operation as an amplifier at a plate input of 1,250 kw at 20 kv; occasional tests

have been made at inputs as high as 1,800 kw.

Field Experience

The ability of high-power tubes having thoriated-tungsten filaments to stand up under continuous industrial service has been well demonstrated by field performance. Tubes of the 100-kw size operating at substantially maximum 17-kv ratings in 165-kc tin-reflow oscillators are still in operation after more than 16,000 hours (approximately 2 years) of trouble-free service. Two tubes which had been held as spares for a year and a half were put into service without any sacrifice in performance due to the long period of storage. A 13-megacycle installation operating at 14 kv and about half rated load has given over 22,000 hours (nearly 3 years) of very satisfactory service in a foam-rubber-drying application. In radio broadcast service, the *RCA-5671*, which is similar to the *RCA-5770* with a finned cooler attached, is still in service after 30,000 hours (about $4^1/_2$ years) with no evidence of deterioration. This record is equal in every respect to the performance of pure-tungsten-filament types.

Advantages in Applications

The high-emission capabilities and low-input requirements of thoriated-tungsten filaments result in several important advantages in the application of high-power tubes. Operating costs are reduced as a result of their lower input requirements, which are roughly one third that of equivalent pure-tungsten tubes. As an example, if service per year is assumed to be 7,500 hours (three 8-hour shifts, 6 days per week) and power is assumed to cost 1/2 cent per kilowatt-hour, the savings in the first year more than off-set the differential in the current list price of the pure-tungsten and the thoriated-tungsten 100-kw tube types. In addition, the lower heating-power requirements permit the use of less costly transformers, contactors, and wiring.

The lower operating temperature of the thoriated-tungsten filament results in appreciably lower temperatures of other tube parts. As a result, these parts have a smaller temperature excursion from room to operating conditions, and thermomechanical problems are reduced. The reduction in glass and seal temperatures also provides greater safety in high-frequency operation under present ratings, and enhances the possibility of extending the high-frequency ratings. In addition, lower glass and seal temperatures permit some simplification of cooling equipment and may in some cases permit elimination of forced-air envelope cooling.

Even with the reduced heating-power requirements, peak emission two to three times that of the pure-tungsten filament can be provided. The reduction in filament power also makes possible a corresponding increase in anode dissipation. In addition, plate characteristics are less compressed in the high positive grid-voltage region.

Conclusion

Experience to date indicates that the life of the thoriated-tungsten filament can easily be made to equal that of the pure-tungsten type. There are some indications that the life of the thoriated-tungsten type may be appreciably better, all other factors being equal. This possibility seems entirely reasonable if appropriate consideration is given to such factors as carbide loss, gas evolution from all tube parts and particularly from the glass envelope, bulb-bombardment effects, and thoria content of the wire. Although operating experience has been obtained only on tubes through the 100-kw size operating at plate voltages up to 17 kv, there appears to be no practical limitation on either the power or the operating plate-voltage level. The successful use of thoriated-tungsten filaments in high-power tubes thus makes possible a broadening of the range of power sizes available for industrial as well as other uses.

No Discussion

The Elements of Electrocardiographic Theory

ERNEST FRANK
ASSOCIATE MEMBER AIEE

Synopsis: A survey of some of the more important theoretical ideas of electrocardiography is presented for the consumption of the electrical engineer. The development, importance, and objectives of electrocardiography are discussed briefly, followed by a description of the electrical activity of the human heart and the potentials it produces at the surface of the body. Standard connections used in electrocardiography are described. A simplified theory is developed based upon a homogeneous, spherical conducting model containing a current dipole at its center, and the weakness of the assumptions on which it is based is pointed out. The concept and use of the heart vector is treated and methods of portraying heart-vector functions, similar to impedance functions, are illustrated. A limited description is given of the new field of vectorcardiography.

THE electrocardiograph is a sensitive recording voltmeter used to produce a record of the potential differences that arise between various parts of the body from the beating of the heart. This record, called the electrocardiogram, is frequently used in medical examination. However relatively few patients understand the nature of the electrocardiogram or appreciate its usefulness and limitations. Being intimately associated with human heart action the electrocardiogram naturally has great appeal to all, but because it is basically a record of electrical phenomena it should be particularly fascinating to electrical engineers.

"In spite of changing trends in medical education it remains true that the practitioner of medicine does not possess, nor can it be expected that he should possess, a background of training in mathematics adequate to enable him to follow the theoretical developments in electrocardiography."[1] It is hoped that this intriguing subject will arouse the interest of electrical engineers to further investigation of this field where there is need for contributions to the basic theory of the electrical phenomena associated with the human heart beat as well as for new ideas in instrumentation.

Some of the essential ideas related to the electrocardiogram are presented here, and a simplified (but often used) theory of electrocardiography is developed. The presentation is distilled from a wide variety of periodical literature and medical books and is translated into language familiar and digestible to the engineer. Certain liberties have been taken with traditional conventions and nomenclature used in this field in order to simplify the subject. Medical terminology is avoided as much as possible.

The seeds of the field of electrocardiography[2] were planted in 1791 by Luigi Galvani who observed a correlation between electrical excitation and muscular contraction in frogs. Some time passed before Kölliker and Müller discovered (1856) that a frog's heart produced an electric current accompanying each beat. Later in 1878 Sanderson and Page used the capillary electrometer[3] to record the electric currents generated by the exposed heart of a frog. Waller demonstrated in 1887 that the electrical effects of the heart beat could be measured without exposing the heart by using electrodes connected to the body. He was the first to obtain a human electrocardiogram, also using the capillary electrometer. The "father of electrocardiography," William Einthoven, perfected and used in 1903 a more sensitive instrument, the string galvanometer,[3] to record the electrical manifestations of human heart action. He also established[4] certain principles and theories of electrocardiography which are still in widespread use today.

Since the turn of the century it has been recognized that the electrocardiogram could be valuable in obtaining information about one of the most important human organs quickly, conveniently, and without need of gaining direct access to the heart. There has been tremendous activity in this field during the past 50 years. Hundreds of thousands of human electrical records have been taken and interpreted and thousands of articles have appeared in the literature. Improved equipment using vacuum-tube circuits and oscilloscopes has been introduced, and standard commercial recording equipment has been developed. A small army, mostly doctors but also some physicists and engineers, on all continents has contributed continuously to an understanding of the electrical aspects of

Ernest Frank is with the Moore School of Electrical Engineering, University of Pennsylvania, and the Edward B. Robinette Foundation Medical Clinic, Hospital of the University of Pennsylvania, Philadelphia, Pa.

The author acknowledges the many helpful suggestions and constant inspiration offered by Dr. Calvin F. Kay and Dr. S. Reid Warren, Jr., during the pursuit of studies in this field. This work was supported in part by grants of the National Heart Institute, United States Public Health Service.

human heart action and the way in which these electrical effects can be used in diagnosis and management of patients with heart disease.

Despite the wealth of knowledge acquired and the huge effort that has been expended, the electrocardiogram is far from completely understood. "It is only one of the objective approaches to an evaluation of the cardiac state and is just as subject to personal bias as any other part of the clinical diagnosis . . . . The interpretation of the electrocardiogram is as subjective as any other form of clinical interpretation, and its value depends . . . on the ability and experience of the electrocardiographer . . . "[5] As the frontiers of knowledge in this field are extended, perhaps this interpretation can become more objective and precise.

Electrical Activity of the Heart

The basic function of the heart is to pump blood through the circulatory system and lungs. The heart consists of two pumping compartments, as indicated schematically in Figure 1, the left side driving the circulatory system of the body and the right side passing blood to the lungs. Blood flowing from the auricles through valves into the ventricles is pumped out with a violent twist-pump action produced by muscular contraction of the ventricles which virtually wrings the blood out into the blood stream.

In the process of pumping, the heart reveals its operations in many ways, each of which has been exploited. One byproduct of heart action is acoustic noise, and the simple stethoscope is a well-known device used to listen to the sounds which accompany pumping action. Much more refined devices, phonocardiographs,[6] have been perfected for studying and recording the audible manifestations of heart action and a vast store of empirical knowledge exists to enable correlation of audio data with the heart function. Another technique, less well known, is used to produce the ballistocardiogram.[7] This is a record of vibrations of a delicately suspended table or chair which holds the patient, the vibrations being produced by mechanical forces and movements associated with heart action. Many other measurable effects are produced within the body each time the heart beats, but perhaps the most fascinating of all are electrical.

One of the important electrical characteristics of muscle, of which the heart is almost entirely composed, is polarizability. When heart muscle is in the resting state (not contracted) a potential difference exists between one side and the other of its cellular membranes. This potential difference, which is on the order of 100 millivolts, is explained in terms of modern membrane theory[8] by considering that each element of resting muscle (which is immersed in an electrolyte) is surrounded by a semipermeable membrane through which positive ions may pass freely but which is impervious to the passage of negative ions. A double layer of charges is formed at the membrane, as a result, and constitutes the polarized state which is the condition of heart muscle before it begins its pumping operation.

The heart beat is initiated in the sino-auricular (s-a) node, the pacemaker of the normal heart, indicated in Figure 1. The electrical disturbance periodically created there has been likened to the action of the relaxation oscillator or multivibrator running at a frequency of about 1 cycle per second. The electrical disturbance travels at an average speed of 1 meter per second through the walls of the auricles and causes depolarization of the polarized auricle membranes; that is, it temporarily disrupts the impermeability of the muscle membrane to negative ions whereupon they diffuse outward causing the double layer of charges and the accompanying potential difference to be nullified. In a sense the membrane acts like a battery that is suddenly short-circuited.

The electrical disturbance reaches a second excitation point, called the auriculo-ventricular (a-v) node, at the base of the ventricles where it is delayed by about 0.15 second. Then the impulse spreads rapidly down the wall between the ventricles and along the inner surface of the ventricles through specialized, highly-conducting heart-muscle fibers indicated schematically in Figure 1. This electrical impulse causes the polarized walls of the ventricles to depolarize, the process taking place in the form of a wave of depolarization that spreads outward through the ventricle walls as suggested in Figure 2. The moving double layer, which passes through the right ventricle wall first (which is thinner than the left wall), disappears in about 0.08 second and initiates the mechanical contraction of the ventricles which forces out the blood. The ventricular depolarization wave can be seen to be intimately associated with the pumping function of the heart and is, therefore, of considerable interest in electrocardiography.

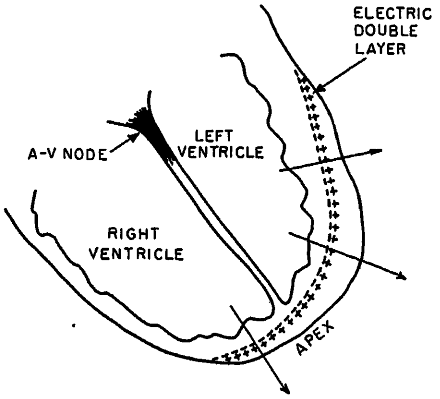

Figure 2. Schematic representation of the electric double layer which moves outward through the ventricle walls initiating muscular contraction of the ventricles

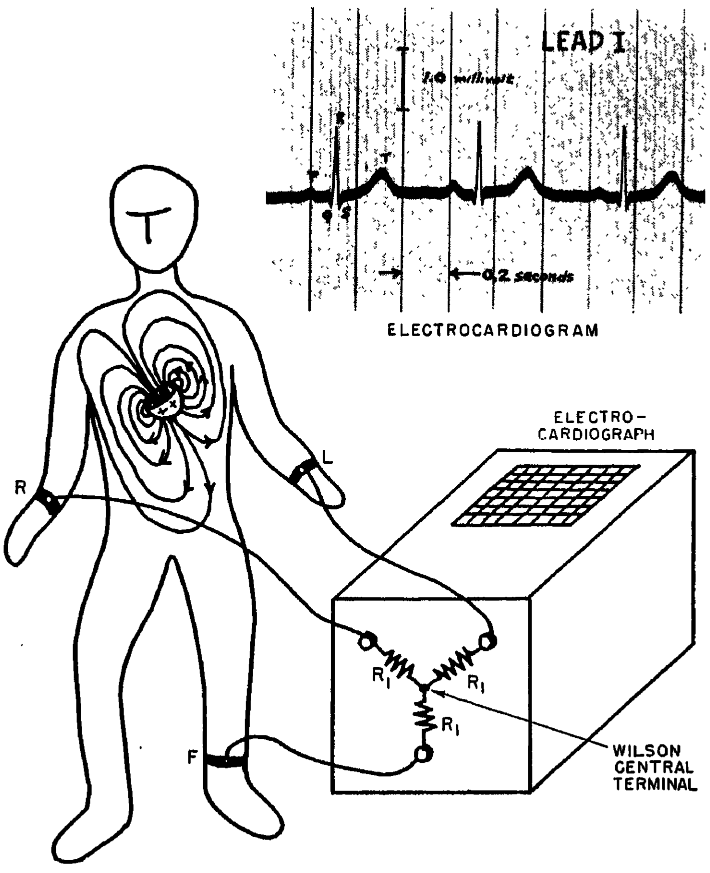
Viewed in gross fashion, the impulse originating in the s-a node can be thought of as quickly depolarizing the polarized resting heart and causing a violent contraction of this intricate blood pump. Another measurable electrical effect occurs approximately 0.37 second after the heart has become completely depolarized when its muscle membranes recover their semipermeable properties thus causing repolarization in preparation for the next impulse from the s-a node.

Potentials at the Body Surface

The sudden changes in potentials across the heart muscles produce electric currents within the body, which is a heterogeneous conductor with resistivity of the order of 10^2-10^3 ohm-centimeters.[9] These currents are distributed throughout the torso but do not penetrate the arms, legs, and neck to an appreciable extent. Body tissues, fluids, and muscle are relatively good conductors; the lungs, which contain air, have about four times the resistivity of tissue; and bones are relatively poor conductors.

A rough suggestion of the current field during the depolarization of the ventricles which are shown as a dome-shaped double layer is given in Figure 3. The strength and shape of the double layer change with time during depolarization and cause the current field to vary. The major frequencies of these currents are in the range 50 cycles per second or less, although some frequency components exist up to about 300 cycles per second.[10] At present, these higher frequency components have no known clinical significance. Although equipment commonly employs bandwidths of 50–100 cycles per second, it is hoped by some electrocardiographers that the use of wider band equipment will enable additional clinical information to be obtained from the electrocardiogram. This represents one of the frontiers of present-day research called high-fidelity



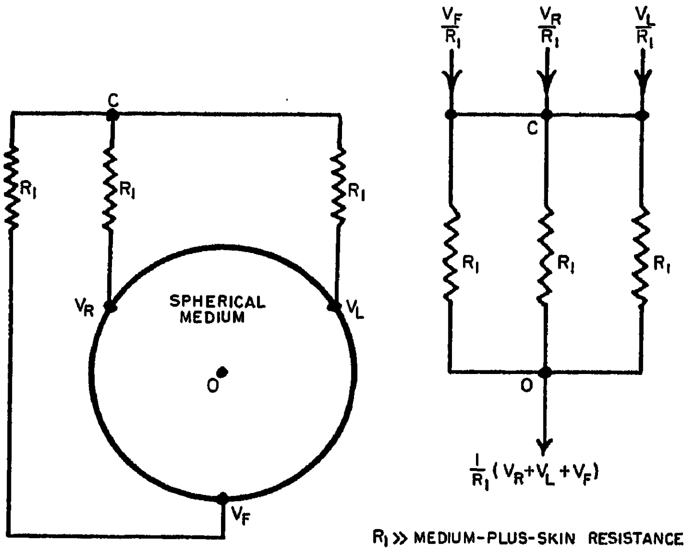


Figure 3 (left). Standard electrodes R, L, and F connected from a human subject to an electrocardiograph. A typical lead I recording during three heart beats is given in the upper right through the courtesy of Dr. C. F. Kay, Hospital of the University of Pennsylvania. The Wilson central-terminal connection is also shown

Figure 5 (above). Wilson central-terminal connection to simplified model along with the node equivalent circuit

electrocardiography.[11]

The currents in the body produce variable potential differences between any two points on the body, a record of which constitutes the electrocardiogram. The potential difference between two points on a given arm or leg is negligible in comparison with that between two points on the torso, as implied by the fact that little current penetrates the limbs. This is an important point in determining the placement of electrodes on the body as will be presently discussed. It can be seen that there are two major influences on the potential differences which appear at the surface of the skin. One is the distribution of current generated at the heart, which can be correlated with certain diseases of the heart; the other is the properties of the medium. The essential value of the electrocardiogram resides in the information contained concerning the generated currents. As a consequence the medium effects play the role of disturbances that distort the desired information.

The standard placement of electrodes (established by Einthoven) is indicated in Figure 3; *R*, *L*, and *F* signifying right arm, left arm, and foot (left leg) respectively. The limbs are chosen because they are essentially equipotential surfaces and therefore the placement of electrodes is not critical and can be reproduced readily in a given patient from time to time, as required. The electrodes usually consist of small german-silver plates strapped firmly to the limb after applying a conducting jelly to the skin which insures good electrical contact. Electrode positions other than on the limbs are also used; in particular, electrodes placed at various standard points on the chest[12] have been found to be of clinical value, but a discussion of these is considered to be beyond the scope of this introductory paper.

Limb-lead voltages are defined as potential differences between pairs of standard electrodes. If V_R, V_L, and V_F signify the potentials at *R*, *L*, and *F* respectively, the three limb-lead voltages are defined as

$$\begin{aligned} V_{\mathrm{I}} &= V_L - V_R \\ V_{\mathrm{II}} &= V_F - V_R \\ V_{\mathrm{III}} &= V_F - V_L \end{aligned} \tag{1}$$

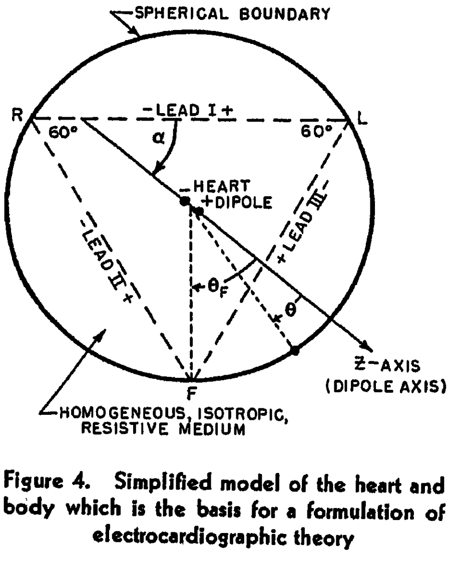

Figure 4. Simplified model of the heart and body which is the basis for a formulation of electrocardiographic theory

and are the potential differences recorded by the electrocardiograph. For brevity, these are commonly referred to as leads I, II, and III. Obviously, these three voltages are not independent being related by

$$V_{\mathrm{I}} + V_{\mathrm{III}} = V_{\mathrm{II}} \tag{2}$$

which is known in electrocardiography as Einthoven's law although it is nothing more than a statement of Kirchhoff's (1824–87) voltage law. The reason for defining leads I, II, and III with this seemingly curious polarity convention (which is not symmetrical as would be the case defining V_{II} as $V_R - V_F$) stems from the fact that normal deflections produced during ventricular depolarization are such that the dominant swing in voltage is positive with these definitions. This arises basically from the fact that the apex of the heart is directed downward and toward the left as indicated in Figure 3.

A typical electrocardiogram for lead I is shown in Figure 3 along with time and voltage scales. A record of only one lead at a time may be made, or multichannel equipment is available for simul-

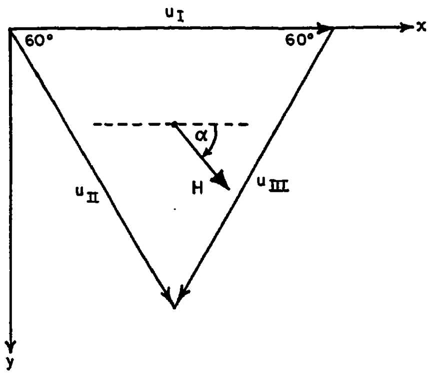

Figure 6. Three unit vectors, aligned with the sides of Einthoven's equilateral triangle, are shown with the manifest heart vector H. The projection of H onto a side of the triangle yields the voltage in that particular lead

taneous lead recording. The record is seen to consist of three separate disturbances called the *P*, *QRS*, and *T* waves, in that order. The *P*-wave results from depolarization of the auricles, the *QRS*-wave (or *QRS*-complex as it is more frequently called) arises from ventricular depolarization, and the *T*-wave is produced by repolarization of the heart muscle. Triple symbols are used for the ventricular wave, which is much larger in amplitude than the *P* or *T* waves, in order to describe the pulse in more detail; *Q* signifies the first downward deflection, *R* the positive peak, and *S* the final downward overshoot. In more complicated cases of multiple irregularities in pulse shape, subscripts are employed on *Q*, *R*, and *S* to distinguish among various upward and downward deflections. It is informative to note that the maximum lead voltage is about 1 millivolt which is only a small fraction of the potential difference across the double layer in the heart. This comes about because the current density diminishes markedly with distance from the heart; consequently, most of the potential drop occurs within the body.

An external connection called the Wilson central terminal[13] is commonly used. It consists of three equal resistors R_1 which are y-connected from *R*, *L*, and *F* to a common junction as shown in Figure 3 and has been the subject of wide controversy and much experimentation. It is claimed that the potential of this junction (with respect to the potential at infinity) does not vary appreciably with time; the theoretical foundation for this is based upon the idealized model to be described. Some experiments have been performed from which it has been deduced that the Wilson central-terminal potential variations are on the order of 20 per cent or less than the maximum lead voltage.[14] The prime advantage of a constant-potential reference junction is that voltage measurements from any point on the body with respect to the junction will reveal the potential variations at that particular point rather than be the result of a combination of two comparable-magnitude varying potentials as is the case using standard leads. Voltage measurements with respect to the central terminal are called "unipolar" as distinguished from the "bipolar" leads I, II, and III and have certain advantages in interpretation of the resulting wave forms in terms of heart activity. Of course the unipolar voltages are still potential differences despite this misleading terminology.

The clinical objective of electrocardiography, no matter what leads are employed, is to analyze the form of the electrocardiogram and to deduce from it the condition of the heart. The subject of interpretation is a tremendous one and a huge quantity of data has been assembled over the past 50 years in which certain quirks and unusual characteristics of the *P*, *QRS*, and *T* waves are associated with known heart disorders. These data are based largely on empirical information, such as post-mortem anatomical findings. Electrocardiographic theory has been very useful in providing a mathematical basis for analysis of the electrocardiogram itself, but has more limited value in interpretation which is still strongly dependent upon empiricism. It is the hope of theoretical workers in this field that continued refinements of the theory will progressively reduce the element of empiricism and supplant it by theoretical considerations which will give greater insight into the form of the electrocardiogram and thereby increase its usefulness.

Simplified Model of Heart and Body

The enormous complexity of the electrical activity of the heart, many details of which have been omitted here, is compounded by the extremely complicated structure of the medium which transmits the heart currents and these factors conspire to prevent an exact mathematical description of the potentials at the surface of the body. Yet it is tempting to perform an approximate analysis, even at the risk of oversimplification, in order to search for a better insight into the factors governing the form of the electrocardiogram.

In 1913 Einthoven[4] described what he called a "schema" that he had found useful in consolidating limb-head data into a single useful concept, the manifest heart vector, which will be defined later. This schema, now known as Einthoven's hypothesis, is in essence the model to be described and analyzed here, although Einthoven presented it in terms of a plane lamina rather than a sphere. It stands today as the cornerstone of electrocardiographic theory upon which has been built many secondary ideas used as an aid in electrocardiographic interpretation. Moreover, the essential assumptions underlying the schema are basic to the new field of spatial vectorcardiography[15] which is in rapidly growing infancy at present.

The simple model cannot be an accurate representation of the actual state of affairs which is understandable in view of the great complexity of the electrical system. The lack of quantitative data on the electrical characteristics of the heart and body has permitted a widespread controversy over a period of many years concerning the degree to which actual conditions depart from those of the simplified model. Today there is no general agreement concerning the value of this model; some being strong advocates of its validity, others discarding it as useless and claiming that it has stunted the growth of the field.

The following assumptions concerning the heart and body define the simplified model that is widely used today:

1. Boundary. It is assumed that the resistivity of air is much greater than that of the body and that the surface of the body can be represented by a sphere.
2. Limb Leads. It is assumed that the limb electrodes are located electrically on the sphere at the corners of an equilateral triangle lying in an equatorial plane of the sphere, this plane being called the frontal plane.
3. Medium. It is assumed that the body is a homogeneous, isotropic, resistive medium.
4. Heart. It is assumed that the heart can be represented by a current dipole of variable strength and orientation but fixed in position at the center of the spherical conducting medium.

These assumptions are represented in Figure 4. The dipole axis, a line joining the current sources, is shown to intersect lead I at an angle α, measured positive in the clockwise direction which is the convention established by Einthoven and firmly rooted today in all of the literature. Using standard spherical co-ordinates (taking the dipole axis to be the *z*-axis) the polar angle between the dipole axis and the radial line to *F* is $\theta_F = 90° - \alpha$. The dipole shown in Figure 4 is really the projection of the actual heart dipole onto the frontal plane and is more accurately termed the effective heart dipole. The actual heart dipole can be resolved into two dipoles at right angles to one another; the one in the frontal plane being shown in Figure 4 while the one perpendicular to the frontal plane is ignored since it does not contribute to the potentials at *R*, *L*, and *F* when the position of the dipole is at the sphere center. It follows that the *z*-axis of Figure 4 is the projection of the actual dipole axis onto the frontal plane.

The principal advantage of the assumptions is that they result in an extremely simple model that can be analyzed easily and which has some consequences of considerable mathematical nicety. However, it is at best a gross approximation to actual conditions. The philosophy underlying the use of such a model, despite its limitations, has been expressed by Dr. F. N. Wilson, a leading authority on electrocardiographic theory.

"... the vast majority of those who have been engaged in the study of the human electrocardiogram have had small acquaintance with, and little interest in, mathematical attacks upon physical problems of the sort encountered in attempts to apply the classical theory of electricity to the analysis of the varying electrical field associated with the heart beat. In theoretical investigations of this kind the actual situation under consideration is always far more complicated than any of those that can be treated mathematically, and it is necessary to make simplifying assumptions that are not strictly in accord with the facts. To assert that all deductions based on such assumptions are *ipso facto* worthless is, so to speak, to deny that mathematics has contributed anything worthwhile to the physical sciences. To maintain, on the other hand, that deductions of this kind represent anything more than a first approximation to the truth or have any great value except in so far as they are supported by experience and by experiments designed to test their validity would be equally unreasonable. It is imperative that those who make use of conclusions of this sort as a guide to further investigations, or who attempt to extend them, clearly understand and constantly bear in mind the postulates upon which they rest."[16]

Heeding the warning in the last sentence, it is fitting to look into some of the more glaring defects of the assumptions.

BOUNDARY

The most valid assumption of all is that the resistivity of air is much greater than that of the body, which averages about 500 ohm-centimeters. The assumption of a spherical shape is not as grossly wrong as might appear from purely geometrical considerations. Since the current generated by the heart penetrate only slightly into the shoulders, thighs, and neck there is small error in discarding the arms, legs, and head. Undoubtedly an ovoid or ellipsoidal boundary would improve the accuracy of the analysis, but a spherical boundary has the great advantage of simplicity.

LIMB LEADS

The triangle formed by the shoulders and left hip (which are the equivalent electrical locations of the limb electrodes) obviously varies considerably with the individual and is not exactly an equilateral triangle. However, the importance of these variations may not be too significant particularly in view of the experimental fact that in most patients the potential difference between the right and left legs is very small compared with that between leg and arm.

MEDIUM

As stated previously, the body is comprised of substances with widely differing resistance. Only limited quantitative data are available concerning the resistivity of various constituents of the body, and moreover, the effect of these inhomogeneities on the limb-lead voltages is open to debate. Indeed, a major controversy has been raging for years concerning the degree to which the medium influences the electrocardiogram. On one hand, it is maintained that there are certain highly favored paths for current conduction in the body which are in good contact with the heart, and consequently, that these favored parts of the heart have a dominant influence on the form of the electrocardiogram. On the other hand, many electrocardiographers contend that the body is a relatively homogeneous conductor and that all of the double-layer elements of the heart make contributions to the potentials at the surface of the body. Corresponding to these divergent views, there is a cleavage in thought on interpretation of the electrocardiogram with the former school of thought adhering to the idea that it be used almost entirely as an empirical tool and the latter groups placing emphasis on simplified homogeneous volume conductor theory of the kind to be presented here. Of course there are many who straddle both views and this seems to be a sensible choice until more knowledge is acquired.

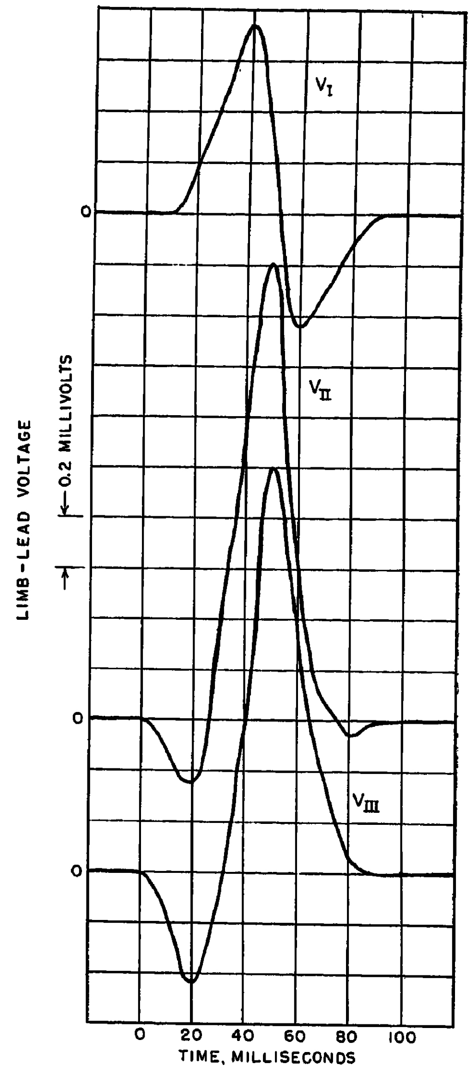

Figure 7. Typical limb-lead voltages during the QRS-complex (adapted from Einthoven)

The medium presents additional difficulties. There is evidence that muscle fibers display certain favored directions for current flow, which casts doubt on the isotropic assumption. In addition, polarization phenomena, distinctly different from heart-muscle polarization previously mentioned, is known to be important in physiological substances and may play some role in influencing the voltage distribution. There is much more to be learned about the electrical characteristics of the medium before any final answer to the medium assumption can be offered.

HEART

The double layer which produces the *QRS*-complex can be represented by an equivalent dipole if the distance from the double layer is very large compared with the dimensions of the double layer.[17] Since the chest diameter is only about three times the diameter of the ventricles the distance requirement is not completely fulfilled, but the error of the approximation has not been evaluated quantitatively. In addition, during some instants of depolarization more than one double layer can exist in the heart and this leads to even less accuracy in using a single dipole. Moreover, the dipole that is equivalent to the double layer, granting large distances to the point where the electrode is placed, is not really located at the center of the medium. Also, it is only in completely symmetrical cases that the component of the dipole perpendicular to the frontal plane does not contribute to the lead voltages. Finally, the position of the equivalent dipole does not remain stationary during the cardiac cycle.

Thus it can be seen that there are serious doubts concerning the validity of this model, and its behavior should be used as a guide rather than the ultimate answer. It should be clear that the theory about to be developed which is based upon these assumptions will, at best, only indicate certain trends and will be unable to explain phenomena that have been ruled out by the assumptions themselves. The analysis of more refined models, which relax some of the restrictions imposed here, represents one direction of study which would lead to an improved understanding of electrical heart action.

Standard Lead Voltages

The potential at the spherical boundary of Figure 4 can be determined for a fixed orientation of the effective current dipole and the results of such an analysis can be used for cases in which the effective dipole strength and orientation are functions of time since the medium is assumed to be resistive and the frequencies of the currents are very low. In order to determine the potential at the boundary of the sphere of radius R in the d-c case, it is necessary to solve Laplace's equation subject to the condition that the normal derivative of the potential is zero at the boundary (which is equivalent to the requirement that no current lines shall pierce the boundary). The potential at any point in the medium a distance $r<R$ from the dipole is[18]

$$V_r=\frac{p}{4\pi\gamma}\left(\frac{1}{r^2}+\frac{2r}{R^3}\right)\cos\theta \tag{3}$$

where p is the dipole moment, γ is the conductivity of the medium, and θ is the standard polar angle shown in Figure 4. The solution satisfies Laplace's equation as well as the boundary condition

$$\left.\frac{\partial V}{\partial r}\right|_{r=R}=0$$

and also reduces to a dipole field in an infinite medium if R is so large in comparison with r that the second term of the sum is negligible in comparison with the first term.

Since the electrocardiographer is concerned with potentials at the boundary, Equation 3 can be reduced to this case by imposing $r=R$.

$$V=\frac{3p\cos\theta}{4\pi\gamma R^2} \tag{4}$$

Expressions for the standard limb-lead voltages can be obtained by recognizing that F, R, and L are defined by the angles $\theta=\theta_F$, $\theta_F+120°$ and $\theta_F-120°$ respectively. Furthermore, with $\theta_F+\alpha=90°$ it follows from equation 4 that

$$\begin{aligned}
V_R&=\frac{3p}{4\pi\gamma R^2}\cos(\theta_F+120°)\\
&=\frac{3p}{4\pi\gamma R^2}\cos(210°-\alpha)\\
V_L&=\frac{3p}{4\pi\gamma R^2}\cos(\theta_F-120°)\\
&=\frac{3p}{4\pi\gamma R^2}\cos(-30°-\alpha)\\
V_F&=\frac{3p}{4\pi\gamma R^2}\cos\theta_F=\frac{3p}{4\pi\gamma R^2}\cos(90°-\alpha)
\end{aligned} \tag{5}$$

Using the definitions of the limb-lead voltages, equation 1, straightforward trigonometric manipulation of equation 5 leads to

$$\begin{aligned}
V_{\rm I}&=\frac{3\sqrt{3}p}{4\pi\gamma R^2}\cos\alpha\\
V_{\rm II}&=\frac{3\sqrt{3}p}{4\pi\gamma R^2}\cos(\alpha-60°)\\
V_{\rm III}&=\frac{3\sqrt{3}p}{4\pi\gamma R^2}\cos(\alpha-120°)
\end{aligned} \tag{6}$$

which are the desired limb-lead voltage equations.

The expressions in equations 5 and 6 have the same form as those which pertain to a balanced 3-phase y-connected power system with V_R, V_L, and V_F resembling phase voltages and $V_{\rm I}$, $V_{\rm II}$, and $V_{\rm III}$ resembling line voltages (note the $\sqrt{3}$ factor) except the reversed polarity convention used in electrocardiography for $V_{\rm II}$ destroys the symmetry. This similarity in form may be taken advantage of in deriving equation 6 directly from a phasor diagram of V_R, V_L, and V_F. Of course Einthoven's law, equation 2, is satisfied by the lead voltages in equation 6 for any values of p and α, which may be considered to be slowly varying functions of time.

It can be seen from equation 6 that variations in the limb-lead voltages are completely specified by two properties of the effective heart dipole, its moment p and its orientation in terms of the angle α.

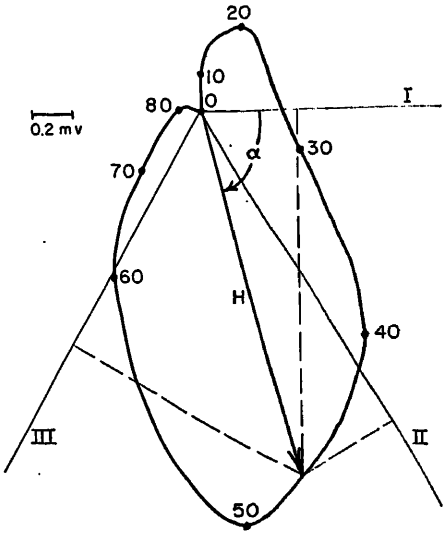

Figure 8. Monocardiogram constructed from the limb-lead voltages of Figure 7. The points on the locus of the tip of H indicate the time in milliseconds. The dashed lines indicate the projections of H onto the three limb-lead directions

The simplicity of the model has led to the conclusion that the variation in lead voltages depends only upon these two important properties of the dipole for fixed body geometry. It has been shown recently[19] that for a completely general shaped boundary and for an inhomogeneous medium that a similar type of conclusion can be drawn, provided the assumption of a fixed position dipole representation of the heart is retained. However, the component of the heart dipole that is perpendicular to the frontal plane does contribute to some extent to the limb voltages in the general case. Thus, the simplicity of the model, which has a high degree of symmetry, has led to an erroneous idea regarding details but nevertheless has led to the same type of conclusion reached in a less restricted analysis.

Wilson Central Terminal

The expressions for the limb-lead voltages can be used to show that the potential of the Wilson central terminal[13] is constant. The most expedient way to do this is in terms of node equations which in this special case can be regarded as an application of Millman's theorem.[20] The central terminal arrangement is shown in Figure 5 along with the node equivalent circuit in which it has been assumed that the y-resistors R_1 are very large in comparison with the internal resistance behind the electrode voltages. The point 0 signifies the centerpotential of the dipole which is arbitrarily assigned the reference value zero. The potential difference between the central terminal Ç and the center potential of the dipole can be written immediately from Figure 5 as the sum of the currents of the current generators times the total resistance between C and 0.

$$V_{C_0} = \frac{1}{R_1}(V_R + V_L + V_F)\frac{R_1}{3} = \frac{V_R + V_L + V_F}{3} = 0 \quad (7)$$

The sum $V_R + V_L + V_F$ is zero for any values of p and α as can be shown by straightforward trigonometry using the expressions in equation 5. This becomes obvious by again considering the phasor representations of V_R, V_L, and V_F since these voltages have equal amplitude factors and are symmetrically oriented at 120° apart. Thus, the theoretical basis has been shown for the claim that V_{C0} will not vary with time despite variations in the strength and orientation of the heart generator.

If the R_1 are not large enough, they will load the model. Originally, Wilson used values of $R_1 = 5{,}000$ ohms, but in current practice values of 25,000 to 50,000 ohms are used, the upper limit on R_1 being imposed by practical difficulties with stray pickup. The fact that the Wilson central-terminal voltage is not exactly constant in practice is not due to the loading effects of R_1 but rather to the defects in the assumptions which have led to the zero potential conclusion. Indeed, it can be shown on the basis of the simplified model but using a dipole that is not located at the center of the sphere that V_{C0} is not zero, even theoretically.[21]

Heart-Vector Theory

The great simplicity of equation 6 enables the limb-lead voltages to be represented geometrically, the phasor representation being one that has been mentioned already. A similar representation can be formulated in terms of vectors which enables each lead voltage to be considered as arising from a dot product of two vectors. This latter idea has been used widely in electrocardiography.

The phasor representation can be established in a manner similar to that used in a-c circuit theory, except the phasors are not considered to rotate at a fixed angular velocity since there is no assurance that α is a constant times the time. Defining $H = 3\sqrt{3}p/4\pi\gamma R^2$, which is a constant times the effective dipole moment p (for fixed radius and conductivity of the model), then the phasors representing the lead voltages can be written as

$$\begin{aligned} V_{\text{I}} &= H\epsilon^{j\alpha} = H\epsilon^{j\alpha}\epsilon^{j0} \\ V_{\text{II}} &= H\epsilon^{j(\alpha-60°)} = H\epsilon^{j\alpha}\epsilon^{j-60} \\ V_{\text{III}} &= H\epsilon^{j(\alpha-120°)} = H\epsilon^{j\alpha}\epsilon^{-j120°} \end{aligned} \quad (8)$$

where $j^2 = -1$. These complex numbers can be interpreted as the product of a heart dipole phasor $H\,\epsilon^{j\alpha}$ times phasors of unit magnitude directed along leads I, II, and III respectively. The lead voltages are the real parts of these complex numbers.

$$\begin{aligned} V_{\text{I}} &= Re(V_{\text{I}}) = H\cos\alpha \\ V_{\text{II}} &= Re(V_{\text{II}}) = H\cos(\alpha - 60°) \\ V_{\text{III}} &= Re(V_{\text{III}}) = H\cos(\alpha - 120°) \end{aligned} \quad (9)$$

and can be interpreted geometrically as the projection of the heart phasor onto the unit phasors directed along each lead.

The customary viewpoint taken in electrocardiography is based upon a vector representation. To establish this formally, define two unit vectors **i** in the positive direct of lead I and **j** perpendicular to **i** and directed downward toward F. These are the standard unit vectors of 2-dimensional rectangular co-ordinates. Expressions for three unit vectors of unit magnitude whose directions coincide with the sides of the equilateral triangle may be written in terms of the standard unit vectors

$$\begin{aligned} \mathbf{u}_{\text{I}} &= \mathbf{i} \\ \mathbf{u}_{\text{II}} &= \mathbf{i}\cos 60° + \mathbf{j}\sin 60° \\ \mathbf{u}_{\text{III}} &= \mathbf{i}\cos 120° + \mathbf{j}\sin 120° \end{aligned} \quad (10)$$

and are shown in Figure 6. The "manifest heart vector" is defined as

$$\mathbf{H} = \mathbf{i}H\cos\alpha + \mathbf{j}H\sin\alpha \quad (11)$$

which is a vector of magnitude H and directed along the dipole axis. The term manifest was introduced by Einthoven to signify that the magnitude of **H** differs from the magnitude of the actual heart dipole moment because of the short-circuiting effect of the medium as well as the fact that the actual heart dipole does not necessarily lie in the frontal plane. The word manifest stems from the idea that **H** represents the heart activity as manifested at the surface of the body in the frontal plane.

With these vectors defined, the lead voltages can be considered to arise from vector dot products of **H** with the unit vector associated with any given lead. For example

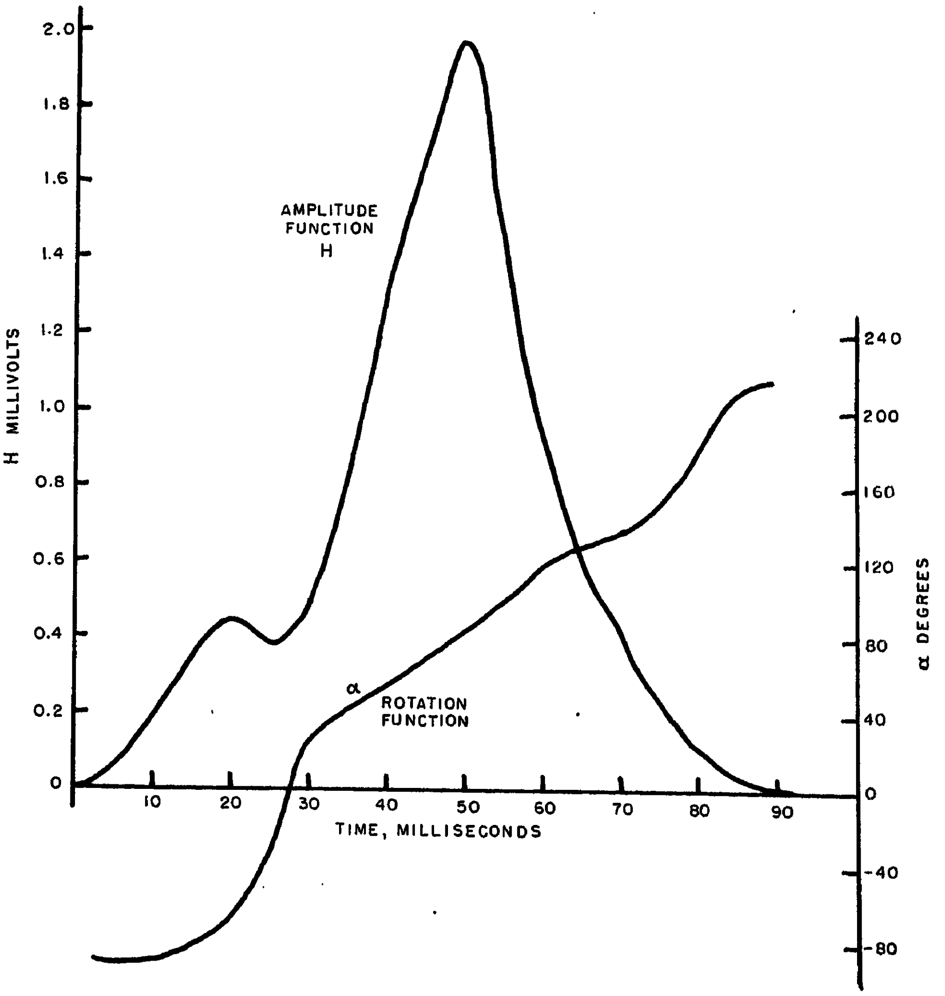

Figure 9. Magnitude and angle of H as a function of time corresponding to the limb-lead voltages of Figure 7 and the monocardiogram of Figure 8

Table I. Correspondence Between Impedance Functions and Heart-Vector Functions

	Impedance Functions	Heart-Vector Functions
Variable	angular frequency ω	time t
Function	complex impedance $\mathbf{Z}=Z\cos\theta+jZ\sin\theta$ $\mathbf{Z}=R+jX$	manifest heart vector $\mathbf{H}=\mathbf{i}H\cos\alpha+\mathbf{j}H\sin\alpha$ $\mathbf{H}=\mathbf{i}H_x+\mathbf{j}H_y$
Magnitude	$Z=(R^2+X^2)^{1/2}$	$H=(H_x^2+H_y^2)^{1/2}$
Angle	phase angle θ $\tan\theta=\frac{X}{R}$	Einthoven's angle α $\tan\alpha=\frac{H_y}{H_x}$
	variable-frequency locus in complex plane: 	variable time locus in xy-plane. Monocardiogram: 	magnitude of Z versus ω: 	magnitude of H versus t. Amplitude function:
	θ versus ω: 	α versus t. Rotation function: 
$$V_I=\mathbf{H}\cdot\mathbf{u}_I=H\cos\alpha \qquad (12)$$

Thus, this representation enables any lead voltage to be regarded as the projection of **H** onto a unit vector associated with the lead in question. It is a concept that enables very convenient and rapid visualization of **H** which is the quantity of interest. For instance, at any instant when the lead voltage is zero this signifies that **H** is perpendicular to that lead. Of course this geometric representation is quite far removed from the physics of the situation, which is basically 3-dimensional current fields and has the danger of distracting attention from the real phenomena that are taking place which may be undesirable in view of the questionable nature of the assumptions upon which this vector-projection representation is based.

Heart-Vector Functions

The application of heart-vector theory to an actual electrocardiogram will indicate the trend of the projected human heart vector and also permit a description of some additional ideas that are important in electrocardiography. For illustrative purposes, three limb-lead voltages adapted from Einthoven's classic paper[4] are presented in Figure 7 for the *QRS*-complex. The *P* and *T* waves have been omitted for simplicity. In the example of Figure 7 lead I is said to have no *Q*-wave since there is no initial downward deflection. Similarly, lead III has no *S*-wave since it has no final overshoot.

The two quantities of principal interest, H and α, are each functions of time. They are the fundamental functions of heart-vector theory and will be called the amplitude and rotation functions respectively. The amplitude function $H(t)$ and the rotation function $\alpha(t)$ cannot be discerned readily from the limb-lead voltages although the experienced electrocardiographer can visualize them from these records with unusual skill and rapidity. Any pair of these simultaneous lead voltages can, however, be used to construct the monocardiogram,[22] which is the locus of the tip of the manifest heart vector **H** that is swept out during the *QRS*-complex. The construction is such that at any instant of time the projection of **H** onto any one of the three unit vectors associated with each lead is equal to the instantaneous voltage in that lead. The monocardiogram corresponding to the lead voltages in Figure 7 is given in Figure 8 where various instants of time in milliseconds during *QRS* are indicated by the points marked on the locus. The manifest heart vector is seen to rotate in a clockwise direction, in this particular case, traversing a total angle of approximately 300 degrees and reaching a maximum value of 2 millivolts at t = 50 milliseconds.

Another way in which $H(t)$ and $\alpha(t)$ can be portrayed is given in Figure 9. This alternative way of plotting the data sometimes reveals properties of $H(t)$ and $\alpha(t)$ more readily than in the monocardiogram. In this example, notice how the notch in the amplitude function at t = 25 milliseconds, which is accompanied by a very rapid change in the rotation function, shows up more distinctly than in the monocardiogram of Figure 8.

The major virtue of heart-vector theory is shown by either of these forms of presenting the data. It enables the limb-lead data, which may be difficult to decipher, to be unified into two heart-vector functions which are consistent with the limb-lead data and which consolidate all of the lead information into a coherent whole.

The two methods of presenting heart-vector data are very similar to those used by electrical engineers to portray impedance functions, as might be expected from the close correspondence between the phasor and vector formulations that have been presented. The correspondence between impedance functions and heart-vector functions is given in Table I.

Many aids have been developed to enable the electrocardiographer to determine H and α conveniently from limb-lead data. Several different types of charts [22,23] are available which permit H and α to be read directly after entering the charts with known simultaneous values of the lead voltages. These charts are similar in nature to impedance charts which can be entered with resistance and reactance values to read off the magnitude and phase of the corresponding impedance. In addition, extensive tables[24] have been constructed for the range of values of V_I, V_{II}, and V_{III} encountered in practice which can be used to look up values of H and α corresponding to measured values of lead voltages. Also, a special slide rule[25] has been devised to speed the determination of H and α from the limb-lead data. Of course, it is essential to have simultaneous lead-voltage data in order to compute the instantaneous values of the heart vector.

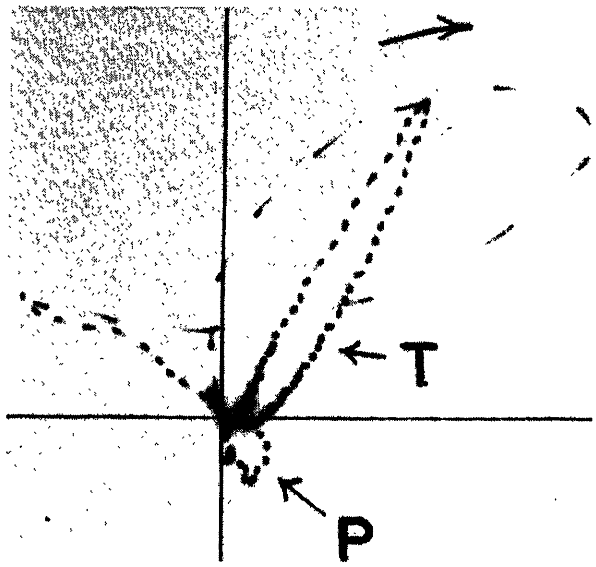

Figure 10. Frontal-plane vectorcardiogram described in the following statement by Dr. W. R. Milnor, Johns Hopkins Hospital, Baltimore, Md., who was kind enough to supply the record: "It was recorded from a 39 year old man who had suffered an acute myocardial infarction (dead region of ventricle wall)." "The P loop is the small loop at about 5 o'clock, and the T loop is long and narrow and points to about 1 o'clock. The rest of the record is QRS, showing a marked slowing in the terminal portion. The timing signals represent 4 millisecond intervals; i.e., 4 milliseconds elapsed from the beginning of one dash to the beginning of the next. The dashes are wedge-shaped and point in the direction of rotation. Two grid lines have been drawn in intersecting at the null point"

The lead voltages given in Figure 7 were obtained by Einthoven with relatively narrow-band equipment (approximately a 50-cycle-per-second bandwidth), and therefore are quite smooth. High frequency wiggles and more abrupt changes are obtained with broad-band equipment and, moreover, certain hearts have much more intricate *QRS*-complexes, sometimes giving rise to multiple-loop monocardiograms and corresponding notches in the rotation function. A more complicated monocardiogram, to be discussed later, is given in Figure 10 to illustrate this point.

In clinical application of heart-vector theory, many quantities associated with the amplitude and rotation functions are used in an effort to find a correlation with certain types of heart ailments. For instance, the value of α for which H is a maximum, the area enclosed by the monocardiogram, the total angle through which the vector sweeps, and other such special features are studied in a search for significant characteristics. The treatment of the data is sometimes more elaborate than is perhaps warranted by the questionable model on which heart-vector theory is based. The fact that $H(t)$ and $\alpha(t)$ can always be determined uniquely for a given pair of lead voltages should not delude one into thinking that they are necessarily significant. In truth, an artificial agreement is established by forcing **H** to yield the measured limb-lead voltages, via vector projection. The acid test of the clinical value of the manifest heart vector, so derived, resolves itself into determining the degree to which this vector agrees with the instantaneous distribution and strength of the depolarization wave in the heart muscle. Unfortunately, there is no easy means for applying this test and the correlation between the manifest heart vector and the electrical activity of the heart remains elusive.

Vectorcardiography

It has been shown that the amplitude and angle of the manifest heart vector are the quantities of focal interest to the electrocardiographer; yet these quantities are not directly observable in the electrocardiogram. A relatively new branch of this field, called vectorcardiography, is one in which H and α are obtained directly as a trace on the face of a cathode-ray tube. Hence, the lead voltages assume, appropriately, a secondary role; the manifest heart vector is observed and dealt with directly and the problem of deriving H and α by calculations based upon limb-lead data is circumvented.

When the monocardiogram is displayed directly on an oscilloscope, the record is called a vectorcardiogram or vector loop. Figure 10 shows an example of a vectorcardiogram. A time scale is provided by the blanked-out portions of the trace, obtained by applying accurately timed pulses to the intensity grid of the cathode-ray tube. The blanking pulses are shaped so that the direction of traverse of the loop is indicated by the way in which the illuminated segments trail off. *P*, *QRS*, and *T* loops are swept out each time the heart beats and the lead voltages are similar enough in shape from one beat to the next (see Figure 3) so that a stationary pattern is obtained.

Several methods can be employed in practice to produce the vectorcardiogram, the theory behind these methods being based on the model equations. One method is to apply one of the lead voltages to the horizontal amplifier of the oscilloscope and to apply to the vertical amplifier the voltage of the third electrode (unused in the horizontal signal) with respect to the Wilson central-terminal voltage. For example, V_I may be introduced into the horizontal amplifier and V_F to the vertical amplifier. The voltage amplification of the vertical amplifier must be adjusted to be $\sqrt{3}$ times that of the horizontal amplifier. To show that the oscilloscope trace obtained under these conditions is the same as the locus of the manifest heart vector, consider equation 12, $V_I = H \cos \alpha$, and equation 5 which becomes

$$VF = (H/\sqrt{3}) \cos (90^\circ - \alpha)$$
$$= (H/\sqrt{3}) \sin \alpha$$

when using $H = 3\sqrt{3}p/4\pi\gamma R_2$. Now, since V_I produces horizontal deflections (x-axis of Figure 6) with which the unit vector **i** has been associated, and $\sqrt{3}V_F$ produces vertical deflections (y-axis of Figure 6) with which the unit vector **j** has been associated, it follows that the instantaneous position of the oscilloscope trace can be expressed in terms of **i** and **j** as

$$\mathbf{i}V_I + \mathbf{j}\sqrt{3}V_F = \mathbf{i}H\cos\alpha + \mathbf{j}H\sin\alpha$$

which agrees with equation 11. Therefore, the oscilloscope trace will be the same as the monocardiogram derived by construction from the limb leads. In similar fashion, the same vector loop can be produced using V_{II} in combination with $\sqrt{3}V_L$ or by using V_{III} with $\sqrt{3}V_R$. It is also possible to produce the vectorcardiogram using any pair of leads without the Wilson central terminal.

The vectorcardiograms discussed here are more accurately called frontal-plane vectorcardiograms since they represent projections on the frontal plane. The locus of the tip of the heart vector is usually a complicated loop in space, not necessarily confined to any plane, and viewing only one projection of this loop limits the amount of information that is obtained. Recognition of this has led to the birth of a new field, called spatial vectorcardiography,[15] in which the frontal-plane vectorcardiogram is only one of three or more projections that are used. A fourth electrode is required to obtain the other projections, and a variety of electrode positions is used, not necessarily the limb electrodes in some cases. The over-all data can be presented as a loop in space, and a wire model of the locus has been found useful for describing the path taken by the tip of the manifest heart vector in three dimensions. Very elaborate equipment has been developed for spatial vectorcardiography research; one such device called a panoramic viewer[26] permits, at the twist of a pair of knobs, direct observation of the projection of the spatial loop on the face of a cathode-ray tube for any plane passing through the body. This is only one of several frontiers of research in this field.

Although there is still much that is not understood about the electrical manifestations of heart activity, the past half century has resulted in a great increase of knowledge and there is every indication that this advance will continue, particularly if electrical engineers can be called upon to help with problems that require more technical knowledge of physical science than is usually found in doctors with medical-school backgrounds.

No Discussion

The RCA 3-Gun Shadow-Mask Color Kinescope

H. B. LAW
NONMEMBER AIEE

IT HAS long been apparent that the ideal reproducer for color television should consist of a single kinescope capable of displaying the color picture directly. Considerable interest in the problem has resulted in quite a number of proposals for single-tube color kinescopes, and much time and effort has been expended in experimental work. No systematic review of the literature will be given nor will a description of the operating principles of the various kinds of proposed tubes be undertaken, for an article covering these subjects has recently been published.[1] Rather, it is the purpose of this paper to give an over-all description of the Radio Corporation of America (RCA) 3-gun shadow-mask color tube including its construction and operating characteristics.

Before proceeding to the tube itself it may be well to review briefly a few fundamental concepts. To accomplish the objective of producing on the viewing screen of the receiver a full color image of the scene being televised, it is necessary not only to portray the relative brightnesses that occur in different areas of the scene but also the hue and saturation of these areas. Some of us are familiar with brightness from our black-and-white experience but are less familiar with the other two concepts, hue and saturation. The hue or dominant wave length of an area tells us whether its color is red, yellow, green, and so forth. The saturation of the color indicates the amount of white light that would have to be mixed with a pure spectrum color of the same hue as the area to match the color of the area. A spectrum color is 100 per cent saturated whereas white light has zero saturation. The saturation attribute of color is generally described by such terms as pale, pastel, deep, and so forth.

Brightness, hue, and saturation are psychological sensations. It is easily

possible to distinguish a large number of combinations of these sensations so that the reproduction of the brightness, hue, and saturation of each element of the scene to be transmitted would be an impracticable task if there were no relation between the stimuli. However, it has been found that color stimuli may be specified in terms of three known stimuli. These three are called primary stimuli, and since the picture is produced by colored light coming directly to the eye from the phosphors, the different colors are produced by the addition of the primary stimuli or, as sometimes stated, by an additive system of color. The primary stimuli are not unique, but are usually taken as red, green, and blue light in order to accommodate a large range of color. The procedure in specifying a color is to give the relative amount of each primary stimulus required to match the color. This is known as the tristimulus system of colorimetry or color specification. It makes possible the specification of the hue and saturation of each element of the scene to be televised by specifying the relative intensity of the red, green, and blue primaries needed to reproduce the color of the element. The brightness is reproduced by adjusting the sum of the intensities of the three primaries.

The shadow-mask tricolor kinescope employs additive color reproduction. Now, it may be said that the basic requirements of any additive color reproducer are:

1. A set of suitable primary lights.
2. A method for adding these primaries.
3. A method for controlling the amount of each primary to be added.

In regard to the first requirement, a set of suitable primary lights, the primaries that are used in the shadow-mask tube have their origin in the excitation of three kinds of phosphor that are placed on a glass plate inside the tube envelope. These phosphors have been chosen as having the best combination of high efficiency and desirable chromaticity that is available at the present time. The gamut of colors that it is possible to produce with these primaries compares very favorably with that possible with the best processes of color reproduction and is much superior to most commercial processes.

Turning now to the method of adding primaries, the system of juxtaposition is used in the tricolor tube. Small phosphor dots of three kinds are placed close together on a glass plate and three electron guns are located in such a position that all phosphor dots capable of emitting one of the primaries may be excited by electrons from one gun independent of the excitation of the remaining two kinds of dots. It is possible in the tricolor tube to use juxtaposition and obtain the effect of superposition. The eye blends the colors even at a close viewing distance because of the smallness of the phosphor dots.

The third requirement, a means of controlling the amount of primary light to be added at each point in the reproduced picture, may well start back at the camera. In the case of the RCA color camera, presently used, light from the scene to be televised is separated into red, green, and blue components and each component focused on the photocathode of a different image orthicon camera tube. The picture is then stored in the form of charge patterns on the target structures of the three image-orthicons until taken off by scanning beams traversing the targets in usual television fashion. The signal obtained from one of the camera tubes then contains the information to be fed to the particular gun in the tricolor tube controlling the excitation of the proper set of phosphor dots. When the output of the three camera tubes is properly fed to the grids of the three guns in the tricolor tube, the excitation of the three primaries in the tricolor tube will be of the proper amount at each point in the picture to reproduce the scene being televised.

Description of 3-Gun Tricolor Tube

Figure 1 is a cross-sectional diagram of the 16-inch color tube showing the major parts and their relative positions. The external metal envelope is made in two parts with flanges so that when placed together the two parts may be joined by a weld. The face plate of clear glass is sealed in place before the weld is made as is also the glass neck.

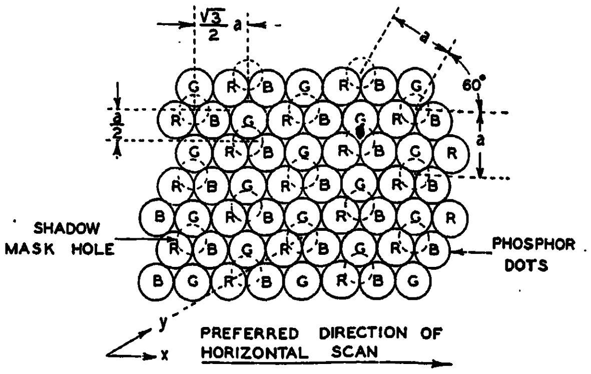

Figure 5 (right) Phosphor - dot array used in the shadow - mask color kinescope. The relation between the shadow-mask holes and the phosphor dots is shown for a region near the axis of the tube

Just inside the outer envelope there is fastened a high permeability metal cone to shield the electron beams from the earth's magnetic field as well as other stray magnetic fields.

Near the face plate is mounted the mask-phosphor screen assembly. It is for the purpose of inserting this assembly that the cone is constructed with flanges for a welded seal. The mask is on the gun side.

Mounted in the neck of the tube is the gun, Figure 2. There are three single parallel guns spaced equidistant from and at angles of 120 degrees about the assembly. The main lens for focusing the beam of each gun is between grids 3 and 4. The grid 4 cylinders of each of the guns open up into a single large cylinder, through which all beams travel. Grid 4 is called the converging electrode because, when the gun is in use, the lens action between the large cylinder and the conductive coating on the neck of the tube is used to converge the three beams on the aperture or shadow mask. Some focusing action on the three beams takes place, but the main function of the lens is to bring the beams together on the shadow mask.

Separate leads are brought out through a 14-pin base for the three cathodes and control grids. The three screen grids are also brought out separately to permit adjustment of individual drive characteristics. There is a common pin for the three first anodes, and the three heaters are connected in parallel to two base pins.

Figure 3 shows an exploded view of the viewing screen assembly for the 16-inch color tube. There are three major parts, the mask, spacer frame and phosphor dot plate.

The aperture mask is made of thin-sheet supernickel alloy, the area inside the border being covered with an array of regularly spaced holes. In the mask shown in Figure 3 these holes are 0.009 inch in diameter and spaced 0.023 inch apart for a total of about 195,000 holes in the picture area. There is an alignment hole and slot in the mask and a corresponding hole and slot in the spacer frame. The spacer frame provides the desired separation between mask and phosphor dot plate.

The glass plate which is to receive the phosphor screen is cut to match the outer contour of the frame and drilled near both ends of its horizontal center line to receive alignment pins that go through the alignment hole and slot in the spacer frame and mask.

Explanation of Tube Operation

As the name implies, the metal mask in front of the phosphor screen serves to mask or prevent the electron beams from reaching the phosphor screen except when the beams are going through the small holes in the mask. The successful operation of the masking principle for reproducing television pictures in color depends on being able to cause the individual electron scanning beams to strike one kind of phosphor only when they reach the phosphor screen. Solving the problem was made simpler because a scanning beam may, to a sufficiently good approximation, be considered as originating from a point and as traveling in straight lines from that point to the phosphor screen. This point may be called the center of deflection of the beam, and if more than one beam goes through the deflection yoke, the centers of deflection define a plane that is normal to the axis of the deflection yoke and lies somewhere near the center of the yoke.

If three beams in going through the yoke pass through the apexes of an equilateral triangle in the deflection plane and converge to a point on a mask placed in front of a phosphor screen, then an arrangement of holes in the mask may be found that permits each beam to strike separate areas on a phosphor screen beyond the mask such that the areas nest together perfectly. The geometry involved is shown in Figure 4, where the axis of the three beams passing through deflection centers are shown going through one hole of the mask and falling on phosphor dots in the plane of the phosphor screen. The holes in the mask are placed at the apexes of equilateral triangles that are oriented in such a way with respect to the deflection plane triangle that the phosphor dots, when in the appropriate places, all nest together perfectly. The relation between the mask holes and the phosphor dots is more clearly shown in Figure 5. The orientation of the beams in the deflection plane is not shown but may be visualized by imagining how the beams would have to go through the mask holes to hit the phosphor dots.

So far a geometrical arrangement has been indicated that makes possible the use of three beams and a shadow mask for separately exciting three types of phosphors. Assume for the moment that a shadow-mask phosphor-screen assembly has been built that fulfills the geometrical conditions just described. It will now be clear that there are three points in space associated with the assembly through which three electron beams must pass, that is, one beam through each point, in order that each beam shall fall at precisely the right place on the phosphor screen. These three points associated with the viewing-screen assembly have been called the color centers of the assembly. A color center is simply a point in space from which can be seen only one set of phosphor dots, that is, dots capable of emitting all the same color, while the other two sets of dots are masked.

For correct operation of the assembly after it has been incorporated into a tube there are then three requirements. First, the yoke should be located so that the plane of deflection coincides with the plane of the color centers. Second, the three electron beams should pass through the three color centers; and third, the three electron beams should pass through the color centers in the plane of deflec-

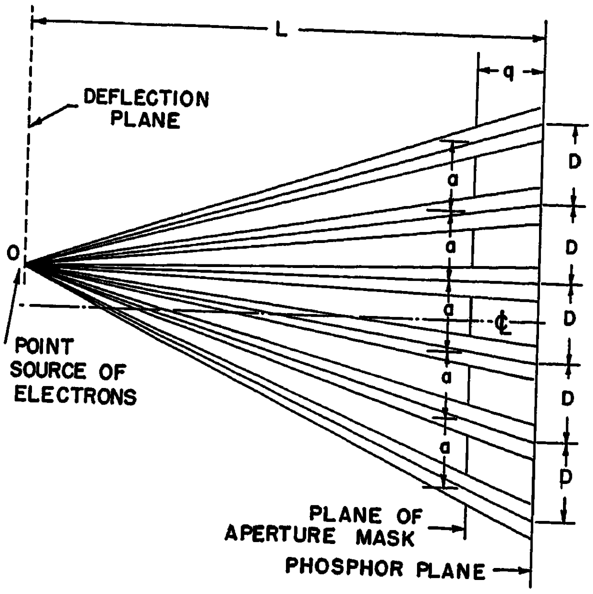

Figure 6 (left). A plane through an axis normal to the plane of the phosphor array and passing through a color center O in the shadow - mask color kinescope

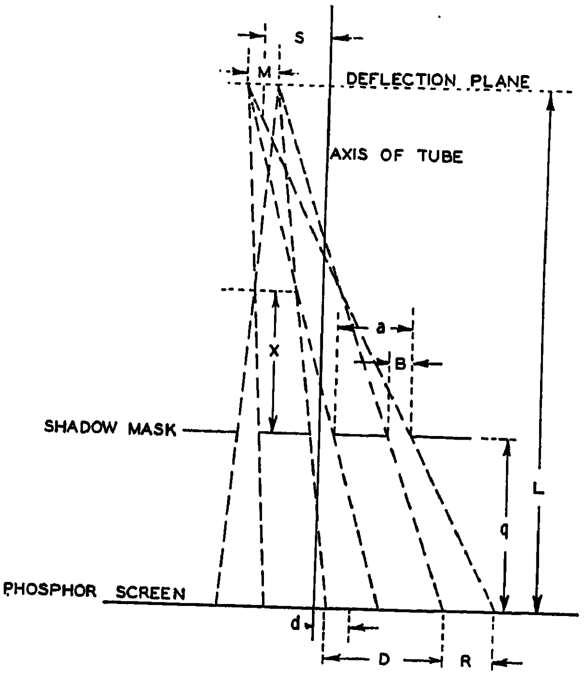

Figure 8 (right). A plane perpendicular to the shadow mask and passing through a row of holes in the y direction as defined in Figure 5. The geometry for a source of diameter M is shown

tion with the correct angles so that they are converged on the aperture mask.

First, the color-center plane and the deflection plane may be made to coincide by sliding the deflection yoke forward or back while looking at a single color field to determine the correct position for the yoke. If the second requirement is not fulfilled, which means that the beams do not go through the color centers because the gun mount is displaced from its correct position, then it is possible, by means of a small transverse magnetic field on the neck of the tube, to bend the beams until they do go through the color centers. The magnetic field is supplied by coils on either side of the neck of the tube and the coils may be rotated about the axis of the tube to obtain the proper direction of the field. This component is called a color-purifying coil.

The third requirement was that the beams should go through the color centers at the correct angle to converge at the mask. The three guns are mounted parallel to conserve space and facilitate accurate construction and alignment. The convergence lens bends each beam inwardly, but if slight misalignment of the guns makes it necessary, correct convergence may be obtained by adjusting the position of small magnets placed outside of the tube and adjacent to the guns so that nearly independent control over the three beams may be used to bring the beams together at the mask.

The geometrical properties of the viewing screen assembly are of sufficient importance to be considered a little further. The holes in the mask are placed at the apexes of equilateral triangles. There are, then, three directions in the pattern of holes in which well-defined rows of holes appear with the holes spaced apart a distance equal to the side of the equilateral triangle. Figure 6 shows a section through a color center and one of these rows of holes in the mask. The color center, *O*, is on the left and an edge view of the mask and phosphor screen is on the right. As indicated, the distance between the centers of the mask holes is a constant and here denoted by *a*. Also, the mask is parallel to the phosphor screen and is located at a distance *q* from the screen. If we consider the triangles made by drawing lines from the color center through the centers of all the mask holes to the phosphor screen, then it is evident that a number of triangles are formed all of which have the same altitude *L*. Consider now the upper triangle. By simple geometry, *D* over *a* is equal to *L* over *L*−*q*. The same proportion holds for each of the triangles and since *a*, *L*, and *q* remain constant, all the *D*'s must be equal. The *D*'s represent the center-to-center spacing of the correct phosphor dot positions, which means that the phosphor dot pattern consists of dots uniformly spaced from one side of the screen to the other. In fact, the phosphor dot pattern is the same as the mask pattern but enlarged by the factor *L* over *L*−*q*.

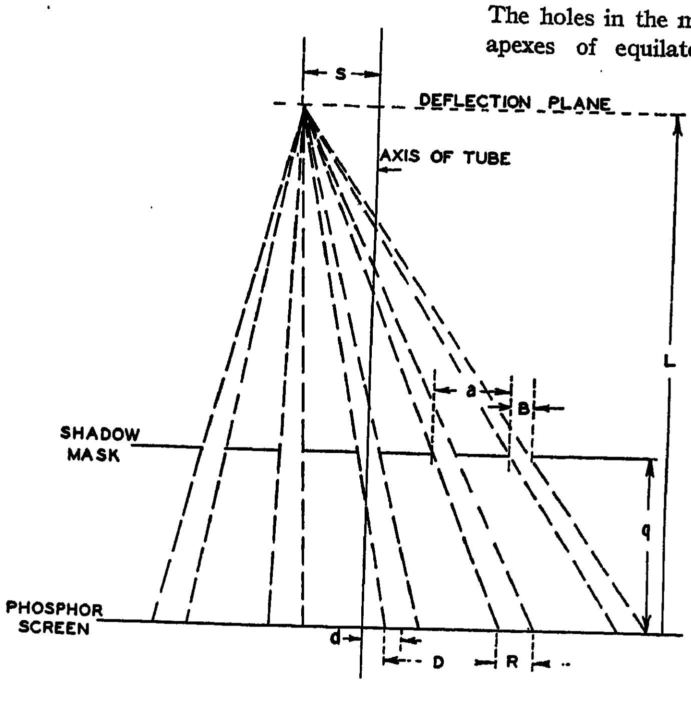

Figure 7. A plane perpendicular to the shadow mask and passing through a row of holes in the y direction as defined in Figure 5. The geometry for a point source is shown

The practical significance of the fact that the phosphor positions are equally spaced for one of the colors is that if a stencil can be made for depositing the phosphor of one color, then the appropriate shift of the stencil will enable the phosphors of the second and third colors to be located because the three phosphor

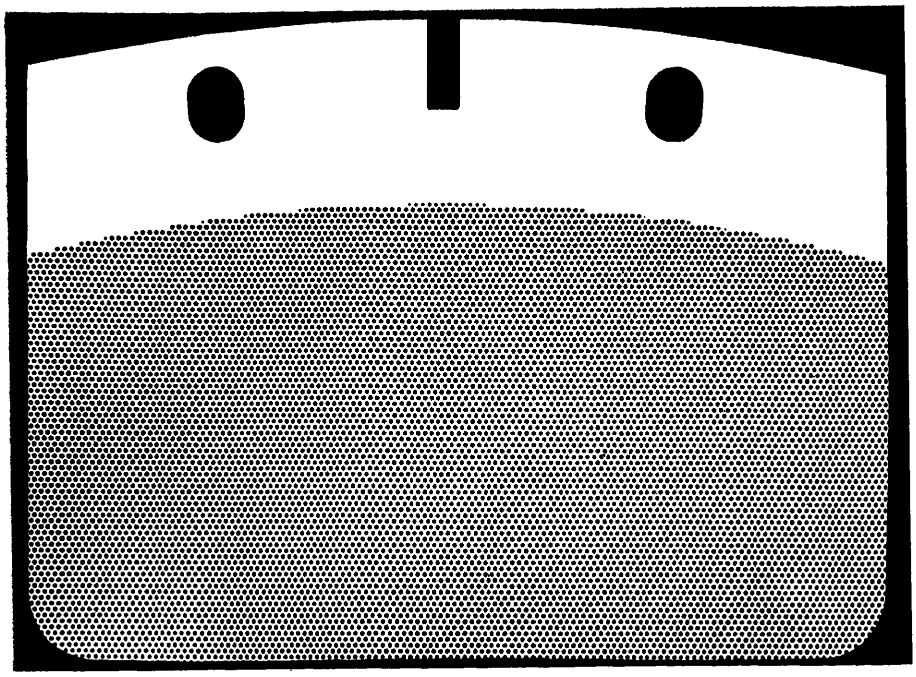

Figure 9. A magnified view of a portion of the aperture mask

patterns are identical and nest perfectly together.

So far, in discussing the geometry of the tube, each electron beam has been considered as originating from a point source at its center of deflection, as shown in Figure 7. This implies that the holes in the mask may be nearly equal in size to the phosphor dots. Since the electron beam at the center of deflection may have an appreciable diameter, the mask holes will have to be reduced from the size they could be in the point source case in order to obtain proper shadowing action at the phosphor screen. To study the effect, a simple approximation is to assume that electrons originate and travel in straight lines from a disk that represents the cross section of the beam at the center of deflection, Figure 8. Assume that peripheral rays define the electron beam as it goes through the shadow mask to the phosphor screen. In Figure 8 only one of the electron beams is shown together with one row of mask holes and the phosphor dots associated with that row. R is the phosphor dot diameter when the 3-color array consists of tangent dots, D is the distance between dots of the same color, a is the distance between aperture holes of diameter B. M is the diameter of the disk that is assumed to be the source of electrons, and the disk is located a distance S from the tube axis. Now the problem is to find the consequence of changing the beam width in the deflection plane from a point to some diameter M. Without going into geometrical proof it can be seen that if M goes to zero the mask hole diameter becomes a maximum. As M goes from a point to some value M, the peripheral rays require a smaller mask hole, and if the geometry were considered carefully it would be found that as the value of M got large enough so that this disk, together with disks for the other two beams not shown, became tangent, then the mask holes for proper shadowing would be zero. Zero mask hole diameter means zero electron current to the phosphor screen, while $M=0$ means zero current in the beam. There must, therefore, be an optimum value of M and B that will allow maximum beam current to get to the phosphor screen. The optimum values will, of course, depend on the current distribution across M, so an answer cannot be found for the size of M and B until further assumptions have been made about the current distribution in the beam.

The problem is not quite so simple, however, for there is another variable S, the distance of the beam from the tube axis. The value S is related to the convergence angle of the beams or the angle between each beam and the tube axis It can be seen that if $S=0$, $M=0$ and again no beam current is possible. However, as S becomes larger M and S may take on values. The larger S becomes the larger M or B may become, and consequently the more beam current may strike the phosphor screen. The conclusion is, then, that the convergence angle, when small, may limit the beam current that can be obtained. There is a reason, however, for keeping the convergence angle as small as possible. If a single deflection coil is to be used, the deflection of the three beams will be more nearly alike the closer the beams are together. A value that has been found practical for the convergence angle is about 1 degree.

Making of the Tube

Differences in the color tube and black and white kinescopes require additional engineering and manufacturing techniques, but they are of such a nature that if adequate manufacturing care and diligence are exercised, production of the color kinescope will impose no more serious problems than those which were experienced in the early days of black-and-white kinescope production. A number of techniques and processes have been worked out to produce shadow-mask color tubes.

The metal mask consists of a large number of holes in a sheet of thin metal with the holes uniform in size and equally spaced. Very satisfactory results have been obtained for pilot plant production of tubes by etching the holes in the masks from rolled metal strips. The alignment slot and hole as well as the border holes for mounting the mask are all made at the same time. In the process a photographic master is prepared having opaque dots where the holes are to be made in the mask. An ultraviolet light exposure through the photographic master or negative is then used to harden an acid resist that has been put on the metal. When developed, after the exposure, the resist washes off where there has been no exposure, or where the opaque dots were, while the space between the dots remains covered. By immersing the metal in suitable chemicals, such as ferric chloride, holes are etched through the metal. Figure 9 shows a magnified view of a portion of the mask including the alignment slot.

The mask is fastened to the spacer frame by means of clamps held by screws. It is important that the mask be under tension on the frame in order that it be held accurately in position with respect to the phosphor screen. As may be visualized readily, a change in the distance between the mask and phosphor screen, particularly near the edge of the picture, would cause color dilution because the beam would strike too far from the axis of the tube or too near depending on whether the mask to phosphor screen distance was too great or too small. A second factor is that the mask may be operated at a higher temperature before looseness occurs if it is initially stretched near its elastic limit. The operating temperature is somewhat higher than room temperature because of the beam power absorbed.

The mask tension may be controlled at the time of mounting by what has been called hot blocking. Heated platens are placed in contact with the mask, but the frame remains cool. While the mask is hot and thus expanded the clamping screws are tightened. When the mask is cooled it contracts and develops a tension that depends on the temperature to which it was raised.

After the mask has been mounted, the next operation is the making of the phosphor screen. As was described earlier, the electron beam may be considered as traveling in a straight line from a point in the deflection plane. It is therefore possible to simulate the electron beam by a point source of light and to locate the correct phosphor dot positions on a photographic plate placed in the plane where the phosphor screen is to be mounted. The apparatus used to perform these operations has been called the lighthouse. Figure 10 shows a schematic drawing that illustrated the apparatus. The mask-spacer frame assembly is placed with the mask down on locating points, not shown, for the purpose of accurately positioning the assembly with respect to the point light source below. A Kodalith plate is placed on the assembly with the emulsion towards the mask, so that the emulsion is in the same plane as the phosphor screen will be later. The point light source is located a distance below equal to the desired distance between the mask and deflection plane in the finished tube. Since the point source automatically fixes one of the color centers of the assembly at its own location when the exposure is made, it is important that the point source be positioned not on the axis of the assembly but off the axis a sufficient amount to give the required angle between the beam and the axis. The position of the point source about the axis is also important in order that the right angular relation between the mask array and the guns may ultimately be obtained.

As the exposure is made there are recorded on the Kodalith plate the positions where phosphor dots of a particular kind should be placed in order that all dots of that kind may be struck by the beam as it scans. At the same time, the alignment hole and slot are recorded on the plate as a guide to be used in positioning the phosphor plate when the phosphor dots have all been applied to form the screen.

From the Kodalith plate with the dots on it, or even directly from the lighthouse, one may proceed to make the phosphor screen in a number of ways, for example, by electrostatic printing, photo printing processes, offset printing, silk screening, and settling. However, only the process that has been most extensively used in pilot production, namely the silk screen process, will be described.

In general, the silk screen process of printing consists of blocking the openings to make a stencil out of a piece of cloth or metal mesh. The holes are blocked by a gelatin layer placed where there is to be no printing. Ink may then be forced through the clear parts of the fabric to the surface to be printed by means of a squeegee drawn across the fabric with the ink being pushed ahead of the squeegee.

The steps in preparation for printing the dot pattern are as follows: The Kodalith plate containing the dot pattern is lacquered and then covered with a light coating of paste wax such as Simoniz wax. A sheet of paper-backed photosensitized gelatin is applied to the emulsion side of the photographic plate. Ultraviolet light is then used to expose the gelatin with the dot pattern acting as a negative. During the development the unexposed areas dissolve out, leaving a gelatin stencil adhering to the photographic plate. The stencil consists of holes in the gelatin corresponding to the dots on the Kodalith plate. While still wet, the gelatin and plate are placed, gelatin side down, on a fine stainless steel wire screen stretched on a frame. The screen has wires 0.002 inch in diameter with 170 wires to the inch. After the gelatin is dry, the photographic plate is removed leaving the stencil adhering to the wire screen ready to use.

The actual printing is done on a table fitted with a vacuum mechanism for holding the glass to be printed. Also there is a crossfeed arrangement for moving the glass in two directions underneath the stencil, the amount of movement being indicated by dial gauges. The stencil is placed over the glass and its mechanism and held stationary. Movement of the glass with respect to the stencil is used for initial alignment of the pattern with the two holes in the glass as well as shifting the glass under the pattern to get the correct position for printing the second and third phosphor arrays. The movement for changing to another phosphor array is about 14 mils.

The printing ink or paste is made by dissolving ethyl cellulose in amyl alcohol and then adding the phosphor powder. Since the same stencil is used for printing each of the three types of phosphor, a thorough cleaning of the stencil after each printing is required in order to keep from mixing phosphors.

After one phosphor array has been printed, the phosphor plate and corresponding mask assembly are put back in the lighthouse to check the positions of the dots visually. The three colors are then printed and the plate is baked in air for 1 hour at 400 degrees centigrade to remove the ethyl cellulose binder. After the bake, a silicate solution is sprayed on to act as a binder to keep the dots from coming off in the subsequent steps of aluminizing. These steps consist of floating an organic film onto the phosphor surface in a tank of water, evaporating aluminum on the film and air baking to drive out the organic film. When these steps have been completed a thin, continuous film of aluminum covers the phosphor screen.

The parts are now ready for final assembly of the viewing screen. A steel alignment pin is pressed into the alignment hole in the spacer frame. The diameter of this pin is matched with that of the hole in the phosphor dot plate which is to fit over it. Next, an alignment bolt is fitted through the opposite hole in the phosphor dot plate and the slot in the spacer frame. Slippage along the horizontal axis, therefore, is permitted to the extent required by the differential expansion between glass and metal, which occurs during tube bake-out. It is to provide for this differential expansion that the slot is used, while insuring that the original alignment be restored after the heating cycles in making the tube are over.

The 3-gun assembly is sealed into the neck, the viewing-screen assembly is bolted to support posts in the lower cone and the upper cone put in place for the final welded seal. After the final seal the tube is exhausted by modified cathode-ray-tube methods. Reduced heating and

cooling rates are desirable to avoid breakage of the phosphor dot plate from thermal shock and overstretching of the shadow mask due to too large a temperature differential between the mask and frame.

Operating Characteristics

In Figure 11 is shown the maximum operating voltage ratings. It will be noted that dynamic-focusing and convergence voltages are used. They consist of superimposed voltages that keep the beams focused and converged at all points on the flat phosphor screen.

Figure 11. Maximum operating voltages for the shadow-mask color kinescope

For satisfactory performance, it is essential that there be no color shift with variation in intensity of light output. Since the phosphors show negligible current saturation in the range of current densities used, the necessary constancy of color requires that the ratios between the final electrode currents from the three guns be held constant over the desired brightness range. When the tube is used to reproduce black-and-white pictures, it is particularly important that the color temperature remain constant for the various shades of gray in the picture to prevent color tinting of the highlights and shadows.

To produce a white of approximately the same color temperature as that produced in a conventional black-and-white kinescope, it is necessary to have about three times as much current from the red gun as from the blue or green gun. One method of driving the three guns involves the use of separate video-gain controls on each of the amplifiers driving the control grids so that the drive can be adjusted as required. Higher drive for the red gun will be required with the present red phosphor. With this method, the control grid cutoff voltage is adjusted to about the same value for the three guns by varying the screen grid voltages.

Another method of driving the guns involves the use of equal-gain video amplifiers with a common master control. With this method, the screen grid voltages are adjusted to produce a low cutoff voltage for the red gun and a relatively high cutoff voltage for the blue and green guns. Adjusting cutoff in this manner will increase the sensitivity of the drive characteristics of the red gun as compared with that of the blue gun or the green gun, and, hence, will produce the desired ratio of currents to give white. This method requires a greater range in the control grid and screen grid supply voltages than the method utilizing separately adjustable driving voltages.

It was stated earlier that the mask operates somewhat above room temperature because of the beam power absorbed. For 20,000 volts on the final electrode an average current of the order of 300 microamperes may be used or of the order of 6 watts. This permits a peak current of 800 microamperes or more on average scenes. It has been found that under these conditions the temperature rise of the mask does not cause a shift of the mast by an amount sufficient to cause color dilution.

Highlight brightnesses of 50-foot lamberts have been obtained with the shadow-mask color tube, but on the average the tubes, are at this time operated at a somewhat lower brightness.

Turning now to the matter of resolution as influenced by the dot structure of the phosphor screen, there are perhaps two aspects to be considered. The first is the texture of the picture. To be sure, if one gets close enough to the phosphor screen the dot pattern can be seen. However, the structure is not visible at normal viewing distances. The other aspect is the resolution capabilities of the phosphor screen. Results obtained on a 16-inch tube indicate that substantially all the resolution can be seen on a test pattern that would be expected with a 4-megacycle bandwidth. Tests performed when no bandwidth limitation existed show that the tube is capable of a horizontal resolution of between 325 and 400 lines and a vertical resolution of between 350 and 450 lines. The fact that the vertical resolution is higher than the horizontal resolution is due primarily to the geometrical property of the pattern of dots. The resolution can of course be increased rather easily by increasing the number of dots. This has already been done in the 21-inch tube recently demonstrated in New York.

Conclusion

A detailed description of the RCA shadow-mask kinescope has been presented. In conclusion it may be emphasized that the technical developments leading to improved kinescopes, particularly since World War II, have formed the ground work to which has been added techniques particularly applicable to color tubes. A color tube has been built and put into pilot plant production that is capable of giving bright, well resolved pictures with excellent color separation. Each of the three primary images in the reproduced picture is separately produced by an electron beam. The use of a shadow mask insures that beam focus does not influence color while a single deflection yoke for the three beams eliminates the need for precisely linear scan.

A New Design 60-Cycle A-C Network Analyzer

J. L. DAVIDSON
ASSOCIATE MEMBER AIEE

ROBERT E. KOLL
ASSOCIATE MEMBER AIEE

ANY power system, either present or proposed, may be reproduced in miniature and studied in careful detail with an a-c network analyzer. This device has become a powerful tool in designing and operating electric systems to cope with the rapid expansion of electrical facilities throughout the country. Its increased usage is reflected in the number of analyzers either built or planned, and in the waiting period of several months required to obtain a position on the schedule of those analyzers available for rental.

Conventional analyzers similar to those installed at the large electrical manufacturers' headquarters are expensive and, in general, can be justified by only the larger utilities and systems. A number of designs to achieve a lower cost device have been made or planned. Various approaches to low cost have included:

1. a 10,000-cycle design;
2. a 5-degree shift method to achieve low cost reactors;
3. a d-c method involving only resistors in conjunction with a special metering scheme;
4. the use of capacitors to replace reactors in a conjugate vector approach;
5. a successive-approximation solution of equations using an International Business Machines card punch calculating machine;
6. a number of homemade analyzers with fixed values of impedance to represent a fixed system.

Some of these methods are in satisfactory operation while others are in the development stage. References to published material on them are given at the end of this paper.

This paper describes a new design of low cost analyzer which has recently become available to the industry. It has been placed in successful operation by one of the smaller utilities having a peak load of approximately 500 megawatts and whose average rate of growth has exceeded 20 per cent per year over the past 5 years. The engineers of this company, as well as those of a number of other utilities, have worked very closely with the manufacturer to produce a flexible and conveniently operated design capable of wide application and usage.

This analyzer has a number of features which are not usually found in recent conventional designs. These features include:

1. operation of all elements at 60-cycle alternating current using moderate size reactors;
2. the use of variable autotransformers for generator voltage and phase-angle control;
3. load units which can be set directly as low as 1 per cent of board base on a single unit;
4. the use of continuously variable resistance and reactance units rather than tapped units with decade switches;
5. a variable reactance-over-resistance ratio adjustment for all generators;
6. load adjustment control which covers a complete voltage range;
7. calibration of resistance, reactance, and capacitance elements against a single decade resistance standard;
8. simultaneous metering of volts, amperes, watts, and vars;
9. accurate direct reading of I^2R and I^2X losses in any unit;
10. the use of solenoid-actuated precision snap switches for instrument selection circuits;
11. the use of a cathode-ray oscilloscope as a null detector in balanced bridge circuits for calibrating purposes.

The first three features mentioned are available in certain other recent nonconventional designs, while the remainder are believed to be unique in this design. In addition to these unusual features, this analyzer is equipped with many of the usual refinements found in most other modern designs such as low-burden electronic metering, push-button selection of any element to be metered, load-calibrating instruments, individual instruments with schedule-setting pointers for each generator, pilot-lamp indication of any element selected by push button, numerous transfer busses, and metered busses.

The total number of components placed in operation on the first board built to this design are:

12 generators (9 at 0 to 110 per cent *X*, 3 at 0 to 500 per cent *X*)
70 Pi lines (0 to 110 per cent *R* or *X*; susceptance 0 to 43 per cent each)
70 lines or loads (not available as lines when used as loads and vice versa)
35 tap changers (boost or buck 20 per cent; 1/2 per cent steps)
5 mutual transformers, 1-to-1 ratio
10 capacitor banks (0 to 103 per cent susceptance)
18 metered jumpers

These components are housed in a metering desk and nine cabinets and when assembled occupy a room 17 feet by 19 feet. The metering desk and typical cabinets are shown in Figures 1 and 2. Connections between components are made by external jumpers from the various sections to the bussing panels or to nearby sections.

Power Supply

A 3-phase 220-volt 60-cycle (or 50-cycle) a-c power supply is required. This voltage is applied to the machine through three delta-connected automatic voltage regulators which hold the voltage to within 1/2 volt. No auxiliary equipment is required for frequency multiplication. Total power requirements are approximately 600 watts.

Load and Line Units

Reactor size for a low-frequency analyzer is a problem because of the large size required for the high-impedance load units. By means of a variable autotransformer inserted ahead of a load unit, the reflected impedance of the load unit as seen by the autotransformer terminal will increase as the square of the transformation ratio. The connections of a load unit are shown in Figure 3. By proper choice of an impedance base, it is possible to use a moderate size reactor for either loads or lines. The resistor and reactor shown in Figure 3 may be independently used as a line unit when reconnected in series. The resistance elements consist of industrial-type wire-wound resistors, either fixed or variable. The reactor units are specially designed units with fixed taps and movable brushes, and hold a constant reactance over a wide range of current.

By metering at the point shown, the losses in the variable autotransformer and in the load-calibrating device are included as part of the total load. The var losses of the transformer are supplied by the small capacitor.

A typical panel containing two Pi lines

J. L. DAVIDSON is with the Long Island Lighting Company, Mineola, N. Y., and ROBERT E. KOLL is with the System Analyzer Corporation, Milwaukee, Wis.

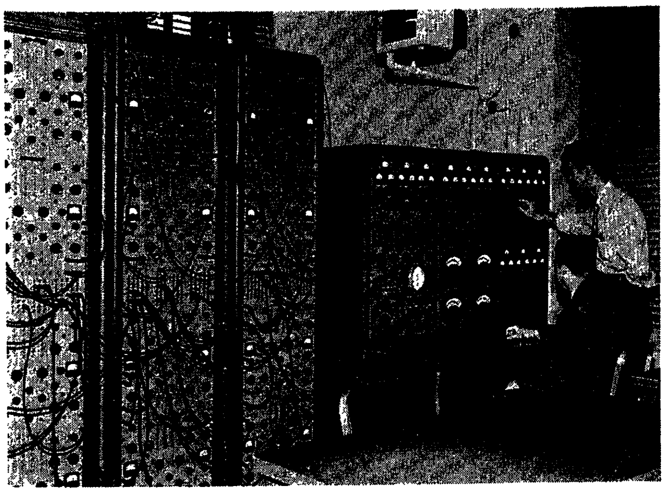

Figure 1. Control desk and cabinets

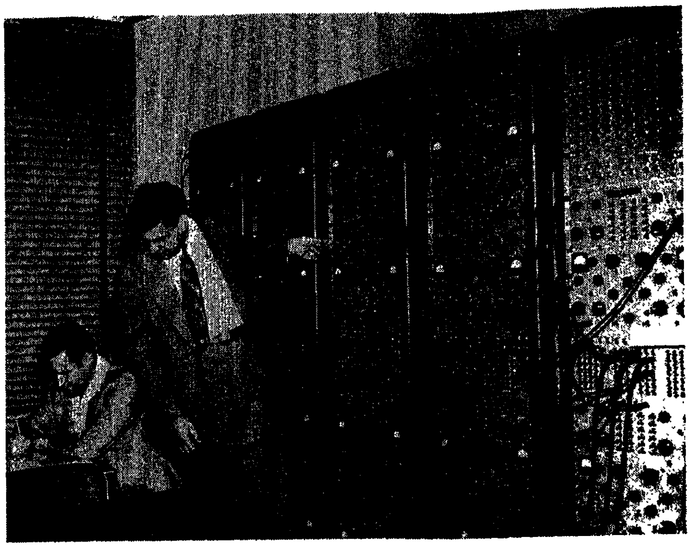

Figure 2. Cabinets located opposite control desk

and two loads is shown in Figure 4. The two Pi lines complete with capacitors are located in the top half of the panel. The two non-Pi lines are located in the bottom half of the panel with the variable autotransformers to convert them to load units immediately above. A tapped autotransformer is located at the bottom center of each of these panel sections. The reactors are arranged behind the panel so that there is no mutual coupling between units.

Generators

In the generator elements, use is again made of variable autotransformers.

These are used to achieve voltage regulation and phase-angle control. The connections, shown in Figure 5, give angle control over a 60-degree range. A complete rotation of 360 degrees is obtained by reconnecting to different phases by means of tap switches. Vernier control of both phase angle and voltage is achieved by a second brush on the variable autotransformer. This auxiliary brush supplies the primary winding of a small step-down transformer. The secondary winding is connected in series with the output terminals. Two concentric shafts are used to operate the two brushes independently. The vernier connections are shown only on the voltage control transformer to avoid confusing the diagram.

The generators are equipped with reactance units similar to those used with the line and load units. Every third generator has additional reactance to represent small machines. An adjustment is provided in each generator which allows the resistance-over-reactance ratio of the generator reactor to be set at any value from 0 to 5 per cent, or from a Q of infinity to 20.

A typical generator panel containing three generators is shown in Figure 6. Individual voltmeters, wattmeters, and varmeters with schedule-setting pointers are provided for each generator.

Calibrating Facilities

With all elements completely variable, it is necessary to adjust and calibrate against a known standard. This standard is a precision decade resistance box with a range from 0 to 10,000 ohms in steps of 0.1 ohm. The desired value is set on the decade resistance box and the unit selected is adjusted to give a null indication on a cathode-ray oscilloscope which is connected in an impedance bridge circuit. Separate bridge circuits are used for resistance, reactance, and capacitance.

Phase angles are read directly on a single-standard phase shifter which is adjusted for null detection on the oscilloscope with respect to the voltage under observation. The calibrating panel is shown in Figure 7 with the decade resistance standard at the top, the oscilloscope at the right, and the phase shifter at the lower left.

Metering Facilities

Four main instruments are provided for simultaneous indication of volts, amperes, watts, and vars. This panel is shown in Figure 8. These instruments are driven by highly stable electronic power amplifiers having a 35-decibel negative feedback. Input to the amplifiers is obtained from low-burden shunts and potential multipliers inserted in the desired metering location by precision snap switches. The instrument scales are hand-calibrated for each range of each instrument. Full-scale ranges are 1.5, 6, 25, 100, and 400 per cent base watts or vars. Full-scale voltmeter ranges are 9, 35, and 150 per cent. Full-scale ammeter ranges are 0.3, 1.2, and 4.8 per unit.

Push-button selection of any element to be metered is provided. The push-button switches actuate solenoid-driven cam shafts which in turn actuate the precision snap switches, each of which is permanently sealed in its own dust-tight housing. The cams are arranged to operate the switches as make-before-break contacts so that no current is interrupted by the metering bus contacts. Push buttons provide for metering of any terminal of any element, including the capacitors on the Pi sections. In addition, a simple switching device is provided to permit direct reading of I^2R and I^2X losses in any section.

The push-button panel with the metering range selector switches is shown in Figure 9. Selection of voltage and current ranges is done by tap switches. Signal lights shown in Figure 8 indicate the proper scales to be read on the watt and var instruments.

Bussing Facilities

The terminal of each generator appears at each cabinet. There are 12 local busses of 5 terminals each and 14 transfer busses of 3 terminals each in every cabinet. Three additional single-terminal transfer busses are also provided. All transfer busses appear in each cabinet. Tap switches for each load section permit that load to be connected to either terminal

of the 2-line sections in the same panel. A view of a combined line and load panel is shown in Figure 4. The two Pi lines are at the top and the two load or line units are at the bottom. Three terminals are provided for each line section for the convenience of connections.

Tap Changers

A 20-per-cent boost-or-buck tap changer with a 1/2-per-cent steps is located in the center bottom of the panel shown in Figure 4. Here again, the var losses are supplied by a small capacitor. The watt losses are approximately 0.3 per cent of board base.

Capacitor-Mutual Panel

Ten capacitor banks with a total susceptance of 103 per cent each in 1-per-cent steps are available and may be used to represent either series or shunt capacitor banks on a system. Five 1-to-1 ratio mutual transformers are available on the same panel. Exciting-var losses of the mutual transformers are also supplied by small capacitors. This panel is shown in the upper right corner of Figure 2.

Base Quantities

The base quantities used on the analyzer are 50 volts, 1/2 ampere, 25 watts or vars, and 100 ohms. The meter scales are marked in per cent volts, per cent watts, per cent vars, and per unit amperes. The thermal capacity of all elements is equal to or greater than 500-per-cent base amperes.

Performance

A thorough check was made by comparing with typical load flow values obtained on other studies, and by checking against calculated values. In checking against results previously obtained on other analyzers, the division of loads among various lines was within a few per cent and voltages were quite accurate. The same applies to checks against known system conditions which were duplicated

Figure 4. Line and load panel showing two Pi lines and two load units. Loads may be used as normal lines. Tap changer is located in lower center

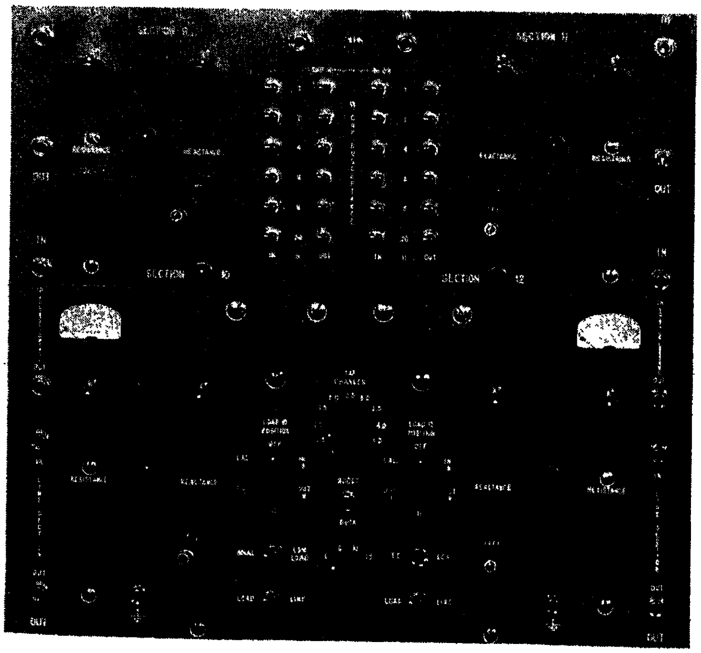

Figure 6. Generator panel showing three generator units

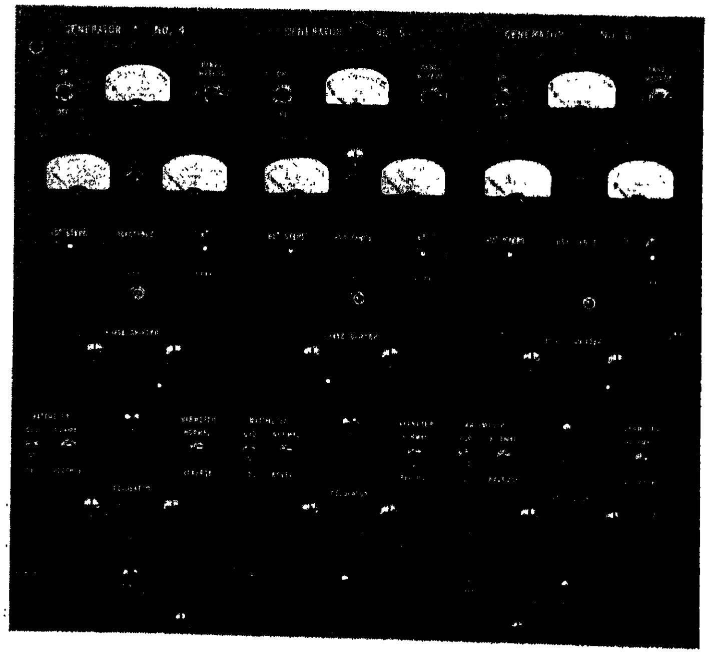

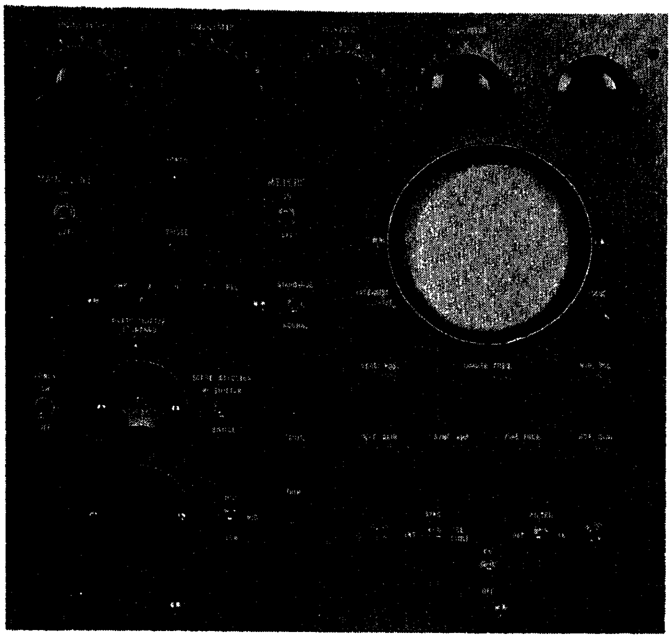

Figure 7. Calibrating panel showing cathode-ray oscilloscope, standard resistance box, and standard phase shifter

on the board.

A check against previously obtained transient-stability swing curves was also satisfactory.

A complete check of the board against itself was made regarding total system losses. Both watt and var losses were obtained by four methods:

1. calculating I^2R and I^2X from current readings and adding to obtain totals;
2. summation of I^2R and I^2X losses as read directly for each element;
3. summation of the in-minus-out differences of each element;
4. subtraction of the sum of the loads from the sum of the generation.

Assuming the I^2R and I^2X calculations from current readings to be 100 per cent, the direct reading method gave results within 1.4 per cent. The two latter methods ranged from 2.8 to 5.0-per-cent error. A larger error was to be expected for these methods since they both involve small differences of large quantities.

During the installation and testing period, quite a few mechanical adjustments and minor replacements were necessary, but no basic problems regarding electrical design or operation occurred.

Conclusion

This device has been in operation for several months and its performance and capabilities have proved to be satisfactory and have met the design expectations. The results have been such as to give confidence to future results obtained from the device.

Oil-Immersed 110-Kv 440-Kw Rectifier Unit for Resnatron Plate Supply

R. P. FEATHERSTONE
ASSOCIATE MEMBER AIEE

C. LING
NONMEMBER AIEE

P. A. CARTWRIGHT
MEMBER AIEE

THE proton linear accelerator installation at the University of Minnesota requires as one of its power supplies a d-c source capable of delivering continuously 4 amperes at 110 kv. This power represents the plate supply for four resnatron tubes which provide the radio-frequency power to excite the resonant cavities of the accelerator proper. The design of a power supply capable of meeting these requirements was complicated by the limited amount of available space.

Discussion of Components

To conserve floor space, a vault was built extending 9 feet below the floor level, a metal liner was provided, the vault partially filled with oil, and the rectifier components placed in it. This not only conserved space but was justified economically since all the transformers could be uncased and used without bushings. A 1-line diagram of the components involved in the power supply is shown in Figure 1. The primary service to the building's outdoor substation is 3-phase 4-wire 4,160 volts. Utilization voltage for the rectifier system is 480 volts and is supplied through a 600-ampere air circuit breaker, which is part of a metal-clad switchgear unit.

Induction Regulator

The induction regulator used for voltage control of the rectifier is an oil-immersed, self-cooled, manually controlled, motor-operated unit. It is rated 250 kva, 480 volts; 100-per-cent raise and 100-per-cent lower. The regulator is provided with a neutral-stabilizing delta tertiary winding, and consists of three single-phase units mechanically connected together, mounted in a common tank, and driven by one operating motor. As is normally the case, the impedance of the regulator varies somewhat with the exact buck-boost position.

Vault

The metal liner for the vault measures 17 feet by 7 feet by 5 feet in depth, is of 11-gauge cold-rolled steel, and has a capacity of 3,500 gallons of inhibited transformer oil. Provision is made for circulating the oil and for cooling it in a heat exchanger. The vault cover is made in two sections, one of which covers the rectifier transformers and the other the rectifier tubes and their filament supplies. Glass inspection ports are provided in the sections covering the rectifier tubes. As a safety measure a disconnect switch in the primary supply is provided in the cover, as can be seen in Figure 2.

The electric connections in the vault are made in such a manner as to allow individual removal of any one of the rectifier or filament transformers. The rectifier transformers are connected delta-delta with the deltas closed on the primary and secondary bus structures. Flexible leads and plug-type connectors allow the transformers to be disconnected from the busses and readily removed. Lowering and raising guides are provided to insure proper seating of each transformer unit, as shown in Figure 2.

Transformers

The rectifier employs a conventional delta-delta 3-phase full-wave connection. Two factors favoring such a choice are the relatively high ratio of the d-c output voltage to the secondary rms voltage, and the possibility of operating open delta at reduced load in the event of a transformer failure. For very high voltage applications, a delta connection of the high-voltage winding is preferred to a wye connection because of its greater stability.[1,2] Each transformer is rated 167 kva with a primary voltage rating of 960 volts and a secondary voltage rating of 90,000 volts. Two primary voltage taps are provided, one at 5 per cent and one at 10 per cent below rated primary voltage, but at rated kva. The impedance of the transformers is approximately 16 per cent. The transformers were oil-impregnated by the supplier and shipped in a sealed, oil-filled tank. A portion of the transformers is shown in Figure 3.

The filament supply transformers for the rectifier tubes are rated 480 volts primary to 20 volts secondary. Each transformer has two secondary windings each rated at 20 volts, 32 amperes, to supply one of a pair of rectifier tubes. The transformer insulation is suitable for 150-kv operation. The tube sockets are mounted immediately above the transformers and are actually part of the transformer assembly. Figure 4 shows some details of this assembly.

Rectifier Tubes

The choice of a 3-phase full-wave bridge as the rectifier circuit required that there be six rectifier tubes, each having a peak inverse voltage rating of at least 130,000 volts, a peak current rating well above 4 amperes, and an average current rating of at least 1.3 amperes. No single kenotron was found which would meet these requirements, so series and parallel combinations of available tubes were considered. The final choice was the *ML-5576/200* kenotron, rated at 150,000 volts peak inverse, 2.5 amperes peak current, and 0.8 ampere average current, with two tubes in parallel at each rectifier position.

These kenotrons have an unusually low average tube drop of about 800 volts, less than 0.8 per cent of the power supply

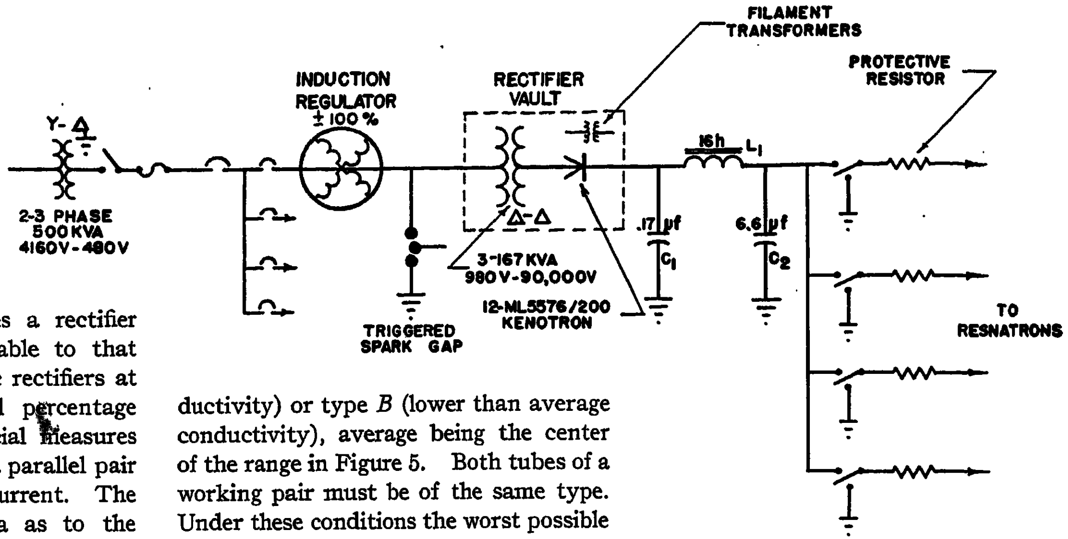

Figure 1. One-line diagram of 110-kv power supply

output voltage. This gives a rectifier efficiency which is comparable to that associated with mercury-arc rectifiers at lower voltages. The small percentage tube drop necessitates special measures to insure that each tube of a parallel pair will carry its share of the current. The manufacturer supplied data as to the range of tube characteristics considered acceptable by his quality control at final test; see Figure 5. It was evident that if a tube near the upper limit of conductivity were paralleled with one near the lower limit of conductivity, the former would be overloaded and would have short life.

A number of possible solutions to this problem were considered, such as adding sufficient resistance in series with each tube of a pair to insure acceptable current division or metering the current of each tube individually and adjusting variable resistors associated with each tube until equal currents were carried by each tube. The plan currently in use, however, is simply that of tube selection. Each tube is tested and classified as type *A* (higher than average conductivity) or type *B* (lower than average conductivity), average being the center of the range in Figure 5. Both tubes of a working pair must be of the same type. Under these conditions the worst possible unbalance within a class will not result in a serious overload for a tube. A simple test set, a bridge in which a tube is compared with a standard resistor, was built. It was found that tubes could be classified quite quickly and easily. Provision has been made for classifying into four, rather than two, subgroups if this should later prove desirable as a means of further improving the balance, and consequently, the tube life.

It is evident that if the filament of one tube of a pair were to open, the other tube would endeavor to conduct double current and would be dissipating many times rated wattage, because of the large voltage drop existing across a tube carrying an abnormal current. This requires that the system be shut down at once whenever any rectifier tube filament burns out in order to prevent damage to the good tube paired with it. A current-sensing relay is connected in series with the primary of each filament transformer, and is adjusted to drop out if the filament of either of the kenotrons supplied by that transformer burns out. Opening of any of the relays removes plate power from the system.

Because the life of rectifiers having pure tungsten filaments is critically dependent on filament voltage[3,4] it is advantageous to operate at reduced filament voltage when less than rated output current is required from the power supply, as will be the case a large part of the time in this application. Should the operator forget to increase the filament voltage when an increased output current is demanded there will be

Figure 6 (above). Circuit for protection of ML-5576/200 kenotrons against excessive anode dissipation

an abnormally high tube drop and excessive anode dissipation. This will overheat the kenotron anodes and, depending on the severity of the overload, may damage them in a short time.

A simple means of avoiding damage of this type was adopted; it is shown schematically in Figure 6. Kenotrons V_1 and V_2 are one of the three pairs in the rectifier having grounded anodes. Care is taken to choose low-conductivity tubes for V_1 and V_2. The cathode-to-ground (and hence cathode-to-anode) voltage of the kenotrons is sampled by the resistance divider R_1-R_2, and the positive excursions due to inverse voltage are clipped by diode V_3. The negative excursions remaining are due to the forward voltage across the kenotrons. The constants of the rest of the circuit are so chosen that if the peak forward voltage exceeds a safe value the plate current of V_4 falls below the drop-out point of relay K_1. Opening of K_1 shuts off plate power to the system.

Filter Design

The filter consists of capacitors C_1 and C_2, and choke L_1, in the circuit diagram of Figure 1. Capacitor C_1 absorbs the energy of a commutating transient which, with only cable and stray capacities present, caused intolerably high ripple voltages (actually repeated damped oscillations superimposed on the normal ripple voltages) at the input to the filter. Because of the relatively high reactance of the plate transformers, the presence of this small input capacitor does not increase the peak current drawn through the rectifier tubes significantly above the choke-input condition. The size of C_1 is not critical and was determined experimentally.

Capacitor C_2 is an energy reservoir for pulsed operation of the resnatrons. The linear accelerator requires such large amounts of radio-frequency power that it must be operated in pulses, at a relatively low duty, to keep the energy requirements and the cooling problem within reasonable bounds. The pulse length is 300 microseconds, and the pulse repetition rate is 60 per second. From conservative estimates of the probable radio-frequency power requirements and of the probable plate efficiency of the resnatrons, it was calculated that capacitor C_2 must be able to supply an average power during the pulse of 24,000 kw.

The larger C_2 is chosen, the more nearly constant the voltage across it will remain during the pulse, but at the same time the stored energy will be increased so that greater damage may be inflicted on a resnatron in the event of an accidental arc-over within the tube. The resnatron manufacturer specified that C_2 be selected such that the voltage across it would not drop more than 10,000 volts during the pulse. From these considerations the required capacitance of C_2 is determined to be 6.52 microfarads.

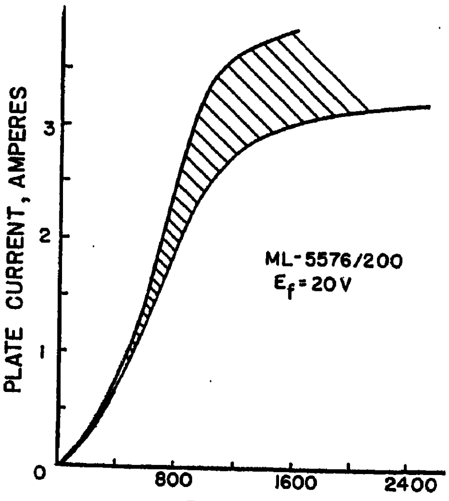

Figure 5. Acceptable range of characteristics of ML-5576/200 kenotron

Since the capacitors available to us were rated at 1 microfarad and 25 kv, the bank C_2 is designed by using five such units connected in series to stand the total voltage and 33 in parallel to make a total capacitance of $33/5 = 6.6$ microfarads. Figure 7 shows the construction of C_2. The division into groups with paralleling only at the top and bottom is done to limit the energy which would be dissipated within any one capacitor in the event it failed.

The filter choke L_1 smooths the current flow which the rectifier supplies to energy reservoir C_2. If there were no choke in the circuit, the rectifier would supply very large currents to C_2 immediately after the pulse, requiring rectifier tubes of uneconomically large peak current capacity. The calculations by which the required value of L_1 was determined are given in the Appendix. The minimum value was calculated to be 10 henrys.

Protective Resistors

This rectifier is to supply plate power for a group of resnatrons which, like other continuously pumped vacuum tubes of high power, are expected to spark over internally from time to time. Because the main filter capacitor will normally have about 40,000 joules of stored energy which will be discharged in any such spark-over, considerable damage to the resnatron tube structure is possible and special measures to reduce the energy delivered to the tubes under fault conditions are required.

The protective technique used is shown in Figure 1. A resistor is inserted in series with the output to each resnatron. It is chosen to be small by comparison to the effective tube anode impedance in normal operation (about 5 per cent) but large by comparison to the impedance of an arc. The resistors are noninductively wound (Aryton-Perry winding), with bare Nichrome wire on grooved insulating forms. They dissipate approximately 5 per cent of the total output power of the

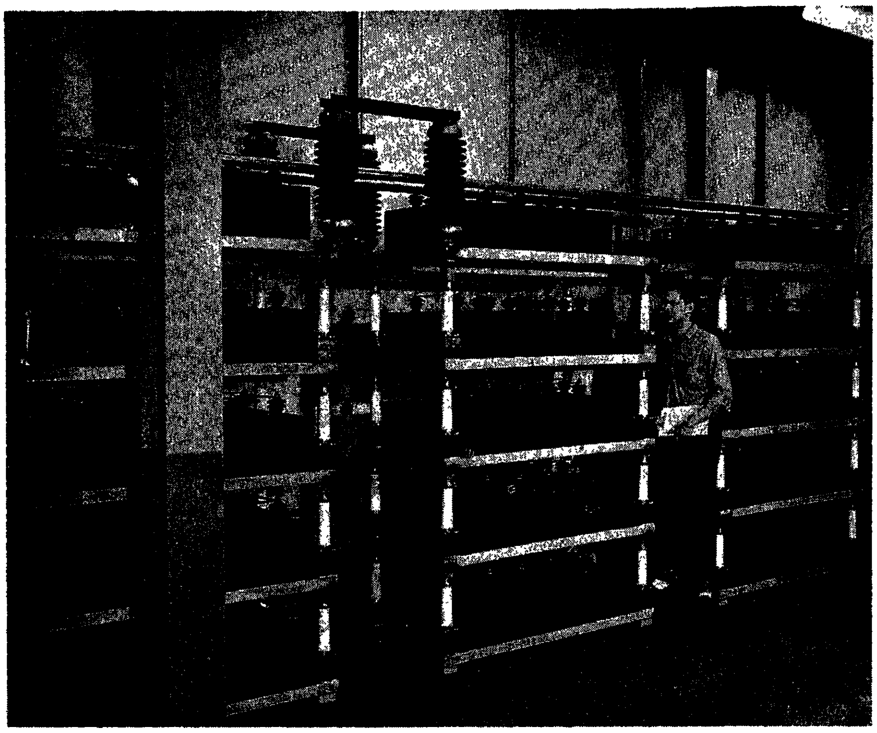

Figure 7. Construction of 6.6-microfarad 125-kv capacitor bank

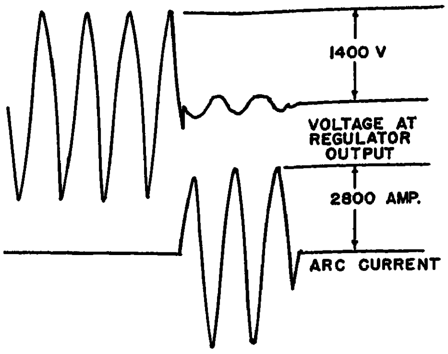

Figure 9. Oscillogram of typical spark gap operation

power supply in normal operation, and are able to withstand full supply voltage from end to end briefly under fault conditions. Any single resistor is able to absorb the stored energy of the capacitor bank without undue temperature rise.

Distribution

The high-voltage cable used for distribution of the vault output is of the type used for X-ray applications and is rated for service at 140 kv d-c. It has an overall diameter of 1.745 inches and a minimum bending radius of five times the diameter. The cable was supplied in six ready-cut terminated sections. The bushing used for the feed from the vault is of the 46-kv class; Figure 4.

System Protection

Fire Protection

Fire protection for the rectifier vault is provided by means of a carbon dioxide system which will blanket the vault area both above and below the vault covers. Temperature sensing units for automatic operation are provided both above and below the covers and the system can be triggered manually from the linear accelerator control room.

Circuit Breakers

As indicated in Figure 1, the rectifier installation is supplied from a 480-volt 600-ampere air circuit breaker with an interrupting rating of 25,000 amperes. This breaker is operated in cascade with the main breaker of the metal-clad switchgear unit. The main breaker has a continuous current rating of 1,200 amperes, and 50,000 amperes interrupting capacity. All the breakers of the metal-clad unit are electrically operated.

D-C Faults

When a fault occurs on the d-c side of this power supply the current limiting characteristics of the kenotrons, Figure 5, will allow relatively little increase in output current. Most of the direct voltage will be developed across the kenotrons, and their anode dissipation ratings will be very greatly exceeded. It may take as much as 5 cycles (1/12 second) for the d-c overload relay to operate and the main circuit breaker to clear the fault, and it is possible for the kenotrons to be seriously damaged in this interval.

A faster means of interrupting or reducing a-c power input was therefore sought. It seemed possible that short-circuiting the supply line from the induction regulator to the rectifier transformers could be done rapidly, would reduce a-c power input to a level which would be safe for the kenotrons during the circuit-breaker clearing time, and would not be excessively hard on the induction regulator and circuit breaker because of current limiting by the reactance of the induction regulator.

It was found that a 3-phase arc could be struck reliably and almost instantly by the circuit, shown in Figure 8. Abnormal current flow in the ground return of the main filter capacitor C_2 causes the thyratron to fire, discharging capacitor C_3 into the primary of the pulse transformer. The high-voltage impulse at the secondary of the pulse transformer is coupled to the initiating electrode of the spark gap, and sparks jump from this electrode to the three line electrodes. For reliable operation, it is essential that all three line electrodes be coupled by arc streams, because the striking impulse lasts for only a few microseconds; if only two line electrodes are short-circuited together, it may occur at a time when the voltage difference between them is too low to start and maintain an arc. The three small inductors shown in series with the phase leads present a high impedance to the steeply rising striking impulse so that the voltage continues to rise even after some of the gaps have broken down. In this way a single striking pulse breaks down all the gaps and all three line electrodes are coupled by arc streams. Once the 3-phase arc strikes, it will sustain itself reliably at normal operating conditions.

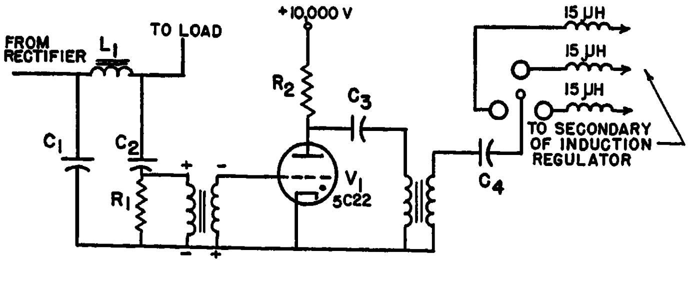

Figure 8. Circuit for sensing d-c faults and triggering 3-phase spark gap

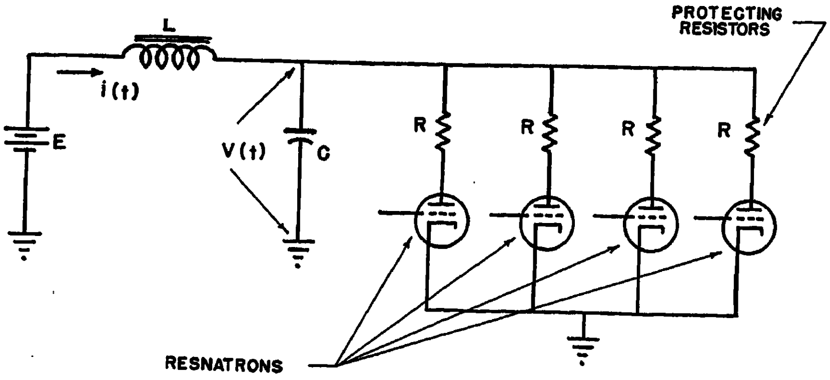

Figure 10. Equivalent rectifier circuit

The main electrodes used are 3/4-inch diameter carbon rods sheathed with copper to minimize resistive drop. The gap spacing used it 1/32 inch at initial adjustment; the gaps are reset after eroding to about 1/16 inch, which occurs after eight operations at full power. Longer gaps could be used except for the fact that the power supply may be used for considerable periods at reduced voltage, in which case the voltage available to maintain the arc is correspondingly reduced. The shorter the gap, the lower the voltage at which the spark gap is able to operate reliably.

Figure 9 is an oscillogram of a typical spark gap operation. The upper trace is the voltage at the rectifier-transformer primary terminals; the lower trace is the current drawn by one arc electrode. It can be seen that the voltage drops immediately from full value to about 100 volts rms, remaining at about the same level for 3 cycles, when the main circuit breaker clears the fault. It has been calculated that the temperature of the kenotron anodes will increase less than 100 degrees centigrade during such a fault, an easily tolerable increase.

Testing and Test Results

TESTS

When the construction of the rectifier was completed a series of tests was performed to determine its operating characteristics. The testing proceeded in these steps:

1. No-load test with no output filter.
2. No-load test with output choke only.
3. No-load test with complete output filter assembly.
4. Load test without filter.
5. Load test with choke only.
6. Load test with choke and capacitor assembly on the output.
7. Open-delta tests.

For purposes of testing under load the rectifier was connected to a water resistor consisting of tap water flowing in four parallel porcelain tubes.

For all tests, the following values were measured and recorded:

1. Output current and voltage.
2. Input current and voltage.
3. Current in the delta primary.
4. Oscillograms of the quantities tested above. For the oscillograms, a Polaroid land camera was used and proved very expedient for this type of work.

TEST RESULTS

The system was tested at no-load voltages as high as 137,000 volts and at currents as high as 4.3 amperes with satisfactory operation. It was run continuously for 7 hours at an output of 4.25 amperes and 120,000 volts, to check heating of components. It will be put into service when the resnatron installation is completed.

During initial tests, an unexpected difficulty was encountered with high ripple voltages at the input to the filter. The filter was initially designed as a conventional choke-input single-L section. The calculated peak-to-peak ripple voltage at the input to the filter at rated output with resistive load, was approximately 17,000 volts. Under test at reduced output, ripple voltages were observed equivalent to 80,000 volts peak-to-peak at full output, which would exceed the rating of the filter choke.

By experimental work on the rectifier and on a small scale model of it, the excessive ripple was identified as being due to shock excitation of the tuned circuit formed by the transformer leakage reactance and the capacitance to ground of the cable which is connected between the rectifier output terminal and the filter choke. It was found that a capacitance of 1/6 microfarad connected in parallel with the cable capacitance did not increase the peak currents which the rectifier tubes must handle, and reduced the ripple voltage at the input to the filter choke to less than 5,000 volts peak. This capacitor was incorporated in the filter design as C_1, Figure 1.

Conclusions

It is the opinion of the authors that a rectifier such as described in this paper is somewhat unique in its field. Many high-voltage supplies have been built but very few with a relatively high current rating. The space-saving features embodied in this design would be useful in any installation where space is at a premium.

Preliminary testing of this rectifier has indicated that the design is basically sound, and there have been no troubles to date with the standard equipment used. Little difficulty has been experienced with the items developed specifically for this application. Future testing may result in minor alterations of the components, but no basic changes in the overall design are contemplated.

Appendix. Calculation of Required Value of Choke Inductance L_1

To simplify the mathematical analysis, the following assumptions are made:

1. The output of the rectifier is a constant direct voltage source, that is, free of ripples.
2. The impedance of the source is zero.
3. The resistance of the choke is zero.
4. The pulse duration (300 microseconds) is negligibly short compared to the pulse interval. See Figure 11.

The energy fed by the capacitor bank to the resnatrons is stored during the charging period from the power supplied through the rectifier tubes and the filter choke L_1. The average charging current flow through the rectifier tubes and the choke L_1 is dependent only on the power consumed by the resnatrons during the pulse

$$i_{av}=\frac{24\times 10^6\times 0.018}{110\times 10^3}=3.92 \text{ amperes}$$

The maximum (or peak) current flowing through the rectifier tubes will be varied for different values of choke L_1; for two *ML-5576/200* rectifier tubes in parallel, a maximum current of 5 amperes is allowable.

In Figure 10, using Kirchoff's Law

$$E=L\frac{di}{dt}+\frac{1}{C}\int^{t} idt+Vc_0 \qquad (1)$$

Differentiating with respect to time

$$L\frac{d^2i}{dt^2}+\frac{i}{C}=0 \qquad (2)$$

Solving

$$i(t)=A\epsilon^{j\omega t}+B\epsilon^{-j\omega t} \qquad (3)$$

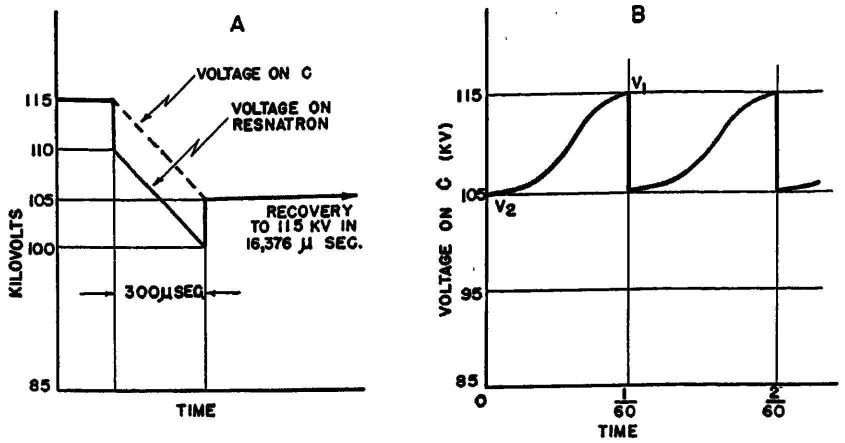

Figure 11(A). Output voltage wave forms—expanded time axis. (B). Output voltage wave forms

where

$$\omega = 1/\sqrt{LC}$$

Let $t=0$ be the time at which the capacitor is discharged to V_2 in Figure 11(B). At this instant the charging current through L_1 is $i = i_0$. Put in equation 3, then

$$i_0 = A + B \tag{4}$$

From equation 1 at $t=0^+$

$$\frac{1}{C}\int_0^t i\,dt = 0$$

so

$$L\frac{di}{dt} = L(j\omega A\epsilon^{j\omega t} - j\omega B\epsilon^{-j\omega t}) = E - V_2$$

At $t=0$

$$A - B = \frac{E-V_2}{j\omega L}\,. \tag{5}$$

Solving for A and B

$$A = \frac{1}{2}\left(i_0 + \frac{E-V_2}{j\omega L}\right)$$

$$B = \frac{1}{2}\left(i_0 - \frac{E-V_2}{j\omega L}\right)$$

$$i(t) = \frac{1}{2}\left(i_0 + \frac{E-V_2}{j\omega L}\right)\epsilon^{j\omega t} + \frac{1}{2}\left(i_0 - \frac{E-V_2}{j\omega L}\right)\epsilon^{-j\omega t}$$

$$= i_0\left(\frac{\epsilon^{j\omega t}+\epsilon^{-j\omega t}}{2}\right) + \left(\frac{E-V_2}{\omega L}\right)\times\left(\frac{\epsilon^{j\omega t}-\epsilon^{-j\omega t}}{2j}\right)$$

$$= i_0\cos\omega t + \left(\frac{E-V_2}{\omega L}\right)\sin\omega t$$

$$= \sqrt{\left(\frac{E-V_2}{\omega L}\right)^2 + i_0^2}\,\sin(\omega t+\phi) \tag{6}$$

where

$$\phi = \tan^{-1}\frac{i_0\omega L}{(E-V_2)}$$

Let σ be the charging period. Then there will be two cases:

Case 1: $\sigma \leq \pi/\omega$

Figure 12 shows the variation of current through the choke and the voltage across the capacitor with time. The average, maximum, and rms currents will next be calculated.

$$\sigma + \frac{2\phi}{\omega} = \frac{\pi}{\omega};\quad \phi = \frac{\pi}{2} - \frac{\omega\sigma}{2}$$

$$\tan\left(\frac{\pi}{2} - \frac{\omega\sigma}{2}\right) = \frac{i_0\omega L}{(E-V_2)},\text{ or }\cot\frac{\omega\sigma}{2} = \frac{i_0\omega L}{(E-V_2)}$$

So

$$i_0 = \frac{(E-V_2)}{\omega L}\cot\frac{\omega\sigma}{2} \tag{7}$$

Putting the value of i_0 in equation 6

$$i(t) = \sqrt{\left(\frac{E-V_2}{\omega L}\right)^2 + i_0^2}\,\sin(\omega t+\phi)$$

$$= \frac{(E-V_2)}{\omega L}\sqrt{1+\cot^2\frac{\omega\sigma}{2}}\,\sin(\omega t+\phi)$$

$$= (E-V_2)\omega C\csc\frac{\omega\sigma}{2}\sin(\omega t+\phi) \tag{8}$$

Maximum current occurs at $t=\sigma/2$.

$$i_{\max} = (E-V_2)\omega C\csc\frac{\omega\sigma}{2}\sin\left(\frac{\omega\sigma}{2}+\frac{\pi}{2}-\frac{\omega\sigma}{2}\right)$$

$$= (E-V_2)\omega C\csc\frac{\omega\sigma}{2} \tag{9}$$

To obtain the average current

$$i_{av} = \frac{1}{\sigma}\int^{\sigma} i\,dt$$

$$= \frac{(E-V_2)\omega C\csc\frac{\omega\sigma}{2}}{\sigma}\int_0^{\sigma}\sin(\omega t+\phi)\,dt$$

$$= \frac{-(E-V_2)C\csc\frac{\omega\sigma}{2}}{\sigma}\cos(\omega t+\phi)\Big|_0^{\sigma}$$

$$= \frac{2(E-V_2)C}{\sigma} \tag{10}$$

The rms current is

$$i_{rms} = \sqrt{\frac{1}{\sigma}\int_0^{\sigma} i^2\,dt}$$

$$= \sqrt{\frac{1}{\sigma}\int_0^{\sigma}\left[(E-V_2)\omega C\csc\frac{\omega\sigma}{2}\right]^2\times\sin^2(\omega t+\phi)\,dt}$$

$$= \frac{(E-V_2)\omega C\csc\frac{\omega\sigma}{2}}{\sqrt{2\sigma}}\sqrt{\left(\sigma+\frac{1}{\omega}\sin\omega\sigma\right)} \tag{11}$$

The following relations may be written down:

$$\frac{i_{\max}}{i_0} = \frac{(E-V_2)\omega C\csc\frac{\omega\sigma}{2}}{(E-V_2)\omega C\cot\frac{\omega\sigma}{2}} = \sec\frac{\omega\sigma}{2} \tag{12}$$

$$\frac{i_{\max}}{i_{av}} = \frac{(E-V_2)\omega C\csc\frac{\omega\sigma}{2}}{\frac{2(E-V_2)C}{\sigma}} = \frac{\omega\sigma}{2}\csc\frac{\omega\sigma}{2} \tag{13}$$

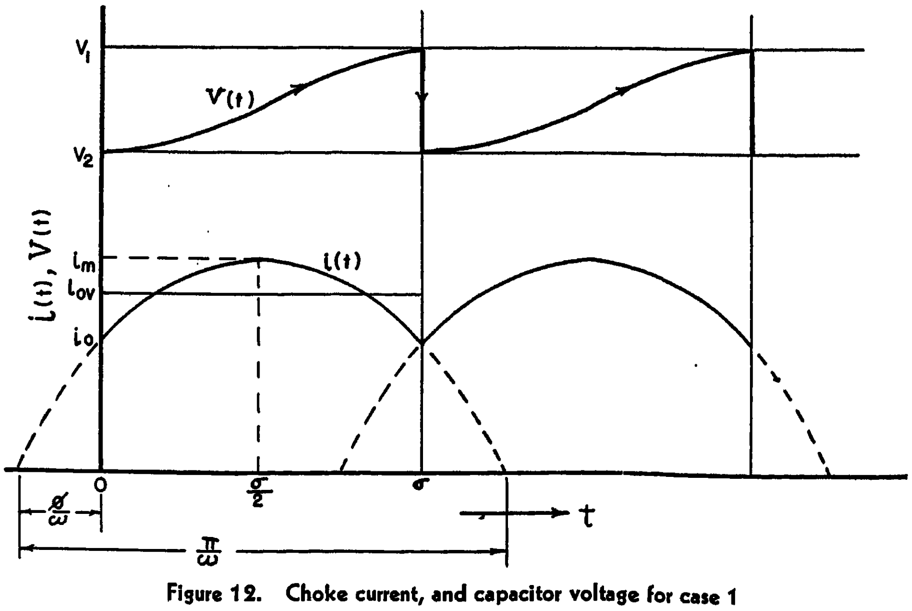

Figure 12. Choke current, and capacitor voltage for case 1

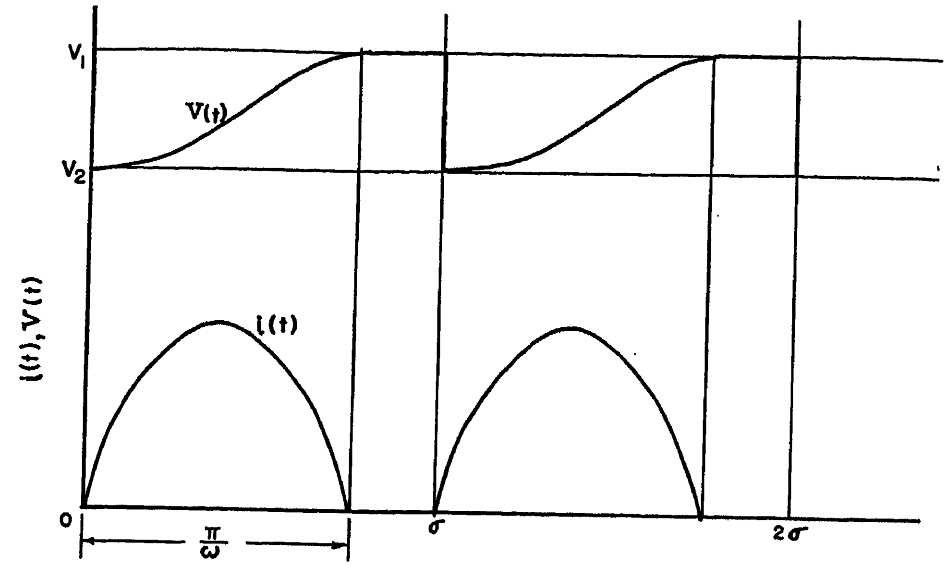

Figure 13. Choke current, and capacitor voltage for case 2

The voltage on C_2 at time $t=\sigma$ is

$$V_1=\frac{1}{C}\int_0^\sigma idt+V_2$$

$$=(E-V_2)\omega\csc\frac{\omega\sigma}{2}\int^\sigma \sin(\omega t+\phi)dt+V_2$$

$$=(E-V_2)\csc\frac{\omega\sigma}{2}\;[\cos(\omega t+\phi)]_0^\sigma+V_2$$

$$=2(E-V_2)+V_2=2E-V_2$$

So

$$E=\frac{V_1+V_2}{2} \tag{14}$$

Case 2: $\sigma>\pi/\omega$.

For this case, the graph of charging current and capacitor voltage versus time would appear as in Figure 13.

$$i_0=0$$

$$i(t)=A\sin\omega t,\ t\leq\frac{\pi}{\omega} \tag{15}$$

$$i(t)=0,\quad \frac{\pi}{\omega}<t<\sigma$$

The constant A is again found from the relation

$$L\frac{di}{dt}+\frac{1}{C}\int_0^t idt=E-V_2$$

At $t=0$

$$E-V_2=L\frac{di}{dt}=LA\omega\cos\omega t=LA\omega$$

So

$$A=\frac{E-V_2}{\omega L}$$

$$i(t)=\frac{(E-V_2)}{\omega L}\sin\omega t \tag{16}$$

for $t\leq\frac{\pi}{\omega}$

Maximum current is simply

$$i_{\max}=\frac{(E-V_2)}{\omega L}=(E-V_2)\omega C \tag{17}$$

The average current is

$$i_{\text{av}}=\frac{1}{\sigma}\int_0^{\pi/\omega} idt$$

$$=\frac{1}{\sigma}\int_0^{\pi/\omega}(E-V_2)\omega C\sin\omega tdt$$

$$=\frac{2(E-V_2)C}{\sigma} \tag{18}$$

The rms current is

$$i_{\text{rms}}=\sqrt{\frac{1}{\sigma}\int_0^{\pi/\omega}(E-V_2)^2\omega^2C^2\sin^2\ \omega tdt}$$

$$=(E-V_2)C\sqrt{\frac{\omega\pi}{2\sigma}} \tag{19}$$

Then

$$\frac{i_{\max}}{i_{\text{av}}}=\frac{(E-V_2)\omega C}{\frac{2(E-V_2)C}{\sigma}}=\frac{\omega\sigma}{2} \tag{20}$$

As before, the voltage across the capacitor just before discharge is

$$V_1=\frac{1}{C}\int_0^{\pi/\omega}(E-V_2)\omega C\sin\omega tdt+V_2$$

$$=2(E-V_2)+V_2$$

$$=2E-V_2$$

So

$$E=\frac{V_1+V_2}{2} \tag{21}$$

In the design, $i_{\text{av}}=3.92$ amperes; $i_{\max}=4.7$ amperes (for the reason of leaving some safety margin on the ripples neglected in the analysis, it is chosen to use $i_{\max}=4.7$ amperes instead of 5 amperes). First, check with case 2: $\sigma>\pi/\omega$

$$\frac{i_{\max}}{i_{\text{av}}}=\frac{4.7}{3.92}=1.2,\ \sigma=\frac{1}{60}=0.0167$$

Using equation 20

$$\omega=\frac{i_{\max}2}{i_{\text{av}}\sigma}=1.2\times2\times60=144$$

Then

$$\frac{\pi}{\omega}=\frac{\pi}{144}=0.0218$$

So

$$\sigma<\frac{\pi}{\omega}\ \text{(contradictory)}$$

Therefore we have to use case 1: $\sigma\leq\pi/\omega$ Using equation 13

$$\frac{i_{\max}}{i_{\text{av}}}=1.2=\frac{\omega\sigma}{2}\csc\frac{\omega\sigma}{2} \tag{22}$$

By cut and try method, we find $\omega=123.8$. Then

$$L=\frac{1}{\omega^2C}=\frac{1}{(123.8)^2\times6.6\times10^{-6}}=10\ \text{henrys}$$

The output voltage of the rectifier circuit should be maintained at

$$E=\frac{V_1+V_2}{2}=\frac{115+105}{2}=110\ \text{kv}$$

◆

Discussion

R. G. Schlawin (General Electric Company, Pittsfield, Mass.): The authors are to be commended for shedding a lot of light on a quite dark subject. Their treatment of the general subject of a d-c power supply and the new application to resnatron tubes is very instructive.

The short-circuiting system for reducing duty on rectifier tubes has not been otherwise covered in the literature to my knowledge. This method, colloquially known to the people working in nucleonics as the "Crowbar," is very important to the proper operation of the system. It is fortunate that this knowledge is now becoming available to others besides nucleonics specialists.

For many applications, an extra power loss of 5 per cent of the power output during normal operation would be disturbing. This loss in the resnatron tube circuit is no doubt necessary to allow sufficient resistance to protect the valuable resnatron tubes. Is there any hope of reducing the loss level for this type of equipment in the future?

It is interesting to know the bushing insulation class (46 kv) used by a laboratory group for this type of d-c apparatus. The normal withstand of a 46-kv class bushing is 120 kv rms, 60-cycle, or 170-kv crest. If one arbitrarily assumes the d-c rating of the bushing comparable to the crest value, there is only a 24-per-cent margin of the withstand value over the no-load direct voltage of 137,000. I would consider this to be too little margin and would rather use about 50-per-cent margin. Since bushing insulation classes are not established considering usage on direct voltages, it will be interesting also to know if any difficulties develop in using the bushing.

In connection with the section on "Test Results," I would be interested in knowing the ripple voltage which was observed and at what value of reduced voltage output. In this same connection, how was the figure of 80,000 volts ripple extrapolated?

It would be interesting if the author gave some details of the filter choke L_1.

My interest in this paper arises from being connected with the design of a 100-kv 3.5-ampere d-c power supply which my company recently furnished for a similar application.

J. J. Halloran (Electro Engineering Works, Oakland, Calif.): There is an interesting point in this article which, from the transformer manufacturer's point of view, is worthy of further discussion; this was the report of initial tests in which ripple voltages were observed equivalent to 80,000 volts peak to peak at full output as compared to a calculated and design value of 17,000 volts.

If this condition had been permitted to continue it would not only have stressed the filter circuit components but also the transformer insulation. The fact that the authors analyzed their circuit conditions and were able to correct the resonant condition which caused this excessive ripple is extremely gratifying to the transformer manufacturer whose equipment might otherwise have been damaged.

As an example of trouble that may be experienced, this manufacturer constructed a 200-kva 500,000-volt oil-insulated transformer for half-wave rectification which, after several months in service, had insulation breakdown on the end coil, although the insulation was actually adequate to withstand full operating voltage in air and had surge shielding adequate to distribute and withstand the impulse voltages required for electric power and distribution transformers. This failure was caused by repeated arcing within the rectifier tube connected to the high-voltage terminal. Once this tube problem was recognized and corrected there was no further trouble.

It is believed timely to point out that the American Standards Association Standards *C57*[1] for transformers, regulators, and reactors cover mercury-arc tube rectifier transformers but do not pursue the subject into the field exemplified by the resnatron plate supply. It is believed that this field is sufficiently mature to warrant a more comprehensive standard, with proper guidance being given to the user of the equipment as well as to the manufacturer. Also, simple little questions like the proper marking (*X* or *H*) of a low-voltage winding of a filament transformer connected to a circuit of higher voltage than the high-voltage winding cannot seem to be resolved by the present standards to the satisfaction of all parties concerned.

It is hoped that the article will accelerate recognition of the need for adequate standards on, as the International Electrotechnical Commission so aptly puts it, "power converter equipment other than rotary converters and motor-generator sets." We are sure that such a program will receive strong support from the manufacturing industry.

REFERENCE

1. TRANSFORMERS, REGULATORS, AND REACTORS. *ASA C57*, American Standards Association (New York, N. Y.), 1948.

R. P. Featherstone, C. Ling, and P. A. Cartwright: In answer to Mr. Schlawin's comment on the 5-per-cent power loss in the resnatron anode protective resistors, there may well be hope of reducing this loss considerably in the future. The resistor value was specified by the resnatron manufacturer, and presumably is a conservative choice because the resnatrons are experimental units being developed on special order for this project and there is no operating experience with such vacuum tubes as yet. After the resnatrons are put into service and we have accumulated a reasonable amount of experience with them, we will be better able to judge the importance of these resistors and perhaps to experiment with changing their values.

Regarding Mr. Schlawin's remarks on the bushing rating, it is true that occasionally for short periods the system may operate unloaded at voltages as high as 137,000 volts, but normal operating procedure will not permit output voltages above 120,000 volts. Thus except for periods of the order of operator response time the margin between the d-c operating voltage and the crest of the a-c rated withstand voltage will be about 40 per cent. It is probably true, however, that if this apparatus were being designed for duty in which continuity of service is paramount a more conservative design would be in order. In our case a flashover a month or even one a week would not be significant compared to the expected rate of arc overs in the resnatrons.

So far there has been no trouble with the bushing or with the 46-kv class station post insulators used elsewhere in the system. We expect to have a low insulator flashover rate because of the favorable conditions of indoor, laboratory operation.

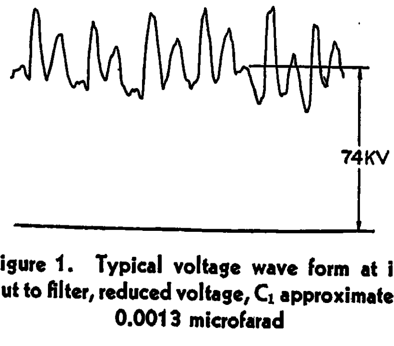

Figure 1. Typical voltage wave form at input to filter, reduced voltage, C_1 approximately 0.0013 microfarad

In answer to the question on ripple voltage, Figure 1 of the discussion may be of interest. It is a tracing of a typical oscillogram of rectifier output voltage wave form (with zero-voltage baseline) with nothing but cable and stray capacity—a total of about 0.0013 microfarad—in the position of C_1, Figure 1 of the paper. This particular oscillogram was taken with 1/60 second sweep, and rectifier output 74,000 volts at 2.7 amperes. The peak-to-peak ripple voltage is approximately 47,000 volts, corresponding to 70,000 volts ripple at full output voltage on a linear extrapolation.

The relative size of the ripple was observed to vary under different load conditions, but no study of its dependence on load impedance has been made. The worst case observed occurred at 50,000 volts and 1.63 amperes rectifier output, with 41,000 volts peak-to-peak ripple. This corresponds to 90,000 volts peak-to-peak ripple at full output voltage with linear extrapolation. In this case, however, the ripple was probably increased somewhat by a 6-per-cent unbalance in the 3-phase primary voltages which was present at the time of that particular test.

It is interesting to note that the presumed shock excitation seems to occur at something over twice the natural 360-cycles-per-second ripple frequency of the system, varying somewhat from phase to phase, presumably with the value of leakage reactance of the three transformers. In the scale model tests it was possible to demonstrate generally similar output voltage wave forms, the frequency of the superimposed shock excitation depending on the adjustment of the transformer leakage reactance and on the capacitance placed across the input to the filter.

Mr. Schlawin has asked about the design of choke L_1. The calculations in the Appendix establish its minimum value as 10 henrys. The cost of a 10-henry 4-ampere choke insulated for the full supply voltage end-to-end would be quite high, and since this system will always be run up slowly we do not require a choke of full voltage rating. Therefore L_1 was specified to withstand 20,000 volts rms end-to-end; this was expected to take care of normal ripple and the load voltage swings, with an adequate margin.

The case of L_1 is oil-filled and air-cooled. The coil is made in two pies connected in series, the beginning of each connected to core and case. It is wound with number 13 paper-enamel wire, with 0.01-inch 100-per-cent rag insulating paper between windings. The core is made up of four Hipersil loops, each $3^1/_8$ inches by $2^5/_{16}$ inches in cross section. Maximum flux density (d-c plus a-c) is 16,000 gausses. It is a linear reactor, most of the reluctance being in the air gap. Its test inductance is 16.3 henrys, its cold d-c resistance is 16.6 ohms. It is protected by a spark gap, which is normally set to break down at 28,000 volts peak. Our attention was first drawn to the problem of abnormal ripple voltage by the firing of this spark gap as the voltage was raised under load.

The authors agree with Mr. Halloran that there is a definite need for improved standards on electronic power converters.

A Nonarmored Submarine Telegraph Cable

Synopsis: Most of the world's submarine cable mileage lies in soft ocean bottom where the customary armor wires are not required for protection of insulation against abrasion. An experimental length of unarmored cable having polyethylene insulation over a central conducting core of cadmium bronze sufficiently strong to permit of laying and repair has recently been laid. This paper describes the mechanical and electrical design features, the problems encountered in laying and repair at sea and their solutions.

THE IDEA of omitting the steel armor wires of deep-sea cables has been in the minds of ocean-cable engineers for a good many years. Necessarily, a cable must be of such construction mechanically that it can be laid on the ocean bottom in sound condition. But once there, a cable lying in the silt of which the ocean floor is composed at depths of the order of one thousand fathoms is subject, under normal conditions, to virtually no physical disturbance, and hence may be presumed to require no extraordinary mechanical protection. It is only the physical stresses imposed on cable during the laying and repairing processes which have made it necessary to include a heavy, expensive steel sheathing in the construction of deep-sea cables. Therefore, engineers have reasoned, cable companies pay a sizable proportion of their deep-water-cable costs solely to put cables on the bottom, not to keep them there. One logical approach, then, to the ever-present problem of reducing cable costs is quite conceivably to be found in the omission of the sheathing. Unfortunately, however, the lack of appropriate materials hitherto has made it impossible to reconcile essential physical and electrical requirements in such a way as to construct a practical, economical cable.

A submarine telegraph cable for deep water service must have several diverse properties, as follows:

1. It must have sufficient tensile strength to support the dead weight in sea water of the length of cable between the ocean bottom and the laying ship, plus the live load caused by the vertical movement of the ship on the ocean swell, at depths that might vary from 1/2 or less to $2^1/_2$ nautical miles, and sometimes more, as the laying operation proceeds. The necessary relation between the strength of the cable and its weight in sea water is expressed as the so-called "cable modulus," which is defined as the ratio of the breaking strength of the cable to the weight in sea water of a nautical mile of the cable. The value of this modulus thus represents the length of cable in nautical miles which, when suspended vertically in sea water, is self-supporting. The required minimum value for modulus will vary with the maximum depth in which a cable will be laid. The safety factor will be given by dividing the modulus by the depth.

2. It must possess sufficient radial compressive strength to transfer the load represented by the weight of cable below the ship onto the drum and sheave over which it is payed out, without mechanical failure or permanent distortion of its component parts. That property which is the measure of ability to resist such forces is commonly called, when applied to a single material, the modulus of compression. For a composite structure like an armored cable, however, the usual definition of modulus is not applicable, and consequently such an attribute has never been quantitatively assigned thereto. For the relatively simple structure of a nonarmored cable, the value of modulus possessed by the outer covering is of great importance and must be considered, since the entire tensile load is being carried by the central member of the cable.

3. It must be of such construction mechanically that sudden changes of tension thereon do not produce distortions such as kinking and knuckling. The former is evidenced by the formation of small loops along the cable as a result of severe twisting about itself, and the latter by the ejection of the conductor from the insulating envelope as a result of the formation of a sharp bend in the conductor. Both of these phenomena result in cable failure: a bad kink will usually cause the conductor to part when tension is regained, and a knuckle ruptures the insulation immediately to produce a fault to ground.

4. It must provide all the electrical properties essential to its operation as a transmission line for telegraphic communication. The so-called "speed of signalling" of a telegraph cable, that is, the maximum rate at which character impulses can be transmitted with sufficient intelligibility, depends primarily upon the capacitance of the insulation and the resistance of the conductor. It is the product of these two parameters that is known as the "time constant" of an electric circuit, and, in earlier days, when applied to cables, was called the "KR Law," which stated simply that the signalling speed was inversely proportional to the product of d-c resistance and inductive capacitance. So propounded, it neglected skin effect, inductance, and conductance, which, at the frequencies of transmission then employed, was a good enough approximation; and, as a matter of fact, still is. Therefore, any appreciable length of cable spliced into an existing line must possess a unit KR value no greater than that of the line, if it is not to slow down the cable circuit as a whole, that is, produce a decrease in the signalling speed employed.

The insulating material of a cable also possesses an electrical parameter that has no effect on signalling speed unless its value is so small as to cause the conductance, ordinarily insignificant, to become large—dielectric resistance. It is, nonetheless, a very important property, for it is used as a measure of insulation quality throughout the life of a cable. The first warning of deterioration and impending failure of the dielectric is usually given by abnormal behavior of the galvanometer in the measurement of electrification current. Such a condition can be discovered, moreover, long before it affects transmission.

5. Once laid, it must be inert in the sea water in which it is immersed. The insulating material surrounding the conductor must deteriorate neither physically nor electrically at a rate rapid enough to interfere with successful operation within a period of time that, in the ocean-cable art, is counted in decades. In deep water, a cable life of more than 50 years is not uncommon. Physical instability, in so far as it has no direct effect on the electrical characteristics and does not act to change them, can be tolerated, but only to a limited extent. For example, if a cable loses its mechanical virtues so rapidly that it cannot be raised to the surface within a reasonable time after being laid, repairs are difficult to make and a fault could result in expensive replacement. On the other hand, under no condition can electrical instability be tolerated, for so long as it exists the cable is an operational liability. If resistance and/or capacitance increase with time, compensatory changes must be made in terminal networks and amplifiers, which can become expensive. When they become impossible, replacement of the cable is the only alternative to the continuance of reliable communication.

It is apparent from a study of these requirements that the omission of the steel wires from the outside of a deep-water cable presents some interesting mechanical problems. First, it is these wires that give the cable its effective tensile strength, for they are of high-carbon relatively low-elongation steel. The conductor, the only other metallic member, is of soft-

Paper 53-163, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted October 22, 1952; made available for printing December 5, 1952.

C. S. LAWTON is with the Western Union Telegraph Company, New York, N. Y. L. H. HUTCHINS, JR., is with the Simplex Wire and Cable Company, Cambridge, Mass.

drawn high-elongation copper and, therefore, contributes substantially nothing thereto. Hence the task of supporting the weight of the cable in suspension falls entirely on the steel. Second, since these wires constitute a helical sheath that completely encloses the core (which is the term applied to the insulated conductor), they serve efficiently as a protective barrier against radial forces. Hence they furnish the cable with the radial compressive strength essential to its laying. The sheathing also poses a minor electrical problem, for, being metallic, the wires help to conduct the earth-return currents and thereby influence the form of the sea-return path. Thus not only circuit resistance but inductance as well is affected by their presence. A cable without this steel armor, then, must be so designed that all these problems are solved with practicality and economy; and it was the commercial production of two recently developed materials that made it possible to do so.

One obvious means of eliminating the outer sheathing wires is to combine as many of their functions as possible with that of the central conductor, and thereby cause the conducting member to serve also as the strength member. The complete cable need only consist, then, of an inner metallic material and an outer insulating material; provided both of them, individually and co-operatively, possess the characteristics imposed by the demands of the service.

With the entire responsibility for supplying the tensile strength of the cable falling on the conductor, the mechanical arrangement of the elements thereof must be given careful consideration. The simplest structure is of course a single, solid wire, but unfortunately it is not a practical one. The possibility of flaws, although remote to be sure with the present high development of the art of drawing and heat treatment, must nevertheless be considered. Also, since joints between coil lengths of bare wire could not be made by welding or brazing, because the high temperatures necessary would change the physical characteristics, and a mechanical-type joint cannot be insulated by an extrusion machine, an excessive number of finished-cable splices would be necessary.

With a solid wire ruled out by reason of mechanical limitations, it becomes necessary to design a conductor made up of several strand elements, and so disposed that the tensile strength of the total area of conducting material is most efficiently realized, with respect to its weight. The most common method of stranding is to spiral six wires, or strands, around a central one, all being of equal diameter. Such a construction, however, is very liable to place a disproportionately large share of the total load on the center strand, by reason of its position within the structure, and result in a reduction of ultimate strength by as much as two-sevenths of the available total. A stretched or ruptured center strand would cost one-seventh, and a brazed surrounding strand another seventh, assuming they occurred at the same cross section, which is quite possible. Adequate spacing of brazes in the individual strands during fabrication would have to be specified, else the conductor could be further weakened to the point of inutility. Suppose, instead, the conductor is arranged as an annulus of n strands of uniform cross section in a single layer. With this configuration, each strand is subjected to the same forces as every other strand and the minimum strength developed can be no less than $(n-1)/n$ fractional part of the possible total, and this at a point where a single-strand joint occurs. The final detail of the mechanical design then becomes the determination of a practical value for n, not a difficult decision to make. An annulus of ten wires was decided on, on the basis of:

1. Feasibility of manufacture, in that appropriate machines were available for the stranding operation.
2. Adequacy of numbers, for it was essential that a sufficient number of strands be present to cause a reasonable reduction on the total available tensile strength at points of strand brazes.
3. Ease of splicing, because there would not be so many strands that complete-conductor (or finished-cable) splices would be exceptionally difficult to make.

With a fundamental configuration decided on, the next step in the design of the nonarmored cable was to make a complete electromechanical analysis of all the parameters of the conductor and dielectric affecting the performance of the cable. Once those were established, it was only necessary to decide on the values of speed and modulus that were considered essential for the cable to possess. A speed constant was selected comparable to that of existing transatlantic telegraph cables. In the selection of the value of modulus, however, present practice could not be used as a criterion. The modulus of armored cables usually runs above 7 nautical miles, not because they are designed to be laid in such extreme depths, but because the armor wires, being exposed to the ravages of the salt water, corrode in the course of time and consequently lose their strength. Therefore, if a ship is to be able to raise the cable to the surface several years after it is laid, within its normal life span, in order to repair a fault, allowance must be made for this diminution in modulus by making it larger than necessary when new. A nonarmored cable, on the other hand, has its strength member within the insulating sheath, completely protected from the action of the sea. Hence, no loss in modulus need be designed for, and the initial value can be as small as is adequate to provide for a reasonable factor of safety during laying and/or recovery. Since deep-sea cables are rarely laid in depths exceeding $2^{1}/_{2}$ nautical miles in the north Atlantic, that value appeared to be a safe maximum to use for the dead weight. More or less arbitrarily, a figure of two for the combined live weight and safety factor was selected, producing a value of five for the modulus.

The one remaining problem, now, in the complete design of the unarmored cable is the determination of the proper materials for the conductor and dielectric. The material selected for the conductor was cadmium-copper, 1 per cent by weight cadmium and 99 per cent copper, having a tensile strength of 90,000 pounds per square inch, a conductivity of 80 per cent International Annealed Copper Standard, and a specific gravity of 8.89 based on pure water. Not only does cadmium-copper (also called cadmium-bronze) possess a remarkable combination of strength and conductivity but it also

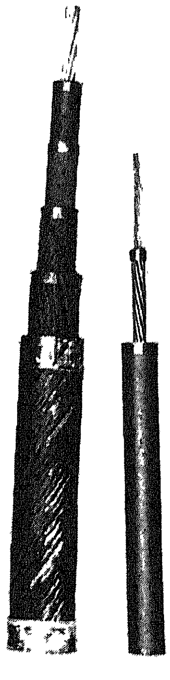

Figure 1. Armored deep-sea cable (left) and nonarmored cable (right)

possesses another extremely useful property—high fatigue resistance—which imparts to it exceptional torsional strength, or the ability to withstand considerable twisting and bending without failure.

The essential properties of the insulating material are its specific gravity and dielectric constant. Actually, not much choice is presented in the selection of a suitable insulator, for only one material, polyethylene, is currently available that makes it possible to construct a cable that is at once technically and economically practical. With a specific gravity of 0.925 and a dielectric constant of 2.28, polyethylene meets all other physical and electrical requirements. It has good compressive strength, good abrasion resistance in heavier walls, fair resistance to cold flow compared with other types of submarine insulations, and an exceptionally low rate of water absorption. It possesses an amazingly high resistance constant, high dielectric strength to both alternating and direct voltages, and low a-c conductance or loss factor, not in themselves of first order importance, but very useful attributes.

To test the new design under service conditions, Western Union decided to construct about 20 miles for insertion in a working cable. Although designed for transatlantic use, one of their coastwise links was chosen for the test because of its easy accessibility, and because a landline fall-back facility was readily available in case of trouble. The first nonarmored cable was manufactured in May of 1950, and had the following construction and constants:

1. 17 nautical miles—type *D-485/600* bronze and polyethylene nonarmored deep-sea ocean telegraph cable.

2. Conductor number 6 American Wire Gauge (AWG) (approximate)—ten number 16 AWG (0.051 inch) hitenso *BB-961* hard cadmium-bronze wires around a polyethylene thread of 0.128-inch diameter, 3.00-inch left-hand lay (preformed and postformed).

3. Wall, 0.180 inch = 0.580 inch insulating diameter polyethylene.

4. Cable modulus = 5.05 nautical miles.

5. Speed constant = 0.69 ohm-microfarad per nautical mile of cable length.

Figure 1 illustrates the physical comparison between the new cable and a conventional transatlantic-type armored cable embodying standard practices.

Table I. Comparison Between Conventional and Nonarmored Telegraph Cable

	Armored		
	Coast-wise	Trans-Atlantic	Non-armored
Diameter, inches	0.90	1.04	0.58
Weight in sea water, pounds per nautical mile	1,950	2,690	360
Breaking strength, pounds	17,250	20,400	1,800

Three fundamental problems arose in connection with the proposal to repair breaks in existing cable lines by the insertion of a nonarmored type of cable, as shown by Table I which gives a comparison between typical conventional armored deep-sea telegraph cables and the nonarmored design. The problems arising were:

1. Handling nonarmored cable with ship's machinery designed for conventional types is like trying to play a trout with gear designed for tuna. The pull necessary to revolve the cable drum with driving gears de-clutched and brakes lifted is 600 or 700 pounds and the usual ship's dynamometer is completely insensitive to tensions below 1,500 pounds. Repair ships like the *Lord Kelvin* are equipped to pay out cable over the bow, but the danger of such light cable fouling the ship's propellers (twin screws are standard in cable ships for maneuverability) obviously made it impractical to pay out the nonarmored cable over the bow.

2. The new cable, having a breaking strength far below that of steel-armored cables, does not possess sufficient tensile strength to support, in a depth of water for which it is designed, the weight of such a length of armored cable. Hence, how may this light, relatively weak cable be spliced to the heavier one, and the combination successfully lowered to the ocean floor?

3. The new cable, having a specific gravity in sea water considerably below that of old cable, will sink far more slowly. Hence, at what laying speed will it be necessary for the ship to run, in order not to trail the cable too far behind it?

As a solution of the first problem, a light, easily-portable paying-out machine was constructed and installed aft, together with a more sensitive brake and dynamometer. A paying-out drum of 39 inches in diameter, equipped with a fleeting knife, was used. It could have been even smaller. The width of tread was 6 inches, which was ample. A duplicate of this steel casting was mounted on the same shaft to serve as a brake drum, fitted with an external steel band having a molded segmented lining. Water cooling was avoided by the simple expedient of using a brake of ample area to dissipate the heat generated. The brake lining provided a frictional coefficient that remained substantially constant at all speeds, including the static condition. A lever arm was provided for loading the brake with weights. The frictional drag of the cable coming up from the ship's tank through bell-mouths and around roller leads was found to be enough to ensure tightness of the turns on the paying-out drum, and although means were provided for putting additional drag on the cable leading onto the drum, they were not used. From the drum, the cable passed through a dynamometer of conventional cable-ship type, but constructed to a much smaller scale, so as to be correspondingly more sensitive. Leaving the dynamometer, the cable left the ship by way of a stern sheave, also 39 inches in diameter, mounted directly abaft the paying-out gear and overhanging the after rail.

Coming to the second problem, consideration was given to buoying the first splice but this would have meant leaving slack in the cable when the buoy subsequently was removed and the bight of cable was dropped. While not serious for an experimental job, this would be unacceptable as a regular practice, both transmission-wise and economically. Therefore, it was decided to interpose between the steel-armored and the nonarmored cables two intermediate designs that would make the transition less abrupt by providing a tapering of strength and weight along the section. The first of these was constructed as follows:

1. One-half nautical mile (3,044 feet)—type *D-485/600–24/13* cadmium-copper and aluminum-armored deep-sea cable.

Over finished nonarmored cable apply:
One 70-pound cutched jute serve, applied wet
Twenty-four number 13 British Wire Gauge (BWG) (0.095 inch) type *56S-H* aluminum-alloy wires (preformed)
One 17/3 impregnated jute serve
Over-all diameter = 0.990 inch.

and then spliced to the second:

2. One and one-half nautical miles (9,131 feet)—type *D-250/430/600* copper, steel, and polyethylene nonarmored transition cable.

Conductor number 6 AWG (approximate)—One strand, 0.117-inch not-tinned copper; Ten strands, 0.051-inch improved plow steel around; 3.00-inch left-hand lay (preformed and postformed)
0.180-inch wall = 0.580-inch diameter polyethylene

which was in turn joined to the 485/600 nonarmored cable at the factory prior to shipment. Table II gives a comparison of the four types involved in this experiment.

The moduli between cables become 5.2, 4.3, and 3.2 nautical miles in passing from steel-armored cable through the transitions to the nonarmored cable, which

Table II

Cable	Breaking Strength, Pounds	Weight in Sea Water, Pounds per Nautical Mile	Modulus, Nautical Miles
Steel armored	17,250	1,950	8.8
Aluminum armored	10,000	1,150	8.7
Copper and steel	5,000	560	8.9
Cadmium-bronze	1,820	360	5.0

proved to be satisfactory for the initial installation in 1,200 fathoms of water.

The solution of the third problem involved first the calculation of the rate at which this new cable would sink into the sea, and second the determination of the relationship between the angle of inclination of the cable with the water surface and the speed of the laying ship. In both cases, only theoretical studies were made, for the equipment necessary for performing the proper experiments was not available. Moreover, precise results were not needed, but merely an idea of the order of magnitudes involved. These calculations showed that pay-out could probably be made at a speed not too much slower than normal, with a reasonable laying angle prevailing.

Echo sounding showed the average depth along the proposed route to be about 1,250 fathoms. Sampling indicated soft mud bottom.

In order to make possible the paying-out of the transition pieces over the ship's bow and the nonarmored cable over the stern, special preparations had to be made. These consisted of leading the end of the first transition piece up from the ship's tank, through the after paying-out gear and dynamometer, thence over the stern sheave, and forward around the starboard side of the ship outside everything (even the ship's rigging) and in again through the bow sheave frame. Via this route, both transition pieces and a short length of nonarmored cable were transferred to the ship's forward well deck, where they were coiled down. The next step was to reverse the coil in order to bring the end of the first transition piece to the top, ready for splicing to the cable in circuit. Meantime, the bight of nonarmored cable was secured along the outside of the ship with rope yarn lashings which could be cut away quickly.

The working cable was hooked, cut, and raised on a grapnel on the east end of the proposed insertion, tested through to Canso, Nova Scotia, suitably prepared for splicing, and temporarily buoyed off. No attempt was made to recover the cable lying on the bottom over the distance within which it was to be replaced, the ship proceeding directly to cut and raise the cable to the westward near the position for splicing on and commencing the pay-out.

The suspended end was brought inboard over the center bow sheave and the starboard picking-up gear and led to the splicing area. After testing through to Hammel, Long Island, the first ship splice (steel-armored to aluminum-armored cable) was made in the conventional manner, by overlapping the steel sheathing with the aluminum sheathing.

The pay-out was begun under a tension of 23 hundredweight, with the first splice passing over the bow without incident. As more of the aluminum cable went out, tension was gradually decreased so that by the time the splice to the second transition piece went over the bow, the tension was only 16 hundredweight. From there on, the tension was tapered off until the splice to the regular nonarmored cable went over. As the cable in suspension gradually became lighter, the angle at which it entered the water diminished, bringing the point of entry farther and farther aft along the ship's starboard side. In order to reach the very low tensions required, it was necessary to keep the paying-out drum in gear and drive it with the engine rather than depend upon the brake. Adjustment of tension near the tail end of the aluminum piece was a matter of judgment as the dynamometer came to rest against its bottom stop before the splice was reached.

As the last of the regular nonarmored cable coiled forward left the deck, the ship was stopped and the cable was held on a manila stopper. The nonarmored cable was lifted off the paying-out drum and dynamometer, and as the stopper rope was eased away, the bight passed through the bow-sheave frame. The lashings along the side were cut one by one as tension came on them until, with the cable suspended freely from the stern sheave, the manila stopper rope was cut away and the pay-out was resumed from aft.

Tension was maintained in the region of 420 pounds, which was about 7 per cent less than the vertically-suspended weight at a depth of 1,250 fathoms in order to avoid residual cable tension on the bottom. A paying-out speed of 4 knots was found to be about the practical limit because the cable was emerging from a small after tank, and the particular lead employed tended to produce some slight whipping.

At this speed, the cable entered the water at an angle of approximately 10 degrees with the horizontal. The buoyed east end was reached with about a mile and a half of cable remaining in the tank. The buoy had been set to the westward by the current, so that in picking up the moorings, the ship had to move eastward, thus making it necessary to continue paying-out the nonarmored cable. By the time the end of the steel-armored cable has been raised to the bow on the buoy moorings, all but 200 fathoms of the nonarmored cable had been paid out over the stern.

With the cable held on a stopper, the surplus was cut off and the end was then transferred to the bow around the outside of the ship for final testing and splicing. The final splice was made by first serving the last few fathoms of nonarmored cable with cutched jute, then carrying the steel sheathing wires of the armored cable well beyond the core joint. The splice so made was then served over with tarred hemp spun yarn in conventional fashion, the bight was lowered over the bow on manila rope and the latter cut away, thus releasing the bight of cable and completing the laying operation.

◆

Discussion

J. J. Gilbert (Bell Telephone Labs., Inc., New York, N. Y.): The nonarmored cable represents a notable departure from submarine cable conventions and the authors are to be congratulated for their ingenuity and courage in engineering the project that they describe. Steel armor has served a useful function through the years, but at a price. The conventional requirement is that the armored cable shall be strong enough to support itself in a depth about three times that in which it is to be laid. To meet this requirement in the case of a deep water cable it is necessary to assign a large part of the strength of the armor wires to the support of the armor itself so that the support furnished to the remainder of the cable is marginal and a lot of steel is needed. This is not only a hardship from the cost standpoint but the tensions involved in laying and recovering such heavy structures are not healthy for the electrical heart of the cable.

The nonarmored cable described in the paper seems to offer a happy solution to these problems. The fact that the strength member is put in a position where it is not subject to corrosion and abrasion is properly emphasized by the authors as one of the advantages of the new structure. This should permit a reduction in the conventional safety factor but the extent of this gain can presumably only be determined by further trials in deep water. From the standpoint of life, conditions certainly look favorable for the nonarmored cable. Time, of course is needed to confirm this. The present trial will be watched with great interest by the submarine cable community.

There is another aspect of the nonarmored cable that may become of importance in cases where high speed operation is employed. Theory indicates that at the higher frequencies in the telegraph range the return conductor of the conventional cable, comprising the armor wires and sea water in parallel, has a higher resistance and a lower inductance than if the armor wires were absent. At high frequencies the nonarmored cable should therefore have superior transmission characteristics.

I. S. Coggeshall (Western Union Telegraph Company, New York, N. Y.): The insertion of a nonarmored sample within a section of armored cable was a necessary step despite its complications, it being evident that the laying problems involved would have to be met whether armorless cable is to be employed in the future either to replace old cable or to be laid as new between shore approaches. Attention will now undoubtedly be focussed on its usefulness for new, deep-sea cables of single conductor or coaxial types.

The exact nature of the sea bottom is surmised to be suitable for the laying of long stretches of unarmored cable in ooze; but there is just enough of an element of doubt as to the existence of rock outcroppings and suspension-fraught gradients to make the determination to lay a transatlantic unarmored cable, at a cost of several million dollars, a matter of courage and faith as well as of skill in design and manipulation.

Perhaps the author would care to comment on these features, as well as on the question regarding the vulnerability of unprotected polyethylene to the ravages of the teredo worm.

Kenneth S. Wyatt (Phelps Dodge Copper Products, Yonkers, New York): As a newcomer to the submarine communication cable field, I should hesitate to enter into this discussion were it not for long experience with polyethylene, which made this new cable possible. The complete elimination of armor represents a sharp break with tradition, and I can well appreciate the courage of the authors in this bold move. They have backed their judgment with installations of considerable magnitude (about 100 miles). It is a real joy to see such independent engineering thinking and action.

The new conception and the reasoning leading up to it are presented in a logical and clear-cut manner. Especially noteworthy is the ingenious method of avoiding a sharp transition from a stiff rigid cable to a light flexible one by tapering the stiffness with intermediate' types of cables.

The properties of polyethylene must be carefully examined to see if it is capable of withstanding the considerable strains to which a deep-sea cable must be subjected. Especially must we consider cold flow, which would permit decentralization of the conductor, abrasion resistance, and compressive strength. In 1945 I introduced polyethylene as a sheathing material for extra high voltage cables of the pipe-line type. The polyethylene sheathed single cores of several thousand feet length are wound up on reels sometimes weighing over 15 tons. The pressure on the polyethylene sheath of the inner turns is very high, yet no flow of the polyethylene has been noticed, nor has there been any trouble with between 100 and 200 miles of such cable.

Our Habirshaw Research Laboratories have done a lot of experimental work on polyethylene. With regard to the possibility that the conductor of Mr. Lawton's cable might cut through the insulation as it passes over the shieve, the following test might be cited: a cable having a conductor of 0.125-inch diameter insulated with polyethylene to a diameter of 0.46 inch was bent over a mandrel 6.3-inch diameter, and a 63-pound weight hung on each end, giving a pressure on the insulation of 160 pounds per square inch. After $7^1/_2$ hours at 98 degrees centigrade, no decentralization could be observed. In the case of the new submarine cable the pull is 420 pounds, giving a vertical component of only 73 pounds. This is far too low to cause cutting or cold flow especially at ambient air temperatures.

Polyethylene has excellent abrasion resistance because it is self-lubricating. Short lengths of heavy power cable, one with lead sheath, and others with a polyethylene jacket over the lead, have been dragged down a concrete road at 3 miles per hour. After 1/2 mile the lead sheath is in bad condition but the polyethylene is merely scuffed. However, polyethylene slices rather easily.

The pressure at a depth of 1,250 fathoms approximates 3,400 pounds per square inch, the temperature being perhaps 40 degrees Fahrenheit. It is difficult to obtain exact figures for the compressive strength of polyethylene, but we believe 3,000 to 4,000 psi at 20 degrees centigrade to be reasonable. At 1,250 fathoms it seems the pressures are approaching the ultimate compressive strength of polyethylene, especially as a certain amount of shear is involved.

For very great pressures we have been turning to a much harder material without any cold flow in the magnitude range under discussion, namely, flexible polystyrene (styroflex).

The new submarine cable has great promise for areas which are free from disturbances and where the bottom is smooth. It is an event of considerable economic importance.

C. S. Lawton and **L. H. Hutchins, Jr.**: A natural question has been raised as to the ability of unprotected polyethylene to withstand the ravages of the teredo worm which has caused a great deal of damage to unprotected gutta peroha insulation in the older cables, particularly in the more temperate zones. Frankly we do not know the answer. It is one of the things we are hoping to learn from this experiment.

However, two circumstances seem to justify a reasonable doubt that this cable will be attacked. The surface is so smooth and waxy that a worm would have a hard time getting started, and experiments have shown that materials susceptible to attack are more apt to be damaged when the worm can get in between two surfaces against which it can brace itself. (This, of course, is the case with conventional cable when there are openings in a sheath of armor wires separated from the insulation by a soft jute bedding.)

The other circumstance is that we have no proof that boring worms live in the greater depths of the ocean. Western Union's maintenance records do not disclose any instance of teredo attack in depths exceeding 1,000 fathoms, although covering thousands of miles of cable exposed for many years at these depths, much of which has no brass tape protection on the gutta percha. Adaptation of a boring organism to a habitat of practically nothing but soft mud and ooze, although possibly achievable through natural processes, presupposes a motive. If we assume that a motive exists, though obscure, what happens to the boring function with nothing harder than mud to work on? It seems likely that the organism itself will cease boring or move to another location. But this is only speculation and as such could turn out to be quite wrong.

Perhaps the best way of summarizing the matter would be to say that there was more to be learned by omitting teredo protection than by providing it on this experimental length.

With reference to Mr. Wyatt's discussion, it should be pointed out that the only installation to date is somewhat less than 20 miles in length. We wish it could have been 100.

The most common bottom temperatures at depths exceeding 1000 fathoms in the North Atlantic are between 35 and 40 degrees Fahrenheit the year around. Under these conditions much greater resistance to abrasion is afforded by polyethylene than at higher temperatures. Notwithstanding that the nonarmored cable compares favorably with armored cable in resistance to abrasion under service temperatures and where bearing pressures are proportional to weights in water, it is not considered suitable for use where there are bottom currents such as exist in shallow water. Currents which would not move a heavier cable at all could cause movement in a nonarmored cable which sooner or later would lead to failure, either through chafing of the insulation or vibratory fatigue of the conductor, although as already noted, cadmium copper has excellent resistance to fatigue failure.

As far as the effect of hydrostatic pressure is concerned, there is no difference between the force exerted on conventional cable core and nonarmored cable. The force being equal all around the periphery, there should be no tendency to cause displacement of the conductor. Polyethylene-insulated cable has been successfully laid in nearly 3,000 fathoms without developing any hydrostatically induced weakness.

Of far greater concern is the tendency of such cable with conventional armor to fail through knuckling of the conductor upon the release of the high tensile and torsional stresses imposed upon it during laying and repairing operations. Ingenious means have been adopted for overcoming this tendency which give promise of being successful but the fact remains that the weight of the armor is a great handicap: so much so that it rarely, if ever, has been possible to pick up conventional cable from depths exceeding 1,000 fathoms in fit condition to re-lay in deep water, even when it has suffered little or no deterioration from exposure to the sea water. That these defects are not caused by hydrostatic pressure is obvious because they can be duplicated readily by tests on shore under atmospheric pressure.

Not the least of the advantages of nonarmored cable lies in the almost complete elimination of torsional forces because of the close grouping of the helically shaped strength members about the neutral axis, and the fact that most of the elongation of the conductor which occurs upon the application of tension is achieved through distortion of the conductor helix, rather than through any reduction in cross-sectional area of the individual wire strands. (It is the stressing of soft copper beyond its low yield point in conventional cable which causes the knuckling tendency when the polyethylene pulls back strongly upon release of tension.)

No obstacle is seen to the design of nonarmored coaxial cable, but as this type usually is associated with submerged repeaters, reinforcement to provide enough strength to carry them to the bottom and raise them for servicing will be required for a reasonable distance on each side of each repeater, except possibly in the case of articulated repeaters of very light weight, and the economic advantage of the nonarmored design will depend upon the spacing of repeaters and their weight in sea water.

That this experiment has aroused so much interest is not too surprising. At a time when there are so many indications of a genuine resurgence of interest in ocean cables as the oldest and most dependable medium for international communications, anything which may affect their cost, their longevity and ease of repair at great depths is bound to be of real concern to those of us in the communications field who are aware of the spectacular advances which are now being made in transmission technique.

There is every reason to believe that this cable can be recovered and re-laid without impairment of its strength or coiling properties; and after a test of about 3 years (it has been in circuit almost 17 months now), assuming it still to be electrically sound, it is planned to do just that, utilizing the opportunity to examine every inch of it for evidence of teredo attack, chafe, and so forth, of course, and relocating it in another area where conditions are known to be none too good.

It is hoped that it will be possible to submit a further report at that time.

Accurate Radio-Frequency Microvoltages

MYRON C. SELBY
NONMEMBER AIEE

Synopsis: The questionable accuracy of radio-frequency microvoltages has been of great concern to the radio field for many years. There is an urgent need for a simple, yet reliable, source of microvolts for measurements in general and for radio receiver sensitivity determinations in particular. Extremely simple devices, which seem to satisfy that need most adequately, were recently developed. They are sources of potential drop obtained across a known resistance through which known currents flow. These devices provide constant voltage sources of accurate microvolts over a range of 1 to 10^6 and wider, at all frequencies to 300 megacycles and higher. They are adaptable for balanced as well as for unbalanced sources. Their electrical constants are simply determined by using known direct voltages and currents. Basic principles, design features, and applications are discussed.

THE RADIO and electronics field has been facing the problem of accuracy of radio-frequency (r-f) microvoltages since sensitivity of radio receivers came into prominence as a competitive index of performance. The reasons for the continued existence of this problem are too well known. There is no need to discuss them other than perhaps to indicate the major ones: namely, 1. the uncertainty in voltage source and load (receiver input) impedance values, 2. the uncertainty in performance of attenuators over wide frequency ranges and attenuations of up to 100 decibels and in many cases of higher values, and 3. the uncertainty in the accuracy and stability of devices monitoring the input voltages to the attenuators.

Considerable progress was apparently made as time went on, and a large section of the field has managed to attain high accuracies despite these difficulties. A recent poll of the field, instigated by the National Bureau of Standards in 1951 to determine the urgency of this problem, revealed the following status. Of about 70 standard voltage-generator manufacturing and applying laboratories (six of them in United Kingdom and France) about one-half believed they had available 1 microvolt at frequencies to 1,000 megacycles with an absolute accuracy of 30 per cent or better. The indicated accuracy was naturally better at lower frequencies. The other half was uncertain of their values in various degrees, in many cases exceeding 100 and in some 200 per cent. About one-half of them desired absolute accuracies of 0.5 to 6 per cent for all frequencies to 1,000 megacycles; the rest desired accuracies of 50 per cent or better.

The critical need of reliable tools to supply or measure microvolts accurately was therefore still very much in evidence. Devices apparently fulfilling this need most satisfactorily were recently developed. They seem to meet the most persistently demanded feature of a standard of microvolts, namely, extreme simplicity and reliability. These devices, referred to, for want of a better name, as "Micropotentiometers,"[1] are described later.

General Description of the Micropotentiometer

BASIC REQUIREMENTS AND PRINCIPLE OPERATION

In searching for a source of accurate and reliable r-f microvolts the following basic requirements seemed indispensable or highly desirable:

1. The output voltages of the source had to be known irrespective of loading conditions, that is, a constant voltage source was necessary.
2. Freedom from frequency corrections was essential at least over reasonable frequency ranges.
3. A reliable, simple, and rugged physical construction with a very minimum of component parts was most desirable.
4. The simplest and a very minimum of calibration requirements were essential.

All of these requirements seem to be satisfactorily achieved with the Micropotentiometer. In basic principle it is a source of potential drops obtained across a known resistance through which known currents flow. These resistances are of the order of milliohms (for microvolt levels), and therefore constitute an essentially zero source impedance (constant voltage source) for all practical present-day needs. A cardinal requirement of

MICROPOTENTIOMETER SECTION OF SYSTEM
CONDUCTIVE ANNULAR FILM SHUNTING THE LINE

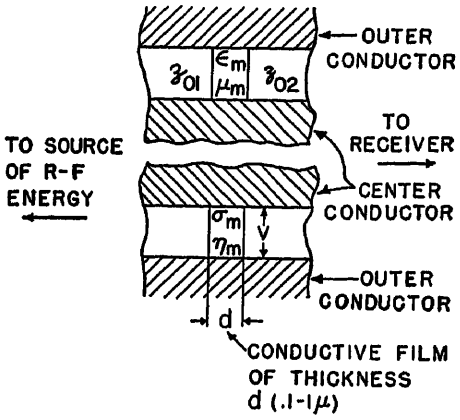
Figure 2 (right). Section of Micropotentiometer showing position of annular element in a low dielectric coaxial line



this impedance, as previously implied, was that its reactive component be negligible compared with its resistive component. This suggested the annular type of resistance element construction. The equivalent circuit of the Micropotentiometer together with the input and output circuits is that of a coaxial line shunted by a conductive film in a plane normal to the axis of the line, as shown in Figure 1. A source of r-f energy supplies current to the Micropotentiometer section of the system through a coaxial line and the voltage output V, from the Micropotentiometer, available across the annulus, is fed to the receiver either directly or through an output line. To a very good approximation the output voltage V is simply the product of the input line current entering the annulus and the d-c resistance of the annulus.

To show that this is true the transfer impedance of a thin conducting film placed as already indicated (see Figure 2) will be considered under the following assumptions:

1. The characteristic impedance of the coaxial lines is of practical magnitude, for example, any value between 20 and 200 ohms.
2. The bridging film has a finite high conductivity approaching that of silver, copper, platinum, and so forth. Perfect contact is assumed between the film and the coaxial conductors.
3. The diameter values of the coaxial lines are very small compared with a wave length.
4. The coaxial line terminating impedance (that is, the receiver input impedance) is of such a value that the impedances along the line, beyond the film, remain fairly high, that is, 1 ohm or higher.

The general field-theory approach[2,3] treats the solid metallic disk (or annulus) as a section of a coaxial line with an intrinsic impedance corresponding to that of the particular metallic medium. Under the preceding assumptions the fields in all the coaxial line sections are that of the dominant transverse electromagnetic (TEM) plane wave mode of propagation.

Let ϵ_m, μ_m, σ_m and η_m designate respectively the permittivity, permeability, conductivity, and intrinsic impedance of an infinite metallic medium. Under the preceding assumptions

$$\omega\epsilon_m << \sigma_m$$

where

$$\omega = 2\pi f$$

For copper at 1,000 megacycles

$$\omega\epsilon_m = 0.17 \quad \text{mhos per meter}$$

as against

$$\sigma_m = 5.7 \times 10^7 \quad \text{mhos per meter}$$

Therefore[3]

$$\eta_m \cong (1+j)\sqrt{\frac{\omega\mu_m}{2\sigma_m}} \tag{1}$$

The propagation constant in the same medium is

$$\gamma_m \cong (1+j)\sqrt{\frac{\omega\mu_m\sigma_m}{2}} \tag{2}$$

The characteristic impedance of a coaxial line with a solid conductor as a propagation medium is

$$Z_0 = \eta_m \frac{1}{2\pi} \ln\frac{r_1}{r_2} \cong (1+j)\frac{(\omega\mu_m)^{1/2}}{2\sigma_m}\frac{1}{2\pi}\ln\frac{r_1}{r_2} \tag{3}$$

where r_1 and r_2 are respectively the large and small radii of the conductors.

The d-c resistance of the annulus of thickness d is

$$R_m = \frac{1}{\sigma_m 2\pi d}\ln\frac{r_1}{r_2} \tag{4}$$

and the depth of penetration is

$$\delta = \left(\frac{1}{\sigma_m \pi f \mu_m}\right)^{1/2} \tag{5}$$

Therefore

$$Z_0 \cong (1+j)R_m\frac{d}{\delta} \tag{6}$$

and

$$\gamma_m = (1+j)\frac{1}{\delta} \tag{7}$$

Using well-known transmision line theory, the output voltage V of a line section equivalent to the annulus terminated by an impedance Z_r is given in terms of the input current I_1 by

$$V_r = \frac{I_1}{\frac{1}{Z_r}\cosh\gamma d + \frac{1}{Z_0}\sinh\gamma d} \tag{8}$$

and the transfer impedance is

$$Z_m = \frac{V_r}{I_1} = \frac{1}{\frac{1}{Z_r}\cosh\left[(1+j)\frac{d}{\delta}\right] + \frac{1}{R_m}\frac{\sinh[(1+j)d/\delta]}{(1+j)d/\delta}} \tag{9}$$

In this application $Z_r >> R_m$, therefore for all practical purposes

$$Z_m = R_m(1+j)(d/\delta)\,\text{csch}\,[(1+j)d/\delta] \tag{10}$$

or taking the first three terms of the expansion[4]

$$|Z_m| = R_m\left|1 - j\frac{d^2}{3\delta^2} - \frac{7}{90}\frac{d^4}{\delta^4} + \ldots\right| \tag{11}$$

The absolute value of the transfer impedance is therefore equal to the d-c resistance of the annulus to better than

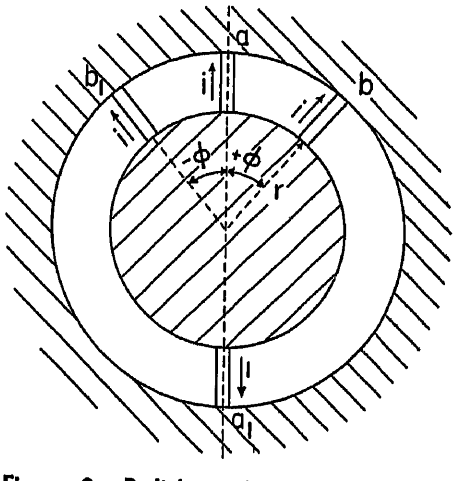


Figure 3. Radial conductor structure approaching that of a solid annular ring

B. Unit using glass bushing as insulator

1 per cent for $d/\delta \leq 0.5$, and

$$|V_r| = I_1|Z_m| \cong I_1 R_m \tag{12}$$

That this is true can also be shown in a simpler but less rigorous manner, as follows.

The input impedance Z_m' of the line section (Figure 1) having a metal as a dielectric and terminated in an open circuit or in an impedance $Z_r >> Z_0$ is

$$Z_m' \cong \frac{Z_0}{\operatorname{tgh} \gamma_m d} = \frac{R_m(1+j)^{d/\delta}}{\operatorname{tgh}\,[(1+j)^{d/\delta}]} \tag{13}$$

For sufficiently small values of d/δ therefore

$$Z_m' \cong R_m \tag{14}$$

Since for small values of d/δ the current in the annulus is uniform over its thickness to better than 1 per cent, the annulus can be treated as a resistance element is ordinarily treated at direct current, and the voltage drop across it is simply the product of its d-c resistance and I_1.

As was already mentioned, the success or failure of this device depended on the requirement of negligible reactance in the annulus. Therefore all possible substantiating evidence was investigated both analytically and experimentally.

In applying the lumped-circuit approach, the top limiting value of the inductance of an annular conductor carrying radial currents was derived as follows.

The annular ring can be looked upon as consisting of a large number of equal radial conductors of finite length and thickness, all connected in parallel. A square cross section may be chosen for these conductors and a maximum possible value of the ring inductance evaluated by computing the effective inductance of the system of radial conductors. Figure 3 shows four of these radial conductors starting at the periphery of the center conductor and ending at the outer conductor of a coaxial line. The coaxial conductors are at right angles to the radial elements and therefore have no mutual inductance with them. The return path for the current in the annulus is assumed far enough away to avoid any influence on the radial elements. Complete penetration of the current, that is, uniform current density in these elements is assumed at all frequencies. Consequently all deductions based on low-frequency analysis may be used at the higher frequencies at which current density remains essentially uniform.

Each radial element has self-inductance and mutual inductance with all the other elements. Assuming an even number of elements, for each element b on one side of a given element a there is another element b_1 located at an angular symmetry which will cancel the mutual effect of b with a. Thus the effective inductance of a will be

$$\begin{aligned} L_a = L_a' + M_{ab} + M_{ac} + \ldots + M_{ab_1} + \\ M_{ac_1} + \ldots + M_{aa_1} = L_a' + M_{aa_1} \end{aligned} \tag{15}$$

where $L_a{}^1$ is the self-inductance of element a and M_{aa_1} is the mutual inductance between element a and a_1 located diametrically opposite a.

Let d be the thickness of the element, and r be the radius of the inner coaxial conductor. Then the total inductance of the annulus, L_A, will be equal to the inductance of all the elements in parallel, or it may be considerably less than this value because of the additional parallel elements not accounted for, which complete the solid annular ring. Thus

$$L_A \leqq \frac{d}{2\pi r}\,(L_a' + M_{aa_1}) \tag{16}$$

The self-inductance of a square bar is[5]

$$L_a' = 0.002l\left[\log\frac{2l}{0.447d} - 1 + \frac{0.447d}{l}\right] \text{ microhenrys} \tag{17}$$

where d = thickness of the square bar in centimeters and l = its length in centimeters.

The mutual inductance between elements a and a_1 will have a negative sign, because they are connected in series bucking, and is given by[6]

$$\begin{aligned} M_{aa_1} = -0.002[(2l+2r)\log(2l+2r) + 2r \times \\ \log 2r - 2(l+2r)\log(l+2r)] \end{aligned} \text{ microhenrys} \tag{18}$$

Computations for a typical annular ring for resistances of the order of one milliohm, having

$l = 0.1$ centimeter
$d = 2.5 \times 10^{-4}$ centimeters
$r = 0.5$ centimeter, result in
$L_a \cong 0.45$ millimicrohenry
$M_{aa_1} \cong 8$ micromicrohenrys
$L_A \leqq 0.035$ micromicrohenry

The series reactance of this inductance is about 22 microhms at 100 megacycles which seems entirely negligible even at considerably higher frequencies, it being in quadrature with the resistive component. The actual series inductive reactance may be much lower, as already indicated, and seems still less important as the annular resistance is increased. The validity of the lumped circuit approach was verified experimentally. Equations similar to 16, 17, and 18 were used to compute the inductances of

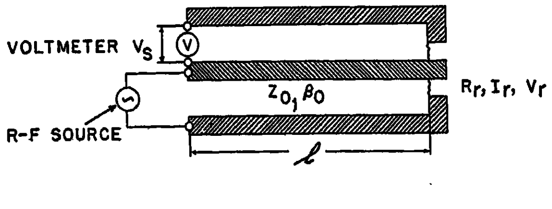

Figure 5. Schematic representation of "coaxial" type Micropotentiometer

symmetrical systems of radial tin (Sn) foil filaments of a centimeter in length and approximate width and thickness of 0.11 centimeter and 10 microns respectively, shorting the output end of a slotted measuring transmission line. The inductances were measured at 200 and 400 megacycles. Figure 4 shows a fairly good agreement between computed and measured values of inductances of these conductors, with a tendency of the measured values to diminish somewhat faster than the computed, with increasing number of filaments.

The only conclusive experimental evidence verifying the preceding analytical predictions was obtained by comparing voltage drops across annular elements with those of a voltage standardization bolometer bridge.[7] These results will be discussed later. Some further supporting evidence was found in the apparent failure to detect inductance in shorting disks of precision slotted transmission lines. None seemed to have been reported in the past anywhere in the field of slotted lines, resonance lines, nor in coaxial resonant cavities. However the impedance values here under consideration require a precision of measurement of voltage-node displacements of the order of a micron or better; such a precision was hardly available to anyone to date.

RANGES OF VOLTAGE AND FREQUENCY

The general conclusion that can be drawn from the preceding is that annular resistance elements of the type described can be used without frequency corrections over the entire ultrahigh-frequency range and higher, and indeed up to the frequency for which the metal-film thickness required is insufficient to maintain a homogeneous, continous metallic medium. This limit (about 0.05 of a micron) indicates that the top frequency of the Micropotentiometer application is dictated by the current indicators and higher modes of propagation rather than by the resistance elements.

At any frequency the resistance of the annulus will remain the same as at direct current to within 1 per cent or better as long as the thickness of the conductive film does not exceed one-half the depth of penetration at that frequency for a thick conductor of the same material. If the film thickness is equal to the full depth of penetration, there may be an error of about 3 per cent in the r-f output voltage. It is necessary to select materials of proper conductivity and choose annular diameters of proper ratios and practical values to obtain various resistances desired to a given top frequency. One might call attention to the fact that the resistance is a function of diameter ratios and not of diameter values. Thus annular resistances of a fraction of a milliohm to 1 ohm and even higher may be used over very wide frequency ranges.

The voltage range of a given resistance element is clearly a function of the power it can dissipate in a particular physical arrangement. However, the power levels in question are generally of such a low level and the annular films are in such close proximity to large and efficient heat conductors that the voltage range of a Micropotentiometer with a given resistance element seems limited at the present time by the current monitoring elements rather than by power dissipation of the resistance films. No appreciable resistance changes were observed on 1- to 10-milliohm silver elements for currents up to an ampere.

Any means to indicate current accurately and independently of frequency are usable with the Micropotentiometers provided they can be physically located in such a manner that the same current is passing through the annular resistor as through the current monitor. This condition becomes more difficult to fulfill as frequency is increased. However, the fact that the annular resistances are very low renders the application of conventional r-f current indicators considerably less critical than in their application with high resistance elements. Thus thermoelements and thermistors were successfully used, as will be shown later, and other bolometer type and thermoelectric elements are applicable for frequencies approaching 1,000 megacycles and perhaps higher.

The low limit of the voltage range is controlled by the smallest practical diameter ratios of the annular elements, by the conductivity of the materials, by the accuracy with which low d-c resistance values can be determined as well as by the accuracy with which low current values can be measured. For frequencies up to the very-high-frequency range the low limit to date seemed of the order of 0.1 of a microvolt; for higher frequencies it was of the order of 1 microvolt.

GENERAL DESIGN FEATURES

In designing assemblies of components and housing of Micropotentiometers only one somewhat critical requirement has to be fulfilled. The resistance films comprising the annular elements and having various thicknesses down to a micron and lower have to be in perfect continuous contact with the outside and inside conductors and must remain mechanically rugged and stable. Other requirements are of the ordinary variety which can be readily met. One of these requirements concerns the proximity of the current monitoring element to the annulus and is not critical because there is a current loop at the annulus; the current falls off as a cosine function with distance towards the current monitor (or r-f power source). This feature tends to equalize the current distribution along heaters of thermoelements as well, and thus extends the frequency range. For example, a distance of 2 centimeters from the resistive film to the current indicator may cause a 1-per-cent error at 300 megacycles. With thermistors as current monitors this question seems of no consequence, even over the entire ultrahigh-frequency range since thermistor beads having diameters of 15 mils can be placed right at the annulus.

Another noncritical requirement concerns the length of the output coaxial connector of the Micropotentiometers. This connector may be considered an integral part of the feeder supplying the standardizing voltage to a receiver or any other monitor. For best results the annular resistance film should be placed in the output plane of the Micropotentiometer and the connectors to the monitor and to the equipment being calibrated in terms of the Micropotentiometers should be mechanically matched. In case this cannot be done, then the annular resistance film should be placed as close as possible to the output plane. The accuracy will then depend on the length of the Micropotentiometer connectors and the input impedance to the monitoring feeder. To be more specific, the output of the Micropotentiometer may be affected in two ways. The first is the actual increase of the shunt admittance across the annulus; since the resistance of the latter is very low the probability of trouble from this cause is remote. The second is the transformation action of the short connector from the resistance film to the physical output plane which may contribute an error of several per cent in the ultrahigh-frequency range, depending on the monitor-feeder impedance. In the extreme case, if that impedance is infinite, there will be a cosinusoidal reduction of the voltage along the short connector as one travels from the output plane towards the annular film; for example, at 300 megacycles a connector 1.5 centimeters in length will have a voltage about 1 per cent higher at the output plane as compared with

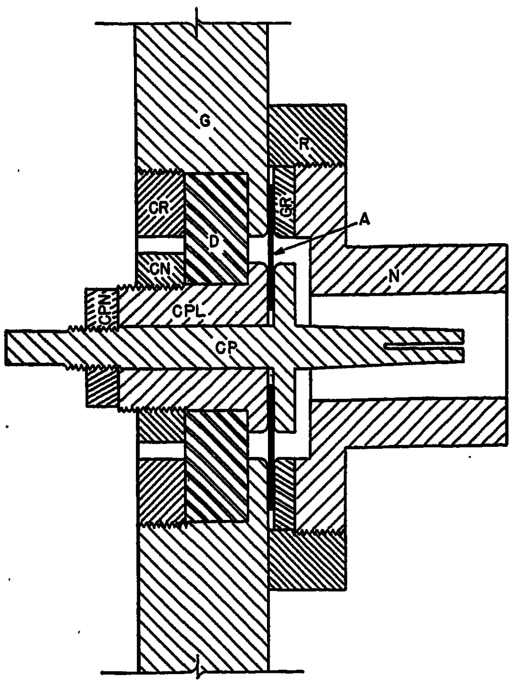

Figure 7 (left). Cross section of interchangeable Micropotentiometer resistance element assembly. Solid black line indicates resistance ring clamped between electrodes

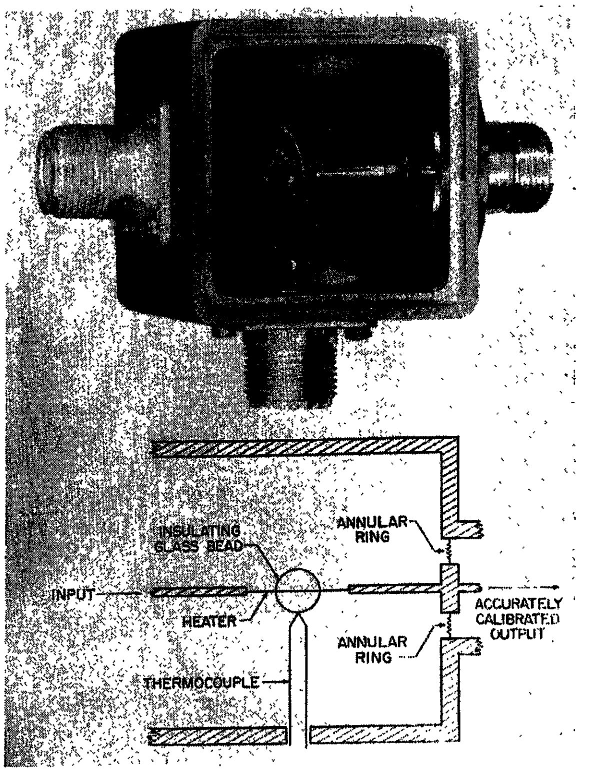

Figure 9 (right). Micropotentiometer employing a thermoelement as a current indicator

the standardizing voltage across the annulus. As the monitoring-feeder input impedance decreases, this error will be reduced and will be zero when this impedance is equal to the characteristic impedance of the connector.

One might point out here a practical advantage of these devices for universal standardization purposes. A known resistor of reliable r-f characteristics may be used as the coaxial center conductor of the output terminal. This would form a well-defined readily reproducible impedance of the source of standardizing r-f voltages when reliable voltage generators with given output impedances are required. Conventional standard "dummy antennas" may of course be used instead, with full certainty that the source impedance in this case is that of the dummy antenna only.

TYPES OF MICROPOTENTIOMETERS

The basic principle of the Micropotentiometers lends itself to balanced circuit applications as well as to unbalanced. Since development work, so far, has been limited to unbalanced requirements, only the latter are discussed here.

The only other classification of these devices as to general type, aside from the preceding, is based on current measuring methods. These affect the basic physical structure of the units. All units using thermoelements may be essentially of the same construction and may have interchangeable annular and current indicating elements to cover a wider voltage range. Insulated-type thermoelements preferably should be used. In this type the structure requires only the thermocouple output terminals in addition to r-f input and output terminals. On the other hand, types employing bolometers (for example thermistors) or directly heated thermocouples require either r-f chokes or d-c blocking condensers, and in some cases, both.

One type, radically departing from the preceding and having some desirable features, is a Micropotentiometer using a reliable voltmeter instead of a current indicator. Figure 5 shows this modification schematically. R-f power is fed into a section of an air or solid dielectric coaxial transmission line having negligible losses. A calibrated vacuum-tube voltmeter connected at the input to the line measures the input voltage. The output end of the line is terminated in a solid metallic disk containing an annulus of one-half the penetration thickness at the highest frequency of interest. Then, to a very good approximation

$$V_s = I_r Z_0 \sin \beta_0 l \tag{19}$$

and

$$V_r = I_r R_r = V_s \frac{R_r}{Z_0} \csc \beta_0 l$$

$$= V_s K_1 \csc K_2 f \tag{20}$$

where

R = the resistance of the annulus, ohms
V_r and V_s = the output and input voltages respectively, volts
I_r = the current in the short circuit, amperes
Z_0 = the characteristic impedance of the line, ohms
λ_0 = the wave length in the line, meters
$\beta_0 = 2\pi/\lambda_0$ = phase constant of the line
l = length of the line in meters
f = frequency in cycles per second

Since K_1 and K_2 are both constants

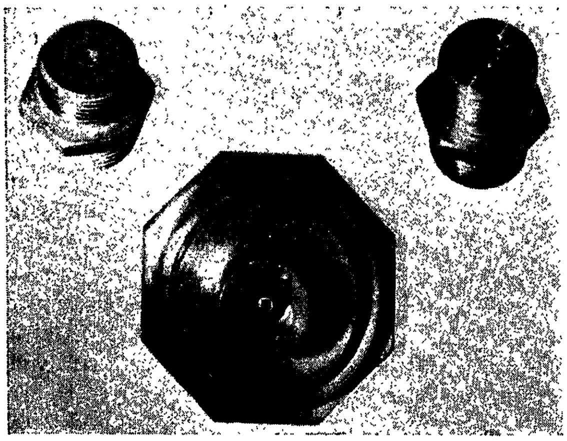

Figure 8. Micropotentiometer interchangeable resistance assemblies

A, B. Units using glass or ceramic bushings and evaporated and plated or fired-on films

C. Unit using clamped carbon disk

for a given air or solid dielectric line, one can compute and plot V_r versus frequency for $V_s = 1$ volt to facilitate the determination of V_r over wide frequency and voltage ranges. A further simplification is obtained by using check frequencies for which the line length is an odd multiple of $\lambda_0/4$, in which case

$$V_r = \frac{R_r}{Z_0} V_s \tag{21}$$

It can be shown that equation 21 holds for any value of R_r, thus a wide range of voltages is available at the output of this type of Micropotentiometer; for example, with $Z_0 = 50$ ohms, $V_s = 0.1$ volt and interchangeable R_r elements of 0.5 to 100 milliohms, one can obtain V_r values of 1 to 200 microvolts.

Practical Micropotentiometers and Verification of Performance

The ideal Micropotentiometer should have a construction whereby the annular resistance element constitutes an integral part of the inner or outer surface of the relatively heavy metallic enclosure. There are numerous ways to approach this ideal and many of them were tried with various degrees of success. Details of construction and fabrication processes are beyond the scope of this discussion. However, three different satisfactory methods will be indicated on the basis of up-to-date experience. Low resistance elements, of the order of 0.2 to several hundred milliohms, were constructed in one of two ways. First, ceramic or glass cylinders were sealed as insulators between the two concentric conductors. For this sealing, metallic paints or pastes (silver, platinum, gold) were fired on the cylindrical surfaces of these insulators; the actual sealing was accomplished by soldering. An annular resistance element was then formed at one end of the coaxial assembly by evaporating and plating a given metal over its entire surface. Second, the same process was used as in the first case except that the metallic paints or pastes were also fired on one of the ends of the glass or ceramic insulators to form the annular resistor; evaporation and plating were thereby eliminated. A third method was applied successfully only to elements of the order of 1 ohms in resistance; carbon (deposited on bakelite) disks were clamped in a solid coaxial assembly; silver painted rings were used as conducting electrodes for the disk at the clamped surfaces. One modification of the low resistance elements made use of commercial Kovar-glass sealed terminals; metallic films fired on, or evaporated and plated over one side of the terminals formed the resistance elements; the terminals were then soldered into an appropriate housing. Figures 6, 7, and 8 show cross-sectional and photographic views of these elements and Figure 9 shows an assembled unit employing a thermoelement.

Once a Micropotentiometer is assembled, all that is necessary in order to determine its voltage output is to measure the d-c resistance of the annular film and to calibrate the current indicating element on direct current. However, in the up-to-date stages of this development, it was necessary to verify the results in terms of other independent methods at all frequencies. Reliability of new units can, of course, in the future be checked against older units with little difficulty. Agreement tests were conducted against the voltage standardizing bolometer bridge, mentioned previously[7] and precision wave guide below cutoff attenuators. These tests indicated agreement well within over-all experimental errors, that is ±1 per cent to about 50 megacycles and ±3 per cent to 300 megacycles. Measurements at higher frequencies have been conducted so far only on the clamped 1-ohm units and resulted in agreements of ±5 per cent to 900 megacycles.

Application of Micropotentiometers

Though the primary objective of these Micropotentiometers is to eradicate the wide uncertainty in the absolute values of voltages in the microvolt range, they can be used for numerous other purposes. The more obvious applications may be briefly indicated as follows:

1. Reference standard for accurate voltages in the range previously indicated for calibration of voltmeters, signal generators, field intensity meters, and so forth. The voltage and frequency range seems to be limited primarily by current-indicating facilities.

2. Sources of accurate voltages for direct use in place of conventional signal generators. The user has complete freedom to vary the internal impedance of these sources for various requirements with a high degree of certainty in the values of this impedance. A compact assembly incorporating an oscillator and Micropotentiometer may be constructed as a standard voltage (signal) generator.

3. Calibration of attenuators directly in terms of voltage ratios.

4. Determination of performance of current indicators, such as of various types of thermoelements.

5. Determination of output impedances of r-f sources. Resistance elements of the Micropotentiometers may be used to short-circuit the output of a source; the voltage output of these elements is then a measure of the short-circuited current of the source and consequently of its internal impedance.

6. Calibration of modulation meters. This application is common to all devices having an accurately known correlation between output and percent modulation, for example, the output of the couple of the thermoelement. Attention may be called here to the fact that presence of harmonics in the r-f carrier will normally have a negligible effect on the couple output, whereas the effect may be very appreciable on a vacuum-tube voltmeter usually employed with conventional voltage generators.

7. Applications where voltages in the microvolt range are desired without the usual Johnson noise of higher impedance sources present.

8. Applications where constant voltage sources are required, for example for Q-measurement circuitry.

9. Applications where a single device to cover the entire frequency range from zero to 300 megacycles and higher is essential.

Discussion

Donald M. Hill (Boonton Radio Corporation, Boonton, N. J.): The micropotentiometer appears to be a worth-while contribution. Some time after the micropotentiometer was announced we had an application for it as the coupling impedance in a Q meter. After conferring with Mr. Selby concerning the methods of construction, we constructed a number of the resistors by firing a platinum-gold alloy on ceramic discs. These were tested over the frequency range from zero to 50 megacycles and found to be suitably free of inductance.

The temperature coefficient of the combination of an annular resistor and a thermocouple was found to be 0.11 per cent per degree centigrade.

One point which has perhaps not been sufficiently emphasized by Mr. Selby is that in order for the inductance to be negligibly low the resistive film must have complete axial symmetry. Until a manufacturing method can be devised which insures perfect symmetry, it will be necessary to test each resistor individually.

Myron C. Selby: The author wishes to thank Dr. Hill for his encouraging discussion. One can hardly question Dr. Hill's emphasis of the axial symmetry of the resistive film because it is a basic requirement of this development. Unfortunately we at the National Bureau of Standards have had no opportunity as yet to correlate degree of departure from symmetry with accuracy. Annular elements of superior symmetry were fabricated by means of evaporation and plating. However, there was no evidence to date that this fabrication resulted in units of higher average accuracy compared with others.

Load-Dropping Tests on a Large Ignitron Rectifier Installation

A SERIES of load-dropping tests on ignitron rectifier circuits was conducted during March 1952 on an aluminum potline at the Mead (Wash.) Works of the Kaiser Aluminum and Chemical Corporation. The purpose of these tests was to obtain fundamental data on current and voltage surges encountered in a large ignitron rectifier installation when the potline load was tripped off by each of the following methods.

1. By a-c circuit-breaker operation.
   - a. With auxiliary power maintained on the rectifier.
   - b. With simultaneous tripping of auxiliary power.
   - c. With simultaneous short-circuiting of all ignitor-firing circuits.
2. By automatic phase back to reduce the potline voltage to approach polarization value, followed by tripping of cathode circuit breakers.
3. By tripping all cathode breakers simultaneously.

Such fundamental data were desired in order to determine the best operating procedure to be used in dropping potline load in proposed higher capacity ignitron installations. In addition, it was desired to establish whether or not measures should be taken to protect existing installations against equipment failure from switching surges.

History

An outstanding development of World War II was the enormous increase in the use of rectifiers for the electrolytic reduction of light metals, both in this country and in Canada. During the war, a number of rectifier potlines operating at approximately 60,000 amperes and 650 volts were placed in service.[1] To meet the needs of the nation's defense, the use of ignitron rectifiers is again rapidly expanding both in total installed capacity and the relatively large number of units operating in parallel. Since the output of metal from the reduction process is almost directly proportional to the current through the pots, potlines which will carry 72,000 amperes at 750 volts are under construction, and lines are being proposed which will operate in excess of 100,000 amperes and 750 volts.

On rectifier installations placed in service during the war, potline loads are usually dropped by master trip of the cathode circuit breakers.[2] Some installations were originally set up to drop load by short-circuiting the ignitors to stop firing, but this method was abandoned because arc backs frequently accompanied the switching operation. On earlier installations, it was observed that dips of the order of 25 per cent in supply voltage caused the firing of the ignitrons to be erratic, resulting in unbalanced division of load between parallel rectifiers. Because of this phenomenon, little consideration was given to dropping load by opening the a-c circuit breaker. An advantage in master-tripping the cathode breakers was that auxiliary power supplying the firing circuits was invariably taken from the load side of the a-c circuit breaker, and it seemed to be desirable to keep the firing circuits energized when load was dropped. These factors led to the adoption of this method in spite of the stress placed on the cathode breakers, the last breaker to clear being required to interrupt approximately one-half of the potline current. In proposed higher capacity installations it would be desirable to relieve cathode breakers of this burden.

There have been a few rectifier transformer failures on installations made early in the war.[3] Some transformer failures were clearly the result of mechanical stresses, probably due to repeated arc backs, as evidenced by Figure 1 which shows mechanical distortion of the winding in the region of the failure. Magnetic forces resulting from short circuits or arc backs may have been responsible for dislodging the pressboard spacers between windings. Once the spacers between coils became dislodged, the high-voltage and low-voltage coils could shift with respect to each other, resulting in greatly increased magnetic forces which cause a part of the winding to collapse and burn out. As a result, replacement windings were constructed with additional bracing to withstand expected mechanical stresses resulting from arc-back currents, and subsequent windings were designed to withstand substantially higher mechanical forces.

Some failures, such as the one shown in Figure 2, do not show any mechanical distortion. This led to the consideration that these coils may have failed because of breakdown of the insulation by transient surges, although no other evidence of the existence of surges in such installations has ever been found. A possible source of excessive voltage surges is the rapid opening of circuit breakers either in normal switching operations or to clear faults. Another possibility is the phenomenon of arc starvation—the sudden interruption of current due to a deficiency of ions in the arc path. While it

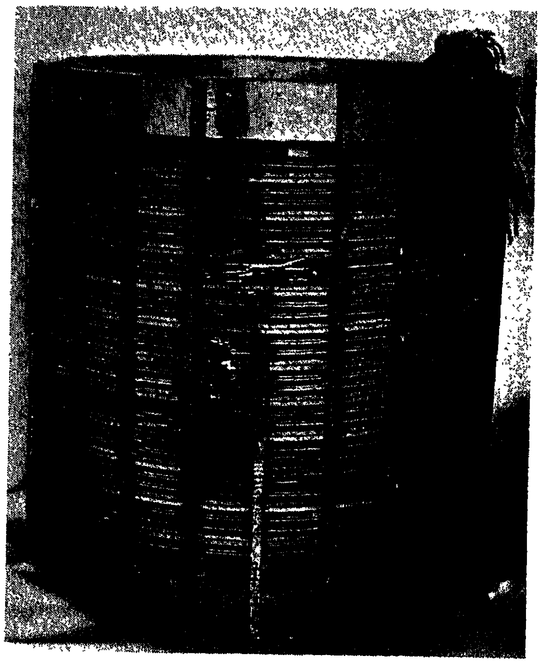

Figure 2 (right). Rectifier transformer failure with no mechanical distortion

is doubtful that arc starvation occurs on ignitrons, a similar occurrence, known as arc extinction, has been observed.[4] Arc extinction in ignitrons is the tendency for the tubes to stop conducting abruptly when small currents, of the order of a few amperes, are flowing. Because of the circuit inductance, the sudden interruption of potline current might produce an extremely high voltage of very short duration.

Transformers on later installations were designed to withstand substantially higher mechanical forces and with higher impulse levels than was the case on the first installations. There have been no failures on these transformers.

Although little attention has been directed to methods of dropping load other than by master-tripping of cathode circuit breakers, a number of investigations have been made, with limited success, in an attempt to run down the cause of transformer failures. For these reasons field tests were undertaken. Tests were expected to lead to the most desirable method of dropping potline load. In addition, if excessive surges do result from switching operations, these could be detected. Such knowledge would be useful to the industry in properly co-ordinating apparatus used in electrochemical installations and in the operation of rectifier circuits and equipment.

Discussion of Tests

Several factors made the Mead Works desirable for the performance of these tests. In the first place, with the method of phase shifting employed at Mead, it was possible to reduce potline voltage by automatic phase control just before tripping the cathode circuit breakers. Secondly, a transformer failure had occurred at Mead, and it was felt that if circuit conditions were the cause of failures these might be discovered. In addition, connections to the neutrals of the four secondary windings are brought out from the transformer tank, permitting voltage measurement between each terminal of the transformer winding and the neutral of the opposite wye. Since these two points are physically adjacent on each phase of the secondary windings, the insulation separating them is the most vulnerable point to surges entering the transformer.

A 1-line diagram of the rectifier potline used in making the field tests is shown in Figure 3. The potline consists of 12 ignitron-rectifier assemblies supplied from six rectifier transformers with double primaries and quadruple-wye-connected secondaries. Figure 4 is a schematic diagram showing one transformer supplying two rectifier assemblies. The circuit has been simplified by representing two parallel ignitron tubes and the associated balance coil by a single tube. The rectifier ignitrons are fired by a saturating reactor-type firing circuit with a phase-shifting network for adjusting the output voltage.[5] The potline is operated as a 36-phase unit by connecting the primaries of three rectifier transformers in delta, three rectifier transformer primaries in wye, and then supplying four of the units through phase-shifting transformers. Switchgear consists of high-speed anode circuit breakers, semihigh-speed cathode circuit breakers, and a plain-break a-c oil circuit breaker of the type used on early rectifier installations. Normal operating

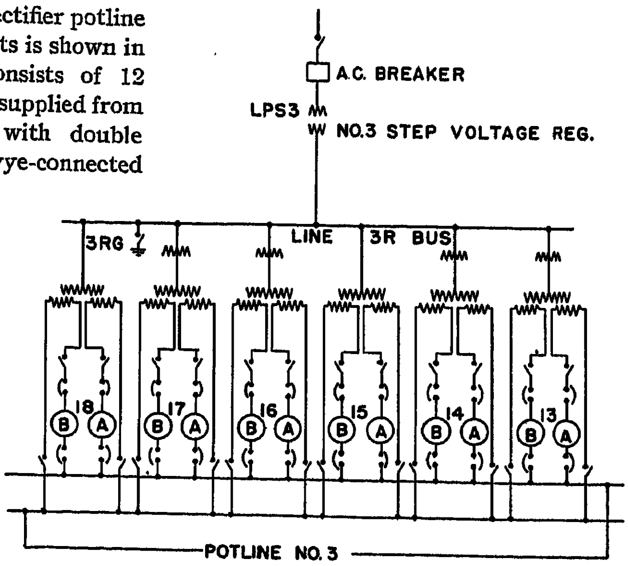

Figure 3. One-line diagram of test potline

current of the potline is about 60,000 amperes at 700 volts.

The tests are listed in chronological order in Table I. In this table, meter readings taken from the operator's board just prior to the test are recorded. In the case of tests 15 and 16, in which potline load was picked up, the readings refer to conditions immediately following the test.

LOAD INTERRUPTION BY A-C CIRCUIT-BREAKER OPERATION WITH AUXILIARY POWER MAINTAINED

Tests 1, 2, 6, and 8 were made in which potline load was dropped by tripping the a-c circuit breaker while maintaining auxiliary power in order to keep the firing circuit energized while dropping the load. In each test involving a-c circuit-breaker operation, simultaneous oscillograms were made of the following: two line-to-line voltages on the transformer primary; six cathode currents, assembly *A* from each of the six rectifier units connected to the potline; all six secondary phase currents of rectifier 13-A; potline current; and potline voltage. Maximum crest values of currents taken from the oscillograms are tabulated in per unit of normal value under load in Table II. The oscillogram for test 8 is shown in Figure 5.

In one case, test 1, two restrikes occurred in the a-c circuit breaker, resulting in two oscillations in potline voltage of maximum value of 1.0 per unit before final interruption. Corresponding oscillations occurred in the recorded currents, but the maximum cathode overcurrent was 1.3 per unit even in this adverse case. No secondary phase current exceeded 1.0 per unit.

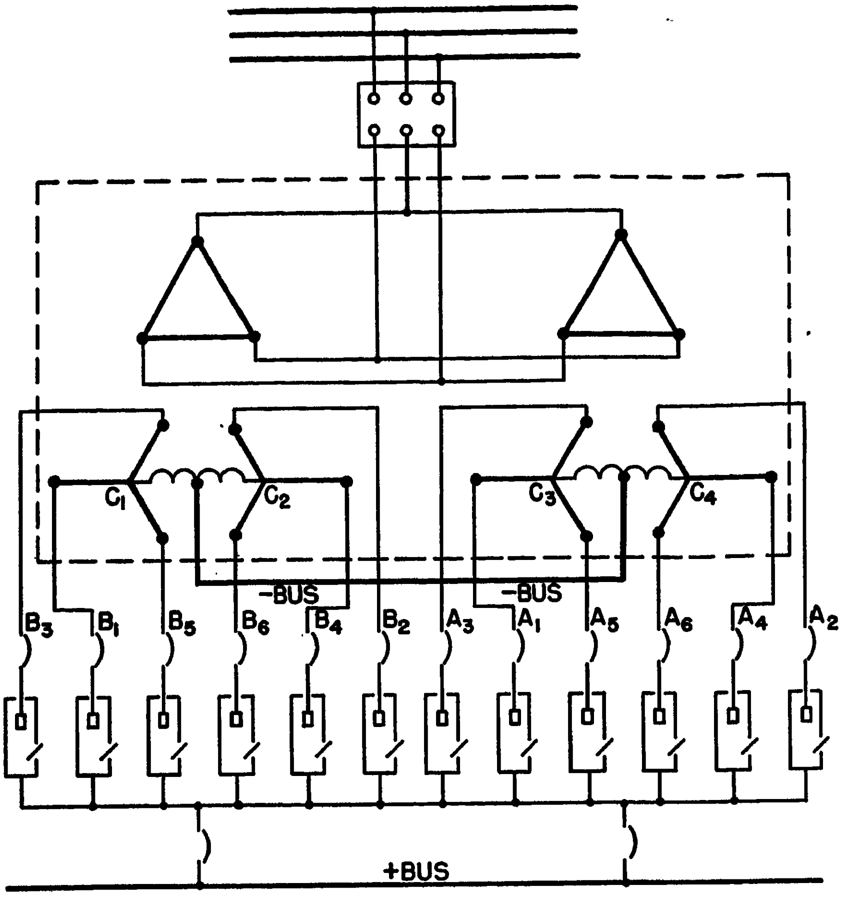

Figure 4. Schematic diagram of transformer connections

Tripping the alternating voltage, as was done in these four tests, removed any tendency for currents between parallel rectifiers to become unbalanced. In addition, the current in the transformer secondary windings was confined to two windings 180 degrees out of phase. For example, in Figure 5, the first phase left holding current, following a-c breaker trip, was phase 6, phase 1 current was reduced slightly, and phase 2 did not conduct. Because of the inductance of the circuit, the potline voltage was forced to a slightly negative value as the breaker attempted to interrupt the flow of current in phases 6 and 1, leaving a positive voltage on phase 3 which forced it to conduct. After the current in phase 1 commutated to phase 3, the arc was extinguished in the a-c circuit breaker without difficulty since only phases 6 and 3, which are 180 degrees out of phase, were conducting. The potline voltage rose from a slightly negative value to zero, and the cathode current in all units decayed smoothly.

The 6-phase ripple on the potline voltage trace prior to load interruption was due to bus drop, the voltage being measured on the bus where it leaves the rectifier room. As long as two or more ignitrons are conducting simultaneously following interruption of the a-c circuit, the potline is effectively short-circuited except for arc drop in the tubes. This phenomenon accounts for the potline voltage falling almost to zero for several cycles.

* Maximum crest value occurred during reversed current.

As soon as conduction stopped, the voltage rose to the back electromotive force of the potline.

The pip in the primary voltage trace about 5 cycles after trip resulted from the flow of exciting current as the potline voltage rose to the counter electromotive force of the potline.

LOAD INTERRUPTION BY TRIPPING A-C CIRCUIT BREAKER AND AUXILIARY POWER SIMULTANEOUSLY

In tests 11 and 12, the a-c circuit breaker and auxiliary power were tripped simultaneously. Such a test is representative of the way the load would be dropped in case of failure of power in the substation supplying the Mead Works. This is also the usual method of operation at Mead.

Figure 6, the oscillogram for test 11, shows that arcing existed in the a-c circuit breaker for about 1 cycle following trip. This test should be compared with test 1 in which quite similar interruption of the a-c circuit occurred. In both cases there was no current disturbance after the a-c circuit was completely interrupted. Referring to Table II, the maximum overshoot of cathode current was about 1.78 per unit, compared with a maximum of 1.33 per unit recorded in test 1. One secondary phase current reached about 2.08 per unit, however, which was considerably more severe than any observed in test 1. In addition, several cathode and phase currents showed a good deal more disturbance. Practically no arcing occurred in the a-c circuit breaker during interruption of the a-c circuit in test 12, resulting in very clean interruption of phase and cathode currents. There were also no restrikes in tests 6 and 8 in which the firing circuits were kept energized while the a-c circuit breaker was tripped. Comparison of test results on this basis indicates that the disturbances of secondary phase and cathode currents in test 11 were the result of arcing in the a-c circuit breaker rather than simultaneous tripping of auxiliary power.

Indications are that this method of dropping load is satisfactory at this installation.

LOAD INTERRUPTION BY SHORT-CIRCUITING IGNITOR CIRCUITS FOLLOWED BY OPERATION OF A-C CIRCUIT BREAKER

Tests 13, 14, and 17 were made by short-circuiting all ignitor circuits simultaneously followed by tripping the a-c circuit breaker several cycles later.

In test 13, the a-c circuit breaker was tripped about $2^{1}/_{2}$ cycles after the ignitor circuits were short-circuited. Although no arcing was observed in the circuit breaker, the potline voltage suffered oscillations between the time the ignitors were short-circuited and the time of tripping the a-c circuit breaker. These oscillations were caused by the alternating voltage applied to the tubes which tended to maintain conduction even though the firing circuits were not energized. As shown in Table II, disturbances in some cathode currents were worse than those observed in tests where the firing circuits were energized; for example, the cathode current in rectifier *16-A* reached a value of 4.0 per unit.

Test 14 was the same as 13 except that operation of the a-c circuit breaker was delayed 7 cycles. The oscillogram for this test is shown in Figure 7. Cathode current in rectifier *13-A* reached an instantaneous value of about 6.0 per unit before the cathode circuit breaker finally operated on overload trip. Some secondary phase currents also reached extremely high values, about 8.0 per unit in phase 3, for example. Erratic behaviour of cathode current was evident on several units, the disturbances being sufficiently severe to show up in the potline current

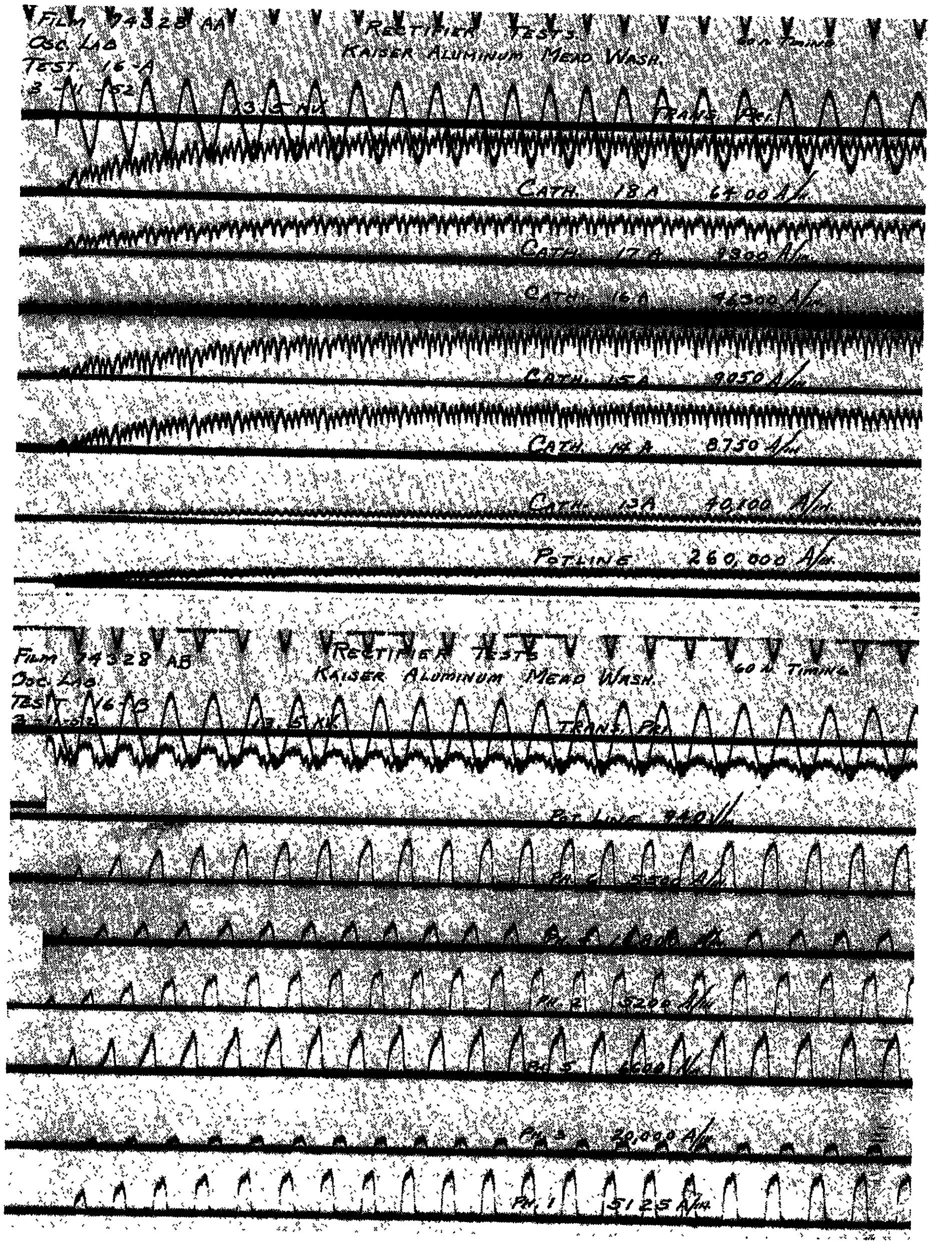

Figure 11. Typical oscillogram picking up potline load by a-c circuit-breaker operation

trace. The 6-phase ripple observed on the potline voltage trace following final interruption of current was picked up across a metering circuit after the cathode breaker in rectifier *13-A* opened.

Test 17 was the same as 14; however, a natural arc back occurred on rectifier *13-A*. Reversal of currents in the cathode circuit and in phases 4 and 6 are clearly shown in Figure 8. This method of load-dropping has been proposed for some rectifier installations. It is obvious that these tests do not support the use of this scheme. In each of these tests, the potline voltage underwent oscillations from the time the ignitors were short-circuited until the a-c breaker opened. Secondary phase, cathode, and potline currents were extremely erratic, arc backs occurring in one test.

LOAD INTERRUPTION BY TRIPPING CATHODE BREAKERS A FEW CYCLES AFTER PHASING BACK THE IGNITORS

In tests 20, 21, and 22 the ignitors were phased back to reduce potline voltage to approach polarization value, followed by tripping of cathode circuit breakers. This method of dropping load is common in Canada and has occasionally been applied in this country.

Operation of the cathode circuit breaker in rectifier *13-A* was delayed approximately 1 cycle in order to force this particular circuit breaker to make the final interruption of potline current. The a-c circuit breaker was kept closed and auxiliary power, energizing the firing circuits, was maintained.

In each test involving cathode circuit breaker operation, simultaneous oscillograms were made of the following: two line-to-line voltages on the primary side of the transformer supplying rectifier *13-A;* voltages between each terminal and the neutral of the opposite wye on the transformer secondary on rectifier *13-A;* two anode-to-negative bus voltages; two anode-to-cathode voltages; voltage and cathode current in rectifier *13-A;* phase-shift current for rectifier *13-A;* voltage across cathode circuit breaker; potline voltage; and potline current. Maximum crest values taken from the oscillograms are tabulated in Table III. A typical oscillogram, the one for test 21, is shown in Figure 9.

None of the oscillograms indicated transient overvoltages on the primary side of the transformer, and no more than 2.0 per unit voltage was evident between any terminal and neutral of opposite wye. The last cathode breaker to clear interrupted approximately one-half of the potline current flowing before interruption. This results because the cathode breakers do not open in perfect synchronization. As the first breaker opens, the current carried by that rectifier is picked up by the other rectifiers because of the inertia effect of the potline inductance. The next breaker must then interrupt a larger share of the instantaneous potline current, and this phenomenon continues until the final breaker out must interrupt the total instantaneous potline current, which by this time has decayed to approximately half value. Cathode current in rectifier *13-A*, in test 21, for example, reached a value of 22,000 amperes, approximately one-half the 52,000 amperes potline current just prior to the test. Interruption of cathode current took place in 0.85 cycle, as evidenced by the duration of arc voltage across the cathode breaker. This is a stringent requirement on the circuit breaker and is the principal objection to this method as there were no serious voltage disturbances.

LOAD INTERRUPTION BY TRIPPING CATHODE CIRCUIT BREAKERS

Tests 23, 24, and 25 were made by tripping all cathode circuit breakers simultaneously without first phasing back the ignitors. Oscillograms were made of the same quantities recorded in the tests where the ignitors were phased back prior to load interruption. The oscillogram for test 23 is shown in Figure 10.

The fact that the potline voltage trace in this test was as smooth as in tests where phasing back was employed indicates that delay of the ignitors does not produce any appreciable improvement in the load-dropping method. The maximum current in the last cathode to clear was larger, 8.0 per unit, but this was expected since phase back reduces the potline current before interruption. Overvoltages were no more severe in this case.

Potline Pickup Tests

Tests 15 and 16 were made to explore the question of transient disturbances when energizing the potline by the method employed at Mead. With the voltage regulators in normal position and the firing circuits energized, load was picked up by closing the a-c circuit breaker. There was no evidence of excessive transient currents or voltages. Figure 11, the oscillogram for test 16, is typical.

Klydonograph Records

In each test involving a-c circuit breaker operation, klydonograph elements were connected from line to ground on each phase of the transformer primary and between the terminals of one secondary wye group and the neutral of the opposite wye on the transformer of rectifier *13-A*.

In the tests involving cathode breaker operation, klydonograph elements were connected between the terminals of both secondary wye groups and the neutral of the opposite wye on the transformer of rectifier *13-A*. As pointed out previously, this is the most vulnerable part of the transformer winding to voltage surges. No indication of voltages as high as 2,000 volts, the minimum voltage which the klydonograph will record, were obtained in any test.

A cathode-ray oscilloscope was available, but intense magnetic fields present in the plant made its use impractical. Actually, klydonograph records having indicated no surge, cathode-ray records would have added little, if anything, to the test data.

Potline Resistance and Inductance

Because of the necessity of having reasonably accurate values of resistance and inductance for the calculation of short-circuit currents and surge voltages, these characteristics of the potline circuit were determined from the oscillograms made during these tests.

Calculations based on test oscillograms gave an average value of 0.0085 ohm for potline equivalent resistance, determined by dividing the difference between potline voltage under load and the polarization volts by the potline current.

Assuming the decrement of potline current to be an exponential, the time constant, L/R, is the time to the intersection of the initial tangent to the current curve and the current zero line. Determined this way, the average value of the time constant was 0.0419 second.

The inductance of the circuit is the product of time constant and resistance

$$\text{Inductance} = (L/R)R$$

Using the average values determined here, the inductance of the potline is 0.358 millihenry.

Rate of Rise of Arc-Back Current

In test 17, shown in Figure 8, an arc back occurred. The rate of rise for the first tube to arc back, measured by a tangent line, is 6.81 amperes per microsecond. The tube next conducting on the same wye also arced back following its conduction period the measured rate of rise in this case being 8.32 amperes per microsecond. This increase might be expected if it is assumed that saturation of the interphase transformer requires some interval of time, or magnitude of current, and hence exerts a modifying influence on the first arc back.

In spite of the high rate of rise, the maximum secondary phase currents were 20,580 and 20,190 amperes respectively for the first and second tubes to arc back. Since this arc back occurred after the ignitors were short-circuited and the record indicates that two rectifier units (*14-A* and *15-A*) did not contribute to the backfeed, the maximum possible arc-back current at this plant is undoubtedly slightly higher than is indicated on the oscillogram.

Conclusions

The primary objects of these tests were to determine the best operating procedure to be used in dropping potline load in proposed higher capacity ignitron rectifier installations and to establish whether or not measures should be taken to protect existing installations against equipment failure from switching surges. The following conclusions have been drawn in the light of these tests.

1. The best method of dropping load is by a-c circuit breaker operation with auxiliary power maintained. Using this method, no serious transient disturbances were observed in either secondary phase or cathode currents. Tripping the primary power supply removed any tendency to unbalance currents between parallel rectifiers, and the current in the transformer secondary windings was confined to two windings 180 degrees out of phase.

2. Load interruption by tripping the a-c circuit breaker and auxiliary power simultaneously is satisfactory at Mead. Observed transients in phase and cathode currents were not dangerously high, but were more severe than when auxiliary power was maintained while load was dropped, leading to the conclusion that provision should be made in proposed higher capacity installations to maintain auxiliary power. However, the tests show there is no cause for concern in cases of power failure in which the auxiliary power supply would be lost.

3. Load interruption by short-circuiting the firing circuits should not be considered in large rectifier installations because of excessive overcurrents and accompanying arc backs.

4. Load interruption by operation of the cathode circuit breakers is not recommended because of the stringent requirement on the last breaker to clear; this particular breaker must interrupt approximately one-half the normal potline current.

5. At Mead, it is satisfactory to pick up load by removing the short circuits on the firing circuits followed by closing the a-c circuit breaker. In general, it is recommended that load be picked up by removing the short circuits on the ignitor circuits after the a-c circuit breaker is closed. Such procedure reduces the maximum transient current on the a-c system since load current does not flow simultaneously with transformer inrush current.

6. The order of magnitude of inductance on aluminum potlines is less than 1 millihenry. This figure, originally arrived at by calculation, was confirmed by these tests.

7. It is improbable that failures of rectifier transformers on earlier installations were caused by voltage surges resulting from circuit-breaker operation.

◆

Discussion

C. C. Herskind (General Electric Company, Schenectady, N. Y.): This paper is of interest for two reasons: first, because the increasing size of rectifier installations will accentuate the problems of load interruption, and second, because of unexplained transformer failures.

Power interruptions on rectifier installations may occur under any of the following four conditions:

1. Involuntary loss of a-c power. Switching operations in the a-c system

may interrupt the a-c supply to either the rectifier transformers or auxiliary power transformers or both. Even though duty on equipment is minimized by maintaining excitation, some interruptions without excitation probably will occur. Also, a wide variety of abnormal voltage and frequency conditions on the a-c system will be encountered just prior to interruption.

2. Involuntary loss of rectifier substation. This may arise from rectifier arc back and progressive tripping of rectifier units on overload.

3. Voluntary emergency trip from cell room.

4. Voluntary manual trip by rectifier operator.

The voluntary trips may be made by tripping a-c circuit breakers or cathode breakers, as appears preferable for any electrochemical installation having appreciable cell line inductance. However, it is not sufficient to consider only the voluntary interruptions in selecting a system of control.

As the size of rectifier installations is increased with a larger number of rectifier units feeding a single potline, load-dropping by means of the cathode breakers will impose greater duty on the rectifier unit which clears last. Not only will the cathode breaker be required to interrupt higher currents but the rectifier tanks will also carry higher currents during the last cycle or two. If these currents exceed the fault current capacity, the rectifier will arc back, imposing greater duty on the transformer in turn. Perhaps the duty during load-dropping may be reduced by co-ordinated action of phase control and breaker trip.

The differences in circuit action obtained with the different methods of load-dropping are clearly described in the paper. When load is dropped by opening the a-c breaker with excitation maintained, the potline current may take any path through the d-c windings of the rectifier transformers, as all anodes are free to conduct. Current flow is established in the anodes connected to windings 180 degrees apart as this gives the lowest inductance. This path presents only the leakage reactance between interlaced windings of the rectifier transformer. Any other path would introduce transformer magnetizing reactance. In the absence of any alternating voltages, the potline current decays smoothly to zero. When load is dropped by blocking ignitors, conduction is locked in those anodes already conductive at the instant of blocking. The average output voltage of the rectifier is zero but the alternating voltages in the transformer windings alternately aid and oppose the flow of potline current through these anodes, thereby causing pulsating currents. In the process the potline current is shifted around in an erratic manner, causing extinction of some anodes and accumulation of all current in the remainder. The process continues as the potline current decays until only one anode is conductive just before extinction.

Rectifier transformer failures similar to that shown in Figure 2 of the paper have occurred at different installations. The nature of the damage indicates that the failures were caused by voltage stress. However, to the best of our knowledge a satisfactory explanation has not yet been developed.

A review of the situations in which failures of this type have occurred on General Electric transformers indicates that the following conditions apply:

1. All failures have occurred on units which are heavily loaded.
2. All failures have occurred on assemblies having only one tank connected to each transformer winding.
3. All failures have occurred on potlines with less than 50,000 amperes rated capacity.
4. Two types of transformers have failed, that is, both zigzag double-wye connected types.
5. Arc backs do not always occur at the time of failure.

In an effort to determine the cause of these transformer failures, extensive studies and tests have been made at the factory on transformer windings and surge absorbers. These tests have not disclosed any weaknesses. In fact, voltage tests have shown that impulse voltages of the order of 50 kv are required to cause breakdown between interlaced windings. These voltages far exceed those expected in service. However, with the hope of reducing the probability of failure, the insulation between interlaced windings has been increased and the thyrite surge absorbers have been modified so as to improve their effectiveness.

Limited tests have also been made in the field with the installation of film-type surge recorders on a few rectifier units. No surge voltages were indicated on the records returned from the field.

Comprehensive field tests for the purpose of determining the cause of failure have been proposed. Lacking a hypothesis regarding the mechanism of failure, the prospect of obtaining an answer appears unfavorable. Further deterents to elaborate field tests of the type required are the hazards to equipment involved in the test and the high cost of tests. In lieu of such tests, the painstaking search for clues as to the cause of failure must be continued.

Lysle W. Morton (General Electric Company, Schenectady, N. Y.): The paper is of outstanding interest to rectifier application and design engineers of my company. The subject is a timely one, for it relates to the perplexing problem of voltage surges in large rectifier installations that have caused rectifier transformer failures.

We have had experience similar to those described by the authors, when rectifier transformers failed. In certain cases the failures appear to be caused by transient voltage surges, while in other cases involving rectifier units of early vintage, the failures obviously resulted from mechanical stresses (evidently repeated arc backs). Failures attributable to mechanical stresses have been eliminated by special bracing and clamping of windings in rectifier transformers and use of high-speed anode switchgear. The failures apparently caused by transient overvoltages are guarded against by improved surge protection and increased dielectric strength of the winding insulation.

High-Voltage Surges

The source of the transient overvoltages has been the subject of much study and exploratory testing in our organization, but no convincing answer to the problem has been found. We infer from the authors' statement of the purposes of tests made at Mead that a similar search for the source of transient overvoltages had an important bearing on the investigation.

One widely held theory was that the rectifier transformers having zigzag windings were particularly susceptible to failure of the transient overvoltage type. This idea has been disproved because failures have also occurred involving rectifier transformers without zigzag windings.

There has been a persistent theory that the source of the overvoltage may be transient disturbances associated with load-dropping of either planned or accidental origin. It was for this particular reason that we studied the paper with such great interest. We regret, as probably the authors also do, that the Mead tests did not find the source of these overvoltages. It is believed that there is enough evidence to establish that such overvoltages are generated at rare intervals and do exist. We agree with the authors' conclusion 7. We believe that the search for the true source of high voltage should continue.

The Best Method of Load-Dropping

With regard to the other conclusions of the paper, there are a few additional remarks that should be made. It is our opinion that the tests made at Mead by the authors brought to light an interesting, new, and workable method of load-dropping for large rectifier installations. The authors have concluded that load-dropping "by a-c circuit-breaker operation with auxiliary power maintained" is best.

The question of whether the new method or the older widely used method of "load interruption by operation of cathode breakers" is best has many pros and cons. Experience has indicated that simultaneous operation of the cathode breakers has, in fact, not been an excessively severe duty on the last breaker to open.

Load-dropping tests made at Mead in 1942 and reported in Figure 6 of reference 2 of the paper agree with these more recent Mead tests that the last breaker interrupts approximately one-half the potline current. But, such values of current are not too high for the type of breakers usually employed as cathode breakers in these large installations. Any breaker suitable for this type of service which finds itself in distress when interrupting overcurrents equal to one-half potline current ought to have attention from the designers. The practice of dropping load by cathode-breaker operation has been employed for more than 10 years in many large rectifier installations without excessive breaker maintenance, according to reports I have received.

Furthermore, it is possible that some users would rather take such maintenance as may be necessary on the cathode breakers than on main a-c power circuit breakers.

There is also a specific objection to the newly proposed method. When the rectifier excitation and auxiliary power is maintained during main a-c breaker operation, the auxiliary power must be supplied from the a-c system from a connection ahead of the main a-c breaker feeding the rectifier units. Tapping auxiliary power at this point complicates the substation layout. In some cases it may even be necessary to add an expensive heavy-duty a-c breaker to control the auxiliary power or else risk hazard to personnel from alternative inadequate protective means.

It is our conclusion that there are now two workable methods for dropping load in large rectifier installations. One may safely make his choice based on his own local requirements and personal preferences.

H. Winograd (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The paper is timely in view of the trend towards higher aluminum potline currents and voltages. It adds useful information to what has been published previously on switching aluminum potline circuits.

Load-switching tests were conducted in March 1939, at the Alcoa plant of the Aluminum Company of America, in the first rectifier installation for aluminum reduction[1] and described by the writer.[2] The tests were made for the purpose of developing a load-switching method without using a potline circuit breaker. As a result of these tests, a potline switching method was adopted using the firing control of the rectifiers (by grid control) for switching on the load and gang-tripping of the cathode circuit breakers for switching it off.

This switching method was applied in the second rectifier installation at Alcoa for a 55,000-ampere 625-volt potline, which was put in operation in May 1940. That was also the first installation where high-speed anode breakers and semihigh-speed cathode breakers were employed, and the a-c line breakers of individual rectifier units were omitted. The switching and protection system of this installation set the pattern for most of the subsequent rectifier installations in aluminum reduction plants and other high-current electrochemical applications. Switching a potline with an a-c line breaker was not feasible because two or more potlines were supplied from a common a-c bus.

Switching off the load by gang-tripping of the cathode breakers is used for many 60,000-ampere potlines operating at 650 to 750 volts. The writer has not heard of any difficulties encountered with this method. In installations with which the writer was connected, the opening time of the individual cathode breakers was adjusted with the aid of an electronic timer, so that the breakers supplying a load circuit opened simultaneously with a time difference of less than 1/3rd cycle.[2] This helped to distribute the interrupting duty among the breakers. Even if the initial adjustment is not maintained, the same breaker is not likely to be subjected to the full circuit interrupting duty repeatedly. However, one breaker should be capable of interrupting the circuit.

A voltage surge resulting from an interruption of the load would appear across the potline circuit, because that is where the major part of the inductance is located. It might have some effect on the rectifier transformer by shifting the negative bus potential to ground in the positive direction. However, the leakage current through the ground between pots which are at different potentials in the potline circuit would tend to reduce the magnitude of the surge.

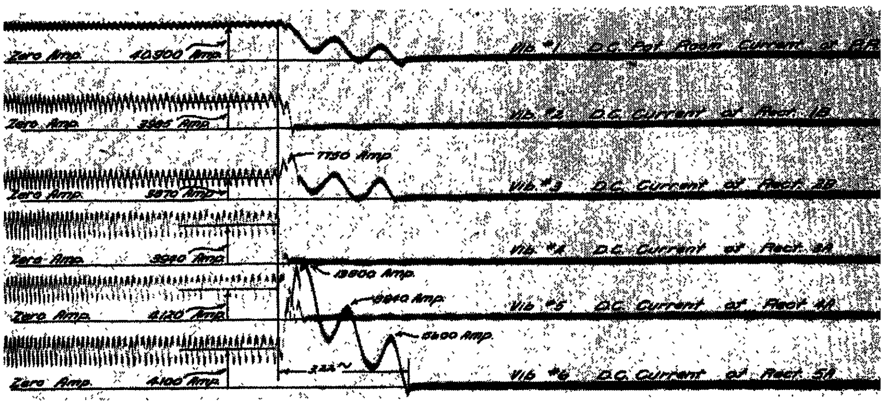

Figure 1. Oscillogram of currents during load-dropping test on aluminum potline by grid blocking of rectifiers

The interrupting duty imposed by a high-current potline on a d-c breaker cannot be minimized. This was pointed up vividly by a test made in March 1940 in the second Alcoa rectifier installation before it was put in service. One of the cathode breakers was tested in the potline circuit, with the pots short-circuited and with an external series resistor for adjusting the current. The potline consisted of four potrooms in series, and the circuit inductance was 0.7 to 0.8 millihenry. The current interrupted by the breaker was increased in steps. On the third test, the breaker interrupted 37,000 amperes. The arcing time was 4.5 cycles, and the fumes from the arc hit the ceiling, about 15 feet above the breaker. The breakers were subsequently provided with larger arc chutes and stronger blowout fields and performed satisfactorily.

With the increase in potline ratings to 100,000 or 125,000 amperes, approximately double that of the present lines, the energy stored in the circuit inductance would be about four times as high. It is unlikely that any existing d-c breaker would be capable of interrupting this circuit successfully. Because of this limitation, the use of an a-c line breaker for switching off the load of these high-current potlines is the best solution available at the present time. With this method, however, some of the operating flexibility of the present installations might be lost.

Figure 1 of the discussion is an oscillogram obtained during the load switching tests at Alcoa.[2] It shows the potline and rectifier currents when the load was switched off by applying grid blocking to all the rectifiers simultaneously. The potline was supplied by five double-rectifier units constituting a 30-phase system. The anodes which were not conducting when blocking was applied remained blocked. The currents of some conducting anodes were transferred to other conducting anodes in the same or another rectifier by commutation between phases. The current transfer between rectifiers was facilitated by their phase displacement in the 30-phase system. The potline current was finally conducted by one phase in each of two units. The potline inductance maintained the current flow over the entire voltage cycle for several cycles until the stored energy was dissipated and the currents reached zero. The 60-cycle components of the currents were produced by the phase voltages. This switching method was not adopted because the overloading of one phase and the anodes connected to it for several cycles was considered undesirable. One phase of one of the units might conduct the entire potline current during its decay.

This test was equivalent to tests 14 and 17 of the paper, in which blocking was applied to the rectifiers by short-circuiting the ignitors. The more irregular decline of the currents in Figure 7 and 8 of the paper was caused by arc backs and reignitions after the ignitors were short-circuited. In Figure 7 there were arc backs in rectifier *17A* and reignitions in rectifiers *13A* and *18A*. In Figure 8 there was an arc back in *13A* and reignitions in *18A*.

The authors should be cautioned not to use the arc-back currents measured during these tests for estimating the magnitude of arc-back currents obtained in normal service. The latter would be considerably higher, because the other phases of the faulted rectifier as well as the other rectifiers would be free to feed current to the faulted anode.

1. ALCOA RECTIFIER INSTALLATION, J. Elmer Housley, H. Winograd. *AIEE Transactions*, volume 60, 1941, pages 1266–74.

2. Discussion by H. Winograd of reference 2 of the paper, pages 964–65.

S. J. Pope, J. K. Dillard, and C. R. Marcum: We wish to express our appreciation to the discussers for the interesting points which have been raised about our paper.

Mr. Herskind indicated that in his experience all rectifier transformer insulation failures had occurred on units where only one tube was connected to each transformer winding and where the potline current rating was less than 50,000 amperes. In our experience most failures have occurred where two tubes were connected to each transformer winding and, while most of the failures have been on potlines with less than 50,000 amperes rating, others have occurred on potlines rated 60,000 amperes.

We also have had surge indicators on certain units in the field. Some of these indicators have been connected for as long as 9 years without any surge indication.

While it is true that transient disturbances in the a-c system may exist just prior to involuntary interruptions of potline load, the excitation circuits are designed to operate down to 50 per cent of applied alternating voltage and with some variation in frequency. There will be some shifting of the phase of the firing peak but this is not important after the alternating voltage is removed.

Mr. Morton points out that master-tripping of the cathode breakers has proved satisfactory where the potline current is 60,000 amperes or less. For the new potlines with rating up to 125,000 amperes the last breaker out may not be capable of interrupting one-half of the potline rated current. Such severe duty is not imposed on the a-c breaker.

Mr. Morton stated that in some cases an additional a-c circuit breaker may be required to obtain the auxiliary power from the system ahead of the a-c breaker. In nearly all large potlines, however, there is other electric equipment in the plant requiring a separate feeder which may be used for rectifier auxiliary power for short periods. In these cases the additional breakers may be low voltage and therefore relatively inexpensive.

Tests made in the laboratory indicate that the excitation circuits will continue to ignite the tubes for approximately 1/2 cycle after the alternating voltage is removed. If this time could be extended to 1 cycle by excitation circuit design, auxiliary power could be obtained from the load side of the a-c breaker and all units would share the current during the load-dropping period. With present excitation circuits, at least half of the units will conduct on two phases which are 180 degrees apart and thereby reduce the potline current to zero without any disturbances.

Our thanks go to Mr. Winograd for confirming a number of points in our paper. We concede that the arc backs shown on the oscillograms of the test were affected by load shifting between tubes and units and by the decay of the potline current. The paper acknowledged that a normal arc back would result in a higher reverse current than indicated by the oscillogram.

All of us seem to be in agreement that work should be continued to locate the source of voltage breakdown failures of rectifier transformers. As larger potlines are put into service, our prediction is that the a-c breaker method of load-dropping will be the accepted practice as it has been at the Mead Plant for some time.

Mechanized Billing of AMA Toll Messages

FRANK D. SLADE
NONMEMBER AIEE

THE billing of 140,000,000 toll messages a month to 17,000,000 toll using customers, representing about 60 per cent of the total telephone customers, is a major operation involving approximately 15,000 Bell System clerical employees. Toll message volumes have more than doubled in the past 10 years, and further growth seems likely. While many important improvements have been made in the billing processes in order to handle the increased volume more effectively, the mechanization of this work continues to remain a challenge.

The introduction of automatic message accounting (AMA) in the Bell System in 1948 presented an opportunity to mechanize some of the operations involved in toll billing, especially the sorting of AMA toll messages into telephone number order and the timing of such messages. The initial AMA system was described in 1950,[1] and a new development in the AMA system, the tape-to-card converter which produces a punched card for each toll message, is described in a companion paper.[2]

Although the number of toll messages now recorded on AMA tapes represents only about 3 per cent of the total toll messages, this percentage is expected to double by the end of 1953 and continued rapid expansion of AMA toll message recording is anticipated.

This paper describes the operations followed by the New Jersey Bell Telephone Company in billing toll messages recorded on AMA equipment. The operations involved in billing long-distance toll messages dialed on a trial basis by customers in Englewood and Teaneck, N. J., are not covered, although the same card is used for billing regular AMA toll messages and long-distance messages. The New Jersey Company at present accounts for about 80 per cent of the total AMA recorded toll messages and is the only Bell System company currently using punched cards for toll message billing. The Illinois Bell Telephone Company and the New York Telephone Company are scheduled to adopt punched card toll billing for AMA messages early this year, and three other Bell companies are planning to introduce this type of billing later in 1953. AMA toll messages billed manually are handled in about the same manner as operator-ticketed toll messages.

For many years experiments have been conducted in an effort to find a mechanical method of rating, sorting, and billing toll messages which would provide economies over the highly efficient manual procedures that had been developed over a period of many years. In the fall of 1948, the New York Telephone Company began a trial of punched card toll billing in its Lexington Accounting office in New York City wherein the significant data shown on toll tickets, prepared in the usual manner by operators, were transferred to punched cards, using a specially designed key punch with an automatic ticket feed. While more than 20,000,000 toll messages were billed by means of punched cards during the period of the trial, the plan was discontinued in December 1950 after much experimentation, when it was concluded that the manual transcription of information from toll tickets to punched cards was uneconomical. One of the principal factors affecting the outcome of the trial was the difficulty encountered in getting the data for each message (generally of low billing value) punched into the cards accurately and at high speed.

With the introduction of the AMA tape-to-card converter, the accurate and rapid preparation of punched cards from original records became a reality, and mechanical billing of AMA toll messages became an economical operation where the volume of toll messages to be billed was at least 200,000 messages per month. While the procedures followed by the New Jersey Company are producing satisfactory results, the many machine and card handling operations involved create a complicated process, which, it is believed, will eventually evolve into a more efficient and simplified procedure.

Preparation of Toll Message Card

The punched card, Figure 1, as it emerges from the tape-to-card converter contains all of the basic information required for rating and billing. The follow-

---

Paper 53-114, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19-23, 1953. Manuscript submitted November 19, 1952; made available for printing December 12, 1952.

FRANK D. SLADE is with the American Telephone and Telegraph Company, New York, N. Y.

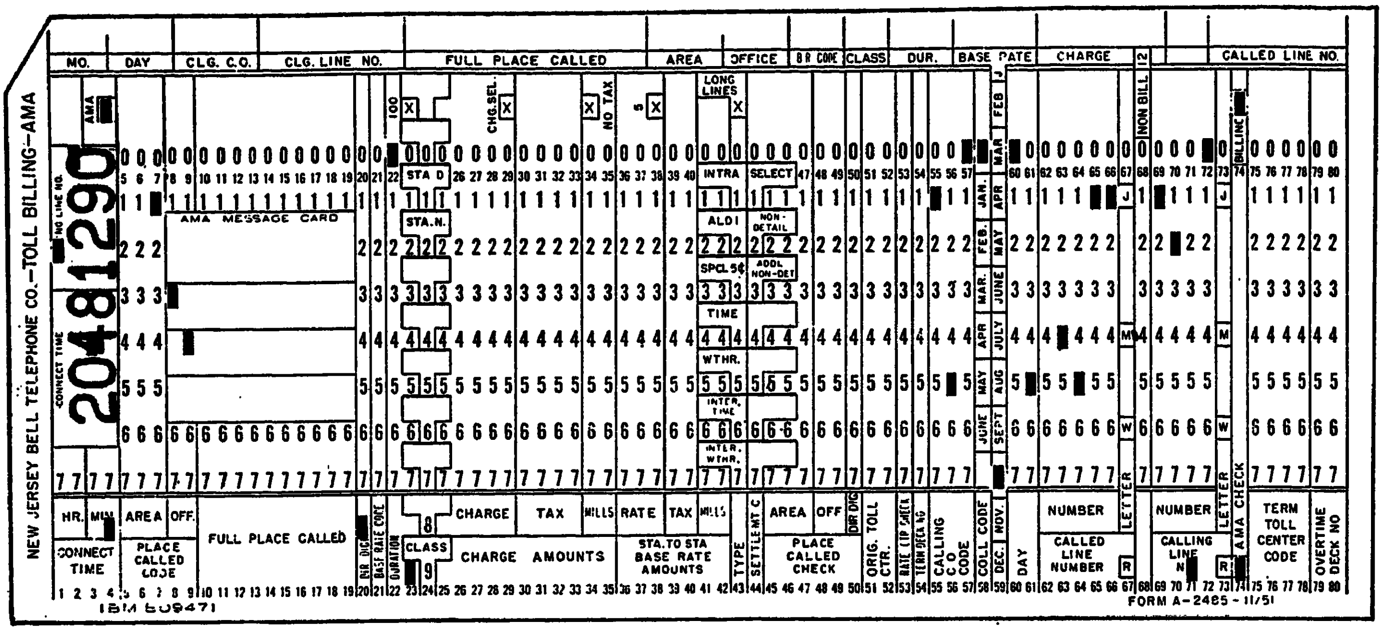

Figure 1. Toll message card as produced by converter

ing data are punched into the cards:

Column	Punched Data
1–4	connect time of message (using 24-hour clock)
4	special X punch to indicate an AMA message
5–7	called area code (column 7 only for a regular AMA message)
8, 9, 20	called central office code
22, 23	duration of conversation in chargeable minutes
55–57	calling central office code
58	month code (for collator date sequence check)
59–61	month and date of message
62–66	called telephone number
67	party letter of called telephone number
69–72	calling telephone number
74	AMA check ("9" punch); indicates all data were received by punch unit of converter from the input tape
74	billing X indicates a billable message

After verifying the count of message cards punched by the converter with the number of messages recorded on the AMA computer registers, the cards are replaced in the regular cardboard boxes used for shipping and are forwarded three times a day to the punched card accounting offices in Newark and Elizabeth, which are, respectively, 1 and 6 miles from the AMA Accounting Center.

The Newark punched card accounting office processes about 1,700,000 toll messages per month and prepares toll service statements for 73,000 customers whose telephone bills are prepared at Newark and Paterson. The Elizabeth punched card accounting office processes about 1,400,000 toll messages per month and prepares toll service statements for 75,000 customers whose telephone bills are prepared at Elizabeth and Pennsauken, near Camden. As a temporary arrangement, in order to produce a more even work load at the two punched card accounting offices, toll statements are also prepared at Elizabeth for a small number of customers billed at Paterson.

Punched Card Machines

The four principal types of punched card machines used in billing AMA toll messages are as follows:

Sorters

Sort cards, one column at a time, into one of 12 numbered pockets or a reject pocket.

Count number of cards sorted.

Rated speed is 650 cards per minute.

Collators

Compare cards for ascending numerical sequence, selecting those out of numeric order.

Compare up to 16 columns in one card with matching columns in following cards, rejecting nonmatching cards.

Rated speed is 240 cards per minute for single-feed, or 480 per minute for double-feed.

Reproducing Punches

Gang punch data from one card into another card.

Detect a double punch or a blank column where one punch should be present.

Compare all columns of one card with the following cards.

Duplicate punches in one card to another card.

Rated speed is 100 cards per minute.

Accountings Machines

Print up to 88 characters on one horizontal line simultaneously.

Accumulate totals into counters and print totals upon recognizing a control punch.

Automatically position new pages of forms to be printed.

Rated speed is 100 cards per minute.

The uses made of these machines in the rating and billing of AMA toll messages are described in succeeding paragraphs.

Primary Rating Operation

The boxes of message cards, upon being received in the punched card accounting office, are examined to insure that all of the boxes for the recorder groups involved have been received, it being the established practice for the AMA accounting office to release all of the cards for a

recorder group at one time. The individual boxes are marked to show the number of the box and the total number of boxes for the recorder group.

A recorder group may consist of a single central office, such as Cranford 6, or it may comprise two or more offices, such as Leonia 4 and Fort Lee 8, calls for which are perforated on common recorders. The central offices in a recorder group may or may not be in the same originating rate center. Since the messages in a recorder group are not separated by central office when being processed through the tape-to-card converter, the first step in the rating operation is to sort the cards on column 57 by originating central office code, if the recorder group includes offices in two or more originating rate centers. In this sorting operation a card count is obtained to verify the number of toll messages recorded by the AMA computer. All cards having the same originating rate center are then assembled manually in order that the maximum number of cards of a common type may be accumulated for the next operation.

The second step is to sort the message cards on columns 20, 9, 8, and 7 by place called, during which operation the message cards are associated with the appropriate terminating point rating master cards. Each originating rate center has a deck of terminating point rating master cards which consists of a card for each central office that can be dialed by customers of the originating rate center. Since all AMA central offices, with the exception of those around Camden, in the southern part of the state, have the same dialing area, the number of cards in the terminating point rating master deck for each originating rate center is approximately the same. The offices in and around Camden have a much smaller calling range and therefore the terminating point rating master decks consist of fewer cards. Currently, the rating decks for northern New Jersey offices consist of about 450 cards and for offices in the southern part of the state, about 125 cards.

The terminating point rating master cards, Figure 2, which are yellow in color, show the following information which is punched into the message cards:

1. The initial period station-to-station day rate (commonly referred to as the base rate), columns 36–38.
2. The related Federal tax in cents and mills applicable to the base rate, columns 39–42.
3. The punching for the established abbreviation of the terminating point, columns 10–13.
4. A code to indicate that the message terminates at an interstate or intrastate point, column 43.
5. The class code, "1" for messages not subject to reduced rates, and "2" for messages to be charged at reduced rates, column 24.
6. The number of the rating deck used, column 54.
7. The area and office code of the place called for checking purposes only, columns 47–50.

The punching of the area and office code of the place called into the message cards from the terminating point rating master cards is done so that a check can be made by comparing the newly punched data in columns 47–50 with the punching in columns 7–9 and 20. Any message cards associated with the wrong master cards will cause the reproducer to stop.

There are only a few AMA central offices which can originate messages to points where reduced rates for night, Sunday, and holiday messages apply. The terminating point rating master cards for these points have a distinctive marking (blue stripe across the top of an otherwise yellow card) and these cards are followed immediately by a second rating master card (all blue in color) for the same terminating point, which carries the reduced rate for night, Sunday, and holiday messages. All of the message cards associated with the all-blue or blue-striped terminating point rating master cards in the sorting operation are manually examined to determine if the connect time which is printed near the left end of the card by the tape-to-card converter is later than 1759 and earlier than 0430, in which case reduced rates are applicable. Those cards subject to reduced rates are filed behind the all-blue master card and the others are filed behind the blue-striped master card.

After the message cards have been associated with their respective terminating point rating master cards, they are gang punched with the pertinent data carried in the master cards. During the punching operation, the machine verifies the accuracy of part of the punching. However, to insure that all columns of the message cards have been accurately punched, the cards are placed in the comparing side of the reproducer, which completes the verification.

The message cards are next sorted by duration (length of conversation), during which operation the terminating point rating master cards are eliminated. The separation by duration is accomplished by sorting the duration rating master cards and the message cards on columns 23 and 22. Message cards of 1-, 2-, and 3-minute duration are, of course completely rated and taxed following the gang punching of data carried in the terminating point rating master cards. Cards completely rated in this manner cover about 60 per cent of the total message cards.

Adjustment for Overtime

The next step in the rating process (for the remaining 40 per cent of the cards) is to sort by base rate so that messages having the same base rate and duration are together immediately behind the appropriate duration rating master cards. In this rating operation, all message cards having the same base rate may be processed at the same time regardless of the originating or terminating central office, since it is the base rate charge, length of conversation, and class of message only that determine the amount to be billed. The duration rating master decks include cards for each minute of duration from 4 to 99 minutes for each base rate charge of 10, 15, and so forth, to 45 cents, inclusive; see Figure 3. In addition, there are special cards in file for rating messages to time and weather service. Messages of more than 99 minutes' duration are rare and are specially handled in the AMA computer, which records the pertinent data for such messages on a "straddle" tape which is processed through the AMA printer and then manually handled.

Following these sorting operations and before gang punching the charge data into the message cards, the duration rating master cards and message cards are processed through the collator to verify that the message cards have been correctly associated with the duration rating master cards. In this operation, a comparison is made of the punching in columns 22 and 23 (duration) 36, 37, and 38 (base rate) of the duration master and message cards. At the same time, any improperly associated message cards are mechanically ejected and after being examined are associated with their proper duration rating master cards.

After the association check has been completed, the charge and tax amounts are gang punched into the message cards in columns 25–35. In addition, an *X* punch is made in column 29, which controls the tabulator selection of the charge to be billed. In the absence of an *X* punch, the accounting machine selects for billing the base rate and related tax amounts punched in columns 36–42. During the punching operation, the machine verifies the accuracy of part of the punching. However, to insure that all columns of the message cards have been accurately punched, a complete verification of the gang punching operation is made by processing the master cards and message cards through the comparing side of the reproducer.

Storing Cards Prior to Billing

The message cards for rate centers having more than one central office are then sorted by originating central office code (column 57), at which time the duration rating master cards are eliminated. The cards for each central office are then sorted by the thousands digit of telephone number (column 69). During this sort, the duration master cards for single office rate centers are withdrawn. In both of these operations the message cards of 1-minute duration are kept separate for subsequent handling in the application of credit tickets.

Before the message cards are placed in file by central offices, they are needle-checked to detect possible discrepancies in date order resulting from (a) the fact that the AMA business day ends at 3 a.m. or (b) any mishandling of cards. At this point, the punching of the message cards has been completed and they are ready for listing on toll service statements. The cards, Figure 4, are filed by thousands in upright storage racks with separators between each day's business.

Handling Claims for Credit

Some errors and claims for credit do, of course, require adjustment and every reasonable effort is made to prevent the billing of erroneous amounts. Customers are requested to notify operators when wrong numbers are reached or when poor transmission or cutoffs are encountered in order that credit tickets may be prepared and adjustments made. The application of credit tickets, which involve less than 0.005 per cent of the total number of messages, is made daily while the message cards are grouped by the thousands digit of telephone number. About 90 per cent of all messages requiring adjustment are located in the cards of 1-minute duration. The message cards involving credits are withdrawn from the billing process and are associated with the credit tickets for subsequent clerical handling.

Message cards involving credits are located by a block sorting process which requires the minimum handling of cards. The identification of a particular card is, of course, facilitated by the presence of the telephone number and connect time which are printed on the cards by the tape-to-card converter.

Most wrong number credit tickets result from incorrect dialing by customers, although some are caused by incorrect handling at terminating manual switchboards. No attempt is made to locate message cards for wrong number credit tickets in the 2-minute and longer

duration cards, since it is assumed that a message of more than 1-minute duration did not involve a wrong number. In rare cases, messages of 2 minutes or more may involve valid wrong number claims and the adjustments are handled by the business office.

Message cards of 2-minute and longer duration are searched, however, in connection with the application of credit tickets for cutoffs or poor transmission. Message cards involved in such claims are removed and associated with the related credit tickets. In allowing credit for cutoffs, the combined time of the AMA message and the reconnection is examined. An allowance of 1 minute is made, and where adjustment is proper, a new card is prepared showing the correct duration and charge. Adjustment of charges on messages involving poor transmission is made in accordance with the agreement reached by the customer and the operator who handled the claim.

All credit tickets properly noted as to disposition are sorted into telephone number order at the close of the billing period and are forwarded to the business office for reference purposes.

Preparation of Toll Statement

To spread the work load as evenly as possible throughout the month, all Bell System companies use rotation or cycle billing. Under this plan, customers are billed once a month, with different groups of customers being billed at different fixed dates during the month. Since toll service statements are issued on the same basis, their preparation is an almost continuous process.

When the message cards for the last date of the billing cycle have been completed, the cards are removed from file and are sorted into telephone number order with date sequence being maintained. In this operation, billing book control cards are mechanically interfiled with the message cards at selected points so that control totals may be established by units. These unit totals are used in balancing the amounts subsequently entered on customers' bills. The telephone number sequence of all message cards is verified in the collator before the cards are listed on toll service statements.

The toll service statements used for listing AMA toll messages are continuous forms consisting of two parts, the customer's portion and the business office portion. The customer's portion, Figure 5, of the toll service statement shows the central office designation and telephone number, date, place called, charge (excluding tax) for each message, and the total tax and total amount (including tax) to be entered on the customer's bill.

The business office portion, Figure

separated by telephone number and the customer's portion is severed from the business office portion of the statement. The message cards used to prepare the toll service statements are not forwarded to the business office, since the business office portion of the toll statement contains all of the billing information shown on the cards. The message cards are retained by the punched card accounting office for a period of one month after billing.

Two different practices are in use for showing the total of the toll service statement on the customer's bill. In the Paterson accounting office, the total amount of the mechanically prepared toll statement covering AMA messages is posted on one line of the bill, and the amount of the manually prepared statement covering operator-handled messages is posted on another line of the bill. In the three other accounting offices, the two toll statements are placed in a jacket. The total of the two statements is entered on the jacket and is posted on a single line of the bill. It is believed that the practice followed by the Paterson accounting office will be generally adopted.

Figure 7 shows the toll billing operations described here, with each step of the procedure in chronological order.

With the introduction of the tape-to-card converter, AMA sorters and printers are no longer required for processing toll messages. The resulting substantial reduction in AMA capital investment and processing time are important advantages which have helped to make the mechanization program economical. Improvements in the design and functioning of AMA equipment and commercial business machines are under way and continued development can be expected. With these developments and improved operating techniques, the mechanization program should provide economies and advantages not now foreseen.

Discussion

Arthur Bessey Smith (Automatic Electric Laboratories, Inc., Chicago, Ill.): In the epoch-making movement toward nation-wide toll dialing, the person-to-person call will always merit consideration. Every day there occur many situations in which it is essential that person A must contact person B, and no other, because only B knows the answer which A needs to have. Also it occurs that A and B must hold a short conference, in which they and only they must exchange information, ideas, and proposals, and come to a mutual agreement (or final disagreement).

Though the person-to-person calls may be in the order of 8 to 10 per cent of the total number of toll calls, they will always be needed. In some local regions the percentage may be much higher.

Though it may not be possible to forecast how far the subscriber can go in dialing toll connections to destination, it seems certain that ultimately automatic switching of toll lines will enable the toll operator to do it with great efficiency and effectiveness. And this will help the person-to-person service.

The movement toward nation-wide toll dialing is part of the general movement toward the mechanization of tools and devices, resulting in increasing application of electric power to industry. Though the relays and magnets used in automatic switching of telephone lines do not seem to amount to much in terms of horsepower, yet they really are electric motors, and replace manual labor.

The more power drive there is, the greater is the work output of each worker, whether of manual labor in a factory or mill, or of a telephone operator. This makes mankind more efficient and living is raised to a higher level. In America we have more horsepower per worker than in any other part of the world. It is one of the important things which has made our nation great and which will maintain our position.

Saturable Reactors with Inductive D-C Load

Part II. Transient Response

H. F. STORM
MEMBER AIEE

Various Representations for Ordinary Linear Resistance-Inductance Circuit

A LINEAR inductive reactor can be symbolically represented in several different ways. The first and most common presentation is shown in Figure 1, where L is a pure inductance and R a pure resistance. The current I as a function of the applied step voltage E is in operational form[1]

$$I=\frac{E}{R+pL} \tag{1}$$

A reactor could also be looked upon as a black box which is stimulated by the voltage E and produces a current I. This concept leads to the block diagram of Figure 2, where the reactor is represented by the rectangle; the voltage E is now viewed as an input quantity and the current I as an output quantity. The ratio I/E is called the transfer function[2] $K_1G_1(p)$, of which K_1 is a time-invariant term, and $G(p)$ a function of p, that is, time variant

$$K_1G_1(p)=\frac{I}{E} \tag{2}$$

In view of equations 1 and 2

$$K_1=\frac{1}{R} \tag{3}$$

$$G_1(p)=\frac{R}{R+pL} \tag{4}$$

Designating the ratio L/R by the time constant T

$$T=\frac{L}{R} \tag{5}$$

Paper 53-20, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted October 17, 1952; made available for printing November 10, 1952.

H. F. Storm is with the General Electric Company, Schenectady, N. Y.

Nomenclature

$\mathfrak{a}$ = per unit ampere-turns
E = supply voltage, average
e = supply voltage, instantaneous
E_C = control voltage, average
E_F = feedback voltage, average
E_O = (nominal) output voltage, average
e_O = (nominal) output voltage, instantaneous
E_m = supply voltage, maximum
f = supply frequency, cycles per second
$F(\mathfrak{a})$ = free-wheeling function (equation 14 of part I[7])
G = response function (time-variant)
G_E = response function of voltage gain
G_2 = response function of feedback
G_L = response function of load
I_C = control current, amperes, average
I_G = gate current, amperes, average
I_L = load current, amperes, average
$j = \sqrt{-1}$
K = gain (time-invariant)
K_{AT} = ampere-turn gain
K_E = voltage gain
K_2 = feedback gain
L_L = inductance of load, henrys
N_C = number of turns of one control winding
N_F = number of turns of one feedback winding
N_G = number of turns of one gate winding
p = Heaviside operator, d/dt
R_C = control circuit resistance, ohms
R_L = load resistance, ohms
R_O = nominal output resistance, ohms
T = time constant, seconds
T_C = time constant of control circuit, seconds
T_L = time constant of load, seconds
T_n = time constant, double root of characteristic equation, seconds
T_1, T_2 = time constant, roots of characteristic equation, seconds
t = time, seconds
u = equation 47
ϵ = base of the natural logarithms
ζ = damping index
ϕ_A, ϕ_B = core fluxes, maxwells
ω = angular velocity, radians per second
ω_n = angular velocity of undamped natural frequency, radians per second
τ_C = time constant of control circuit, cycles
τ_L = time constant of load, cycles

Bars over the symbols indicate incremental variables.

Per-unit quantity $\mathfrak{a}$ is indicated in text by an Old English letter, and in the illustrations by a bar underneath the symbol.

---

one obtains for $G_1(p)$

$$G_1(p)=\frac{1}{1+pT} \tag{6}$$

and the transfer function of equation 2 becomes

$$K_1G_1(p)=\frac{1}{R}\,\frac{1}{1+pT} \tag{7}$$

In a third form of representation, a reactor can be regarded as a closed-loop system, consisting of a forward transfer function $K_1G_1(p)$ and a feedback transfer function $K_2G_2(p)$, as shown in general form in Figure 3, where Θ_i signifies the input and Θ_o the output. Rudimentary algebra[3] leads to the over-all transfer function Θ_o/Θ_i

$$\frac{\Theta_o}{\Theta_i}=\frac{K_1G_1(p)}{1+K_1G_1(p)K_2G_2(p)} \tag{8}$$

where $K_1G_1(p)$ is the forward transfer function

$$K_1G_1(p)=\frac{\Theta_o}{\Theta_\epsilon} \tag{9}$$

and $K_2G_2(p)$ is the feedback transfer function

$$K_2G_2(p)=\frac{\Theta_F}{\Theta_o}. \tag{10}$$

The feedback signal Θ_F is connected in such manner to the summation point 1 so as to subtract from the input signal Θ_i, as indicated by the signs.

For reasons that will become more obvious later, the reactor can now be represented as shown in Figure 4. Then, the forward transfer function is

$$K_1G_1(p)=\frac{I}{E_\epsilon}=\frac{1}{pL} \tag{11}$$

and the feedback function

$$K_2G_2(p)=\frac{E_F}{I}=R \tag{12}$$

as can be quickly proved by substituting equations 11 and 12 into equation 8, which becomes identical with equation 1 for $\Theta_i=E$ and $\Theta_o=I$.

Block Diagram of Saturable Reactor with Purely Resistive Load

For a series-connected saturable reactor operating in the proportional region and having a core material which can be approximated by a rectangular magnetization line, and with further restrictions listed in reference 4, the load current $\bar{I}_L$ can be expressed by the control voltage $\bar{E}_C$ (equation 40, reference 4)

$$KG(p)=\frac{\bar{I}_L}{\bar{E}_C}=\frac{1}{R_C}\,\frac{1}{1+pT_C}\,\frac{N_C}{N_G} \tag{13}$$

The bars over the symbols signify incremental variables, as used for performance calculations by means of Bode or Nyquist diagrams.[5] The numerical value for time constant T_C of a saturable reactor with purely resistive load is listed in reference 4 (equation 35)

$$T_C=\frac{1}{4f}\,\frac{R_O}{R_C}\,\frac{N_C^2}{N_G^2} \tag{14}$$

where R_O designates the entire resistance of the saturable reactor circuit between the a-c terminals.

In analogy to Figures 3 and 4, the saturable-reactor circuit can now be represented by the block diagram of Figure 5, where

$$K_1G_1(p)=4f\frac{1}{R_O}\,\frac{N_G}{N_C}\,\frac{1}{p} \tag{15}$$

and

$$K_2G_2(p)=\frac{\bar{E}_F}{\bar{I}_L}=R_C\frac{N_G}{N_C} \tag{16}$$

Again, the proof consists in substituting equations 15 and 16 into equation 8, which becomes identical with equation 13 for $\Theta_i=\bar{E}_C$ and $\Theta_o=\bar{I}_L$.

The load current $\bar{I}_L$ is the immediate result of the line voltage acting on the circuit resistance R_O during the conduction interval. Calling the aforementioned voltage the nominal output voltage $\bar{E}_O$, one obtains

$$\bar{I}_L=\frac{\bar{E}_O}{R_O} \tag{17}$$

or in the form of a transfer function

$$K_LG_L(p)=\frac{\bar{I}_L}{\bar{E}_O}=\frac{1}{R_O} \tag{18}$$

where $K_LG_L(p)$ is called the load transfer function.

One can now split the transfer function $K_1G_1(p)$ of equation 15 into two parts

$$K_1G_1(p)=K_EG_E(p)\,K_LG_L(p) \tag{19}$$

such that the first part $K_EG_E(p)$ is associated only with the saturable reactor

$$K_EG_E(p)=\frac{\bar{E}_O}{\bar{E}_\epsilon}=4f\frac{N_G}{N_C}\,\frac{1}{p} \tag{20}$$

and the second part, namely $K_LG_L(p)$ is associated only with the load (equation 18). The new block diagram is illustrated in Figure 6, showing the separation between the saturable reactor and its load.

Block Diagram of Saturable Reactor

The block diagram of the saturable reactor itself emerges now from Figure 6 as the part inside the dashed rectangle. The presentation of a saturable reactor in block-diagram form offers the following advantages:

1. When a saturable reactor is part of a larger feedback control system, such as a

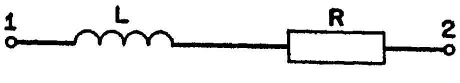

Figure 1. Linear inductive reactor, consisting of inductance L and resistance R

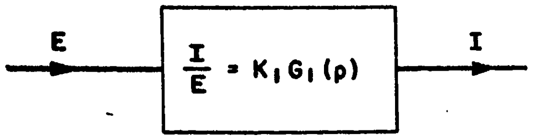

Figure 2 (above). Linear inductive reactor, represented by block with transfer function $K_1G_1(p)$

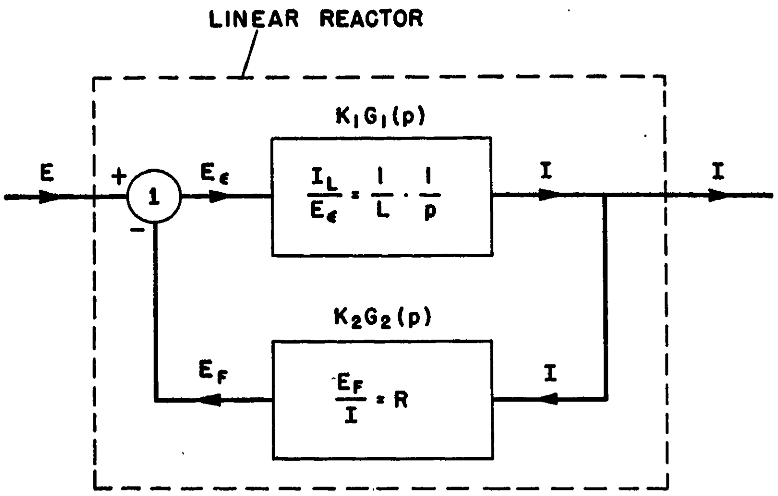

Figure 4 (right). Linear inductive reactor of Figure 1, represented by a forward function $K_1G_1(p)$, a feedback function $K_2G_2(p)$, and a summing point 1

voltage regulator, the representation of a saturable reactor in block-diagram form permits its immediate integration into the block diagram of the over-all system.

2. The representation of the saturable reactor in block-diagram form offers immediate capitalization on the techniques already developed in conjunction with feedback control systems when analyzing the transient behavior of a saturable reactor with inductive d-c load.

3. The servo block diagram offers a better insight into the mechanics of operation of saturable reactors.

FORWARD (VOLTAGE) TRANSFER FUNCTION $K_BG_B(p)$

By letting $R_C=0$, the feedback function $K_2G_2(p)$ (equation 16) vanishes, and the load current becomes a function of the forward function only. At the instant of application of the incremental control step voltage $\bar{E}_C$, and this instant can be chosen at random, the core fluxes φ_A, φ_B begin to rise, and rise linearly with time

$$\bar{\varphi}_A+\bar{\varphi}_B=\bar{E}_C\frac{10^8}{N_C}t \qquad (21)$$

From equations 24, 10, and 11 of reference 4, and equations 17 and 21 of this paper, one arrives with certain reservations at

$$\bar{E}_O=4f\bar{E}_C\frac{N_G}{N_C}t \qquad (22)$$

The nominal output voltage E_O is defined as the average value of the instantaneous, nominal output voltage e_O, when averaged over half a cycle. In view of this definition, the time t in equation 22 cannot mean any time. The most elementary stipulation would be to make t a multiple of π/ω which is half a cycle. It can be shown, however, that more general values for the time t can be obtained by taking the time differences between the application of the step voltage $\bar{E}_C$ and the instants when the a-c line voltage reaches crest values. $\bar{E}_O$ can now be determined from equation 22 with values for t as specified in the previous sentence, and when plotted as a function of t on linear graph paper, the points representing $\bar{E}_O$ are located on a straight line; moreover, if this line is extended toward the start until it intersects the time axis, (abscissa) the intersection occurs at exactly the point of application of the step function $\bar{E}_C$. In other words, when viewing the train of $\bar{E}_O$ values, it looks as if this train started exactly with the application of $\bar{E}_C$. This means that as far as the train of $\bar{E}_O$ values as a whole is concerned, there is no transportation lag between the inception of the step function $\bar{E}_C$ and the start of that train.

With these qualifications in mind, one may state that the output voltage $\bar{E}_O$ rises linearly with time (equation 22) regardless of the instant at which the step function is applied.

In view of

$$\frac{1}{p}=t \qquad (23)$$

the forward transfer function $K_BG_B(p)$ (equation 20) becomes identical with equation 22, and all that has been stated in connection with equation 22 is valid for equation 20. Since voltage amplification is involved, $K_BG_B(p)$ will be called the voltage transfer function, and on account of the form of $G_B(p)$

$$G_B(p)=\frac{1}{p} \qquad (24)$$

the transfer function $K_BG_B(p)$ is called an integrating function.

FEEDBACK TRANSFER FUNCTION $K_2G_2(p)$

During the conduction interval, one of the two saturable reactors (Figure 3, reference 4) is unsaturated and the sum of ampere-turns is zero (equation 9(*A*), reference 4).

$$\bar{I}_C=\bar{I}_G\frac{N_G}{N_C} \qquad (25)$$

With a series-connected saturable reactor and resistive load

$$\bar{I}_G\equiv\bar{I}_L \qquad (26)$$

and therefore the load current I_L, substituting the gate current I_G, may be shown in Figure 6 and in equation 16 as directly operating on the feedback function R_CN_G/N_C.

As a result of the transformation (equation 25) a current $\bar{I}_C$ flows in the control winding, requiring a voltage $\bar{E}_F$

$$\bar{E}_F=\bar{I}_CR_C \qquad (27)$$

This voltage $\bar{E}_F$ substracts from $\bar{E}_C$ (Figure 6), leaving only $\bar{E}_\epsilon$ to the voltage transfer function. Since the voltage $\bar{E}_F$ subtracts from $\bar{E}_C$, the feedback is called negative. The saturable reactor can be viewed as a device which tries to con-

tinuously increase its output voltage $\bar{E}_O$, but which is held in check by the negative feedback of voltage $\bar{E}_F$.

For the sake of completeness, it is pointed out that equation 13 can also be written as follows

$$K_{AT}G(p) = \frac{\bar{I}_LN_G}{\bar{E}_C\frac{N_C}{R_C}} = \frac{1}{1+pT_C} \tag{28}$$

leading to the block diagram of Figure 7 for the entire circuit. Both output and input are now expressed in ampere-turns and therefore the saturable-reactor circuit can be viewed as an ampere-turn amplifier. The steady-state ampere-turn gain is

$$K_{AT} = 1 \tag{29}$$

and the transient response is

$$G(p) = \frac{1}{1+pT_C} \tag{30}$$

with T from equation 14.

The feedback function $K_2G_2(p)$ becomes

$$K_2G_2(p) = 1 \tag{31}$$

This feedback function of unity subtracts at the summing point from the input, and one concludes that the saturable reactor with resistive load has an ampere-turn feedback gain of minus one.

General Transfer Function of Saturable Reactor with Inductive D-C Load

The circuit is shown in Figure 8 and is described in detail in reference 7. Its block diagram is illustrated in Figure 9, which is similar to Figure 6 except as follows:

1. The load transfer of an inductive load is (equation 7)

$$K_LG_L(p) = \frac{\bar{I}_L}{\bar{E}_O} = \frac{1}{R_O}\,\frac{1}{1+pT_L} \tag{32}$$

where R_O signifies the entire circuit resistance when lumped into the load resistance (equation 28, reference 7). The load time constant T_L is

$$T_L = \frac{L_L}{R_O} \tag{33}$$

2. The gate current $\bar{I}_G$ no longer equals $\bar{I}_L$ as shown in equation 26. Instead

$$\frac{\bar{I}_G}{\bar{I}_L} = \frac{1}{F'(\alpha)} \tag{34}$$

as follows from equations 14 through 17 of reference 7. As a result, the feedback transfer function $K_2G_2(p)$ now becomes different from equation 16.

$$K_2G_2(p) = \frac{\bar{E}_F}{\bar{I}_L} = \frac{\bar{E}_F}{\bar{I}_G}\,\frac{\bar{I}_G}{\bar{I}_L} = R_C\frac{N_G}{N_C}\,\frac{1}{F'(\alpha)} \tag{35}$$

where F' (α) is the derivative of the free-wheeling function F (α) with respect to, α (equations 12, 13, and 14 and 38, reference 7).

With all component transfer functions established (see Figure 9), the total transfer function can be obtained from equation 8

$$\frac{\bar{I}_L}{\bar{E}_C} = \frac{F'(\alpha)}{R_C}\,\frac{N_C}{N_G}\cdot\left[\frac{1}{p^2T_LT_CF'(\alpha)+pT_CF'(\alpha)+1}\right] \tag{36}$$

where T_C is the time constant of the control circuit of the saturable reactor in the absence of inductance in the load circuit (equation 14).

As in the foregoing, the time-invariant part K is the steady-state gain. The response function $G(p)$ is in a form which has been solved in the past in connection with feedback control problems.[8–11] A formidable amount of time can now be saved by the direct application of the results of the analysis of feedback control systems to the saturable reactor with inductive d-c load.

The response function $G(p)$ has variable coefficients, a fact which makes a rigorous solution very difficult. However, for the evaluation of stability in feedback control problems, the response needs to be determined only in the immediate vicinity of a steady-state operating point. Then, for the small excursions of the incremental variables, to which this analysis is restricted, the response function can be considered as having constant coefficients. With constant coefficients, the quadratic response function $G(p)$ represents a second-order differential equation similar to the equation for the

charge of a capacitor as a function of the terminal voltage in a linear series network consisting of capacitance, inductance, and resistance. The response of such a system to a step-function disturbance of the terminal voltage can be classified into overdamped response, underdamped (oscillatory) response, and critically damped response for the boundary between the two aforementioned cases.

In analogy to the capacitance-inductance-resistance circuit, let us now introduce the damping index ζ and the undamped, natural angular velocity ω_n

$$\zeta=\frac{1}{2}\sqrt{\frac{T_C F'(\mathfrak{x})}{T_L}} \tag{37}$$

$$\omega_n=\sqrt{\frac{1}{T_L T_C F'(\mathfrak{x})}} \tag{38}$$

With these substitutions, the response function of equation 36 becomes

$$G(p)=\frac{\omega_n^2}{p^2+2\zeta\omega_n p+\omega_n^2} \tag{39}$$

whose denominator when equated to zero is called the characteristic equation. Equation 39 can also be written in the form

$$G(p)=\frac{1}{(1+pT_1)(1+pT_2)} \tag{40}$$

where

$$T_{1,2}=\frac{T_n}{\zeta\mp\sqrt{\zeta^2-1}} \tag{41}$$

and

$$T_n=\frac{1}{\omega_n} \tag{42}$$

OVERDAMPED RESPONSE ($\zeta>1$)

With $\zeta>1$, the time constants $T_{1,2}$ (equation 41) are real and different. The response function $G(j\omega)$ can be easily plotted in the attenuation-frequency plane.[10] The two time constants T_1 and T_2 are different from $T_C F'(\mathfrak{x})$ and T_L and lie between $T_C F'(\mathfrak{x})$ and T_L. A practical case is shown in Figure 10 where $T_C F'(\mathfrak{x})=3$ seconds and $T_L=1/3$ second. The damping ratio $\zeta = 1.5$ (equation 37). The two time constants follow from equation 41: $T_1 = 2.62$ seconds, $T_2 = 0.38$ second. The asymptotes of the attenuation-frequency diagram can now be plotted by the well-known procedure,[9,10] resulting in the three straight lines *OABC*. For geometric reasons, the extension of *CB* intersects the zero-decibel axis at point *D*, which is located at $\omega=\omega_n$. With the asymptotes established, the attenuation-frequency characteristic and the phase-angle–frequency characteristic can be quickly obtained by simple standard methods.

The operational form of equation 40 can be converted into an amplitude-time function,[12] resulting in

$$G(t)=\frac{T_1}{T_1-T_2}\left(1-\epsilon^{-\frac{t}{T_1}}\right)-\frac{T_2}{T_1-T_2}\left(1-\epsilon^{-\frac{t}{T_2}}\right) \tag{43}$$

One recognizes that the amplitude response of the saturable reactor to a step-function control voltage consists of the difference of two exponentials.

One boundary case results for zero load inductance: $T_L=L_L/R_O=0$ and hence $\zeta=\infty$. One obtains from equation 41 $T_1=T_C F'(\mathfrak{x})$ and $T_2=0$. The response as a function of time is a simple exponential and is shown in Figure 11 by the curve marked $\zeta=\infty$.

As the load inductance L_L is increased, the damping index declines. For $T_L=$

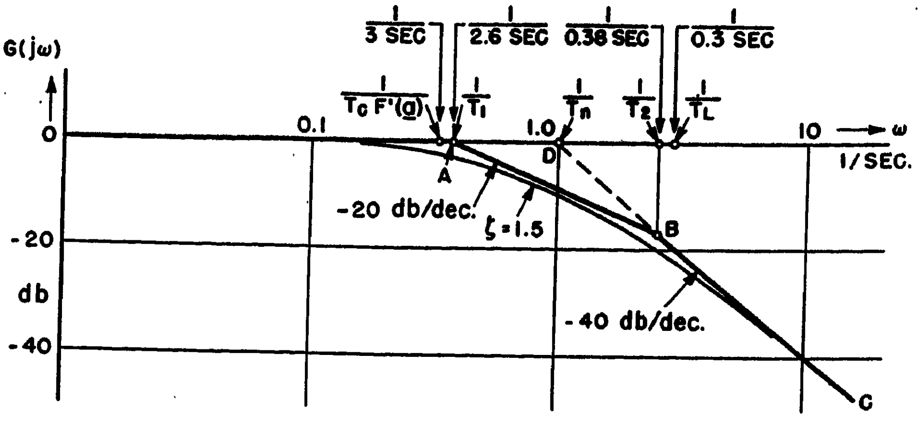

Figure 10. Attenuation frequency response of load current for overdamped system

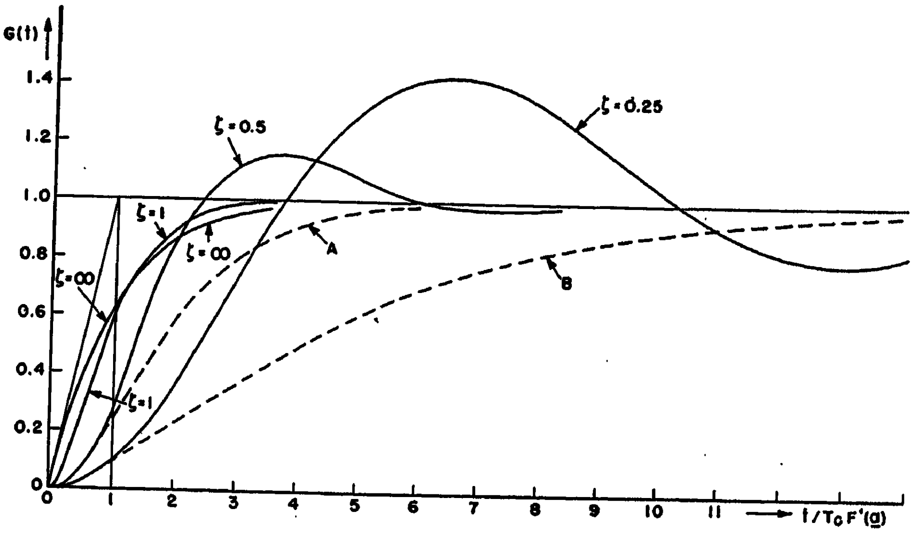

Figure 11. Amplitude-time response of load current for various degrees of damping

$(1/4)T_CF'(a)$ the damping index reaches the other boundary, namely $\zeta=1$, which is discussed in the next section and shown by the curve marked $\zeta=1$. The response for any overdamped case lies between the two boundary curves just mentioned. One will recognize that during the initial period of the transient the load current with inductive load is smaller than for the case with resistive load. Later during the transient the two currents become equal, and finally the current in the inductive case stays ahead of the current in the resistive case. The latter conclusion is rather arresting, and this seeming paradox of a more rapid current build-up in the inductive case becomes more conspicuous yet for $\zeta>1$.

CRITICALLY DAMPED RESPONSE ($\zeta=1$)

By increasing the load inductance L_L until $T_L=(1/4)T_CF'(a)$, the damping index $\zeta=1$ and one now obtains coinciding values for the two time constants (equation 41) corresponding to a double root of the characteristic equation. The response function $G(p)$ degenerates into

$$G(p)=\frac{1}{(1+pT_n)^2} \tag{44}$$

The amplitude time response[12] corresponding to equation 44 is

$$G(t)=1-\epsilon^{-\frac{t}{T_n}}\left(1+\frac{t}{T_n}\right) \tag{45}$$

and is illustrated in Figure 11. The critically damped case is characterized by the load current reaching the vicinity of its asymptote $G(t)=1$ most quickly without causing an overshoot.

UNDERDAMPED OSCILLATORY RESPONSE ($\zeta<1$)

By further increasing the load inductance L_L, $T_L>(1/4)T_CF'[a]$, and hence $\zeta<1$. The time constants of equation 41 become complex conjugate and thereby lose their original meaning. The attenuation-frequency and phase-angle–frequency characteristics no longer can be obtained quickly from the asymptote. By replacing p by $j\omega$ in equation 39 and by substituting

$$u=\frac{\omega}{\omega_n} \tag{46}$$

one obtains

$$G(ju)=\frac{1}{-u^2+2\zeta ju+1} \tag{47}$$

This equation appears in many feedback control problems and its numerical evaluation has been repeatedly published;[11] it is again shown in Figure 12 for various amping indices.

By transforming the attenuation-frequency response into the amplitude-time response,[12] one obtains equations 48 and 49

$$G(t)=1-\frac{\epsilon^{-\zeta\omega_nt}}{\sqrt{1-\zeta^2}}\sin\left(\omega_n\sqrt{1-\zeta^2}\,t+\phi\right) \tag{48}$$

$$\phi=\tan^{-1}\frac{\sqrt{1-\zeta^2}}{\zeta} \tag{49}$$

An inspection of equation 48 reveals that the load current is a damped oscillation. One may expect an oscillation in a circuit containing an inductance and a capacitance, but to find an oscillation in a circuit which contains two inductances is a phenomenon which is rather unexpected. For instance, for $T_L=T_CF'(a)$, the damping index $\zeta=0.5$, and the current in the load inductance as function of the application of a step-function control voltage is shown in Figure 11 by the curve marked $\zeta = 0.5$. For a larger T_L, namely $T_L = 4\ T_CF'(a)$, the curve marked $\zeta=0.25$ results. The load current overshoots and undershoots the asymptote $G(t)=1$ and gradually approaches it in the form of a damped oscillation.

Not only is the oscillatory character of the load current quite unexpected but the rate of current rise is another surprising feature. Suppose one energizes the field of an exciter from the armature of a pilot exciter, each machine having a transfer function of the general form $1/(1+pT)$. The response of the exciter field current as a function of a step voltage applied to the field of the pilot exciter is then given by equation 43, where T_1 is the field time constant of the pilot exciter and T_2 is the exciter field time constant. For $T_2=T_1$, the exciter field current will respond according to the dashed curve A in Figure 11 with t/T_1 as abscissa. However, if the same exciter field is energized from a saturable reactor such that $T_CF'(a)=T_1$, the curve marked $\zeta=0.5$ results, as previously discussed. For $T_2=4T_1$ the exciter field current responds according to curve B when energized from the aforementioned pilot exciter. However, when

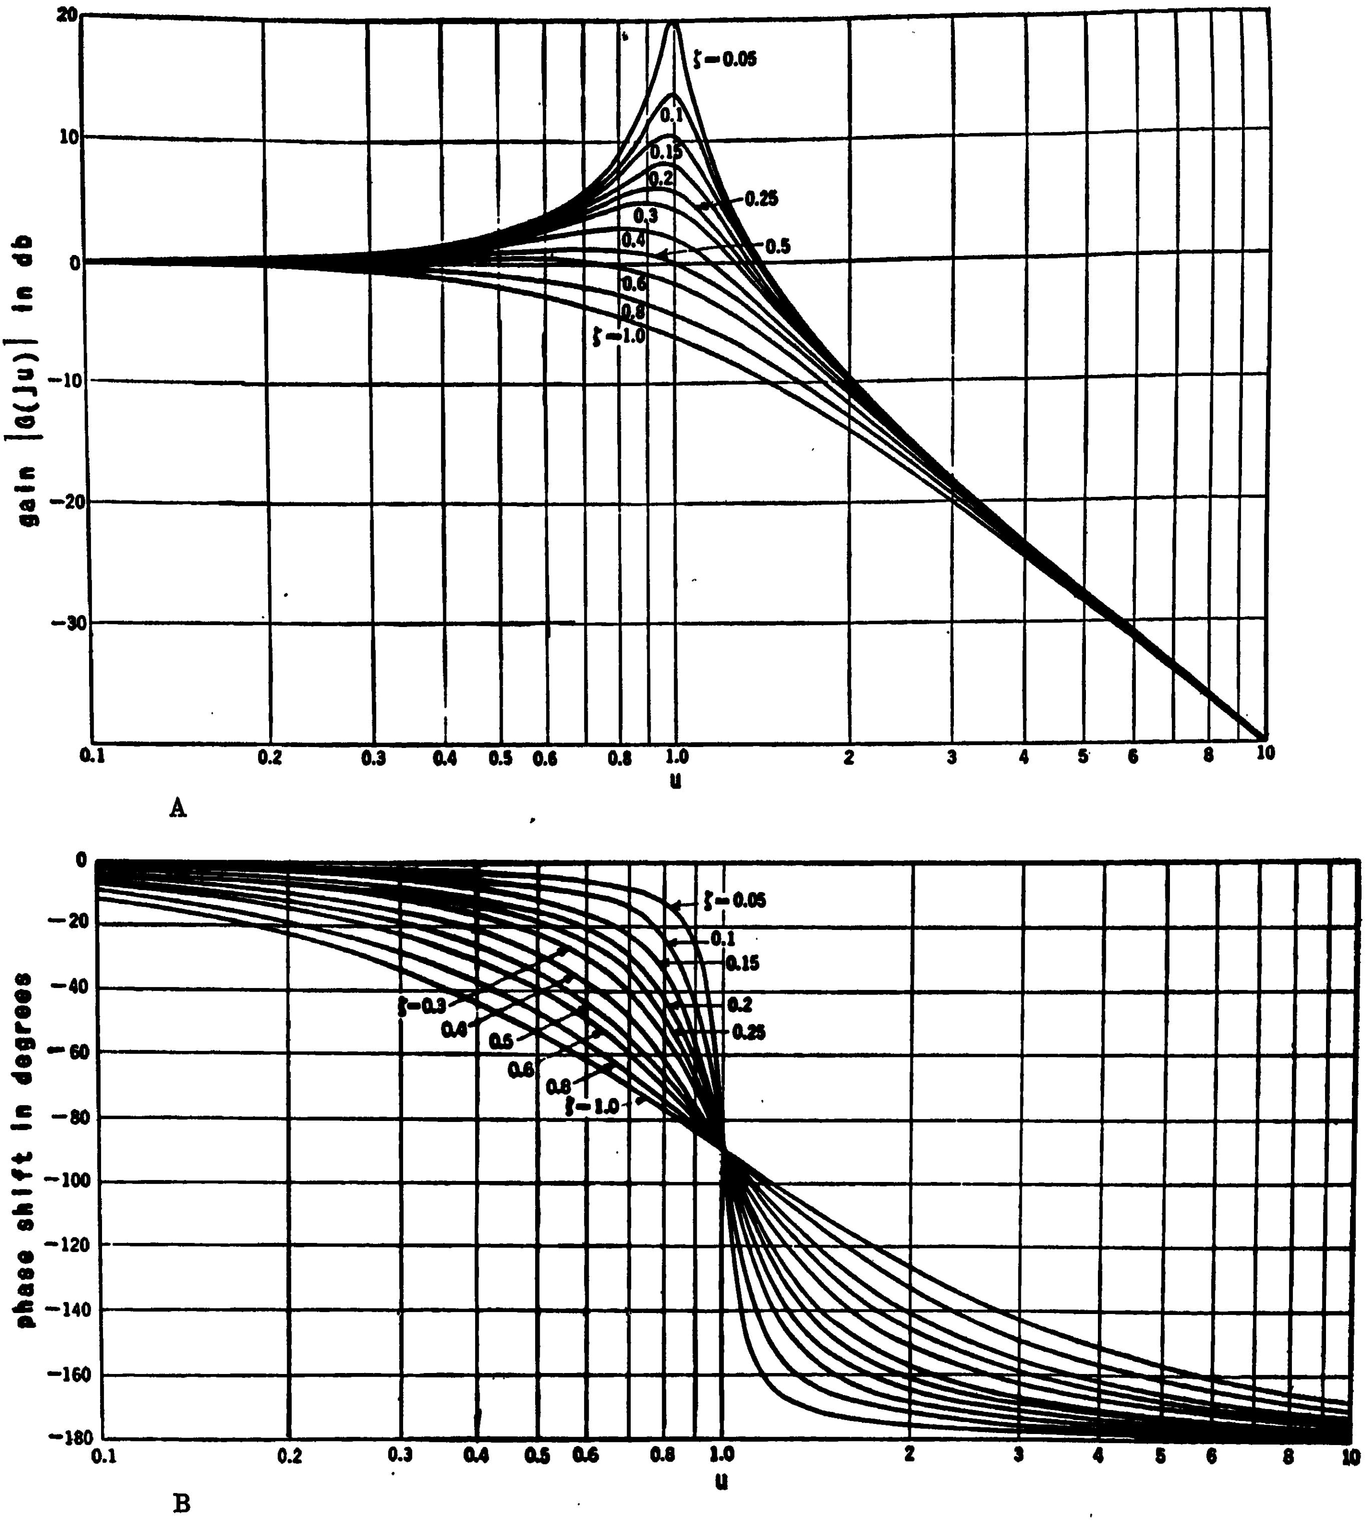

Figure 12. Underdamped system

A. Attenuation-frequency response of load current

B. Phase-angle–frequency response of load current

energized by the aforementioned saturable reactor, the exciter field current responds as shown by the curve marked $\zeta=0.25$. One concludes that, with equal time constants, a saturable reactor taking the place of the pilot exciter gives a much quicker response of exciter field current, and hence exciter armature voltage.

Figure 13 illustrates the load current i_L through the load inductance as the result of a suddenly increased control voltage E_C of the saturable reactor, energizing the load inductance (Figure 9). The upper trace in the oscillogram is a time wave obtained from the 60-cycle supply voltage. The measured value for the load time constant τ_L equals 9 cycles, the control time constant τ_C equals 2.5 cycles and the average value of $F'(a)$ equals 1.6, resulting in a damping ratio of $\zeta=0.33$. The ratio of the maximum amplitude of the load current with respect to the final steady-state value is measured from the oscillogram as 1.35. The calculation of the maximum overswing from equations 48 yields 1.33, which is in close agreement with the measured value.

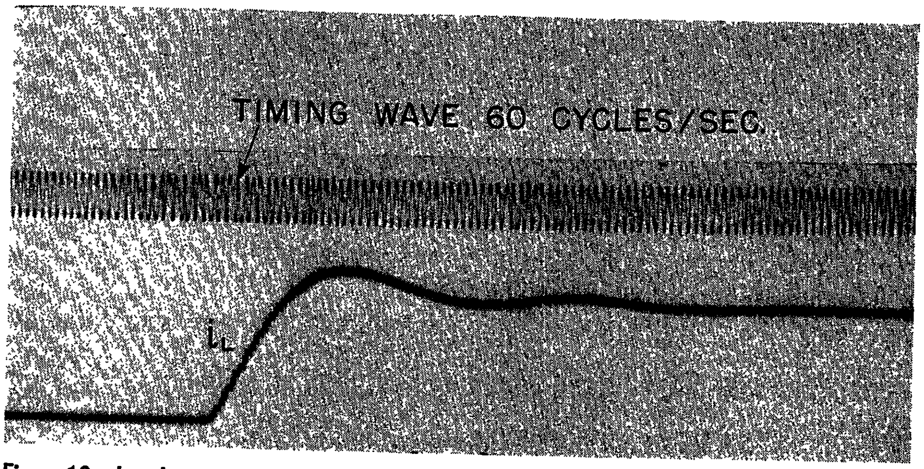

Figure 13. Load current i_L in inductive d-c load, as result of suddenly increased control voltage E_C of saturable reactor

Block Diagram of Saturable Reactor with External Feedback (Also Amplistats)

As shown in Figure 14, feedback windings (*Z1*, *Z2*) and a feedback rectifier bridge have been added to Figure 8. The rectified gate current flowing in the feedback windings induces opposite ampere-turns in the control windings, with the result that the control current becomes reduced by the factor $1-(N_F/N_G)$ (equation 39, reference 13). Then the feedback transfer function $K_2G_2(p)$ (equation 35) becomes reduced by the same factor (Figure 15)

$$K_2G_2(p)=R_C\frac{N_G}{N_C}\,\frac{1}{F'(x)}\left(1-\frac{N_F}{N_G}\right) \tag{50}$$

For $N_F=N_G$, the external positive feedback completely nullifies the internal negative feedback, resulting in an amplifier without feedback; the feedback link as represented by $K_2G_2(p)$ in Figure 15 vanishes, and the forward function $K_BG_B(p)$ becomes the total transfer function of the magnetic amplifier. Instead of applying external positive feedback for the cancellation of the inherent negative feedback, the latter can be eliminated more directly by the interposition of rectifiers. These rectifiers block the flow of gate current in that direction which would cause the negative feedback; such circuits are called amplistats,[14] self-saturated,[18] self-feedback[19] amplifiers.

The forward function $K_BG_B(p)$ (equation 20) has been derived under the assumption of the theoretical rectangular flux-density–field-intensity line which, by its very nature, will not engender exciting currents. With actual core materials, however, exciting currents are present. These exciting currents cause voltage drops on the resistance R_G of the control winding and therefore less than $\bar{E}_\epsilon$ becomes available for producing a flux change. As long as there is considerable negative feedback present, the over-all transfer function $KG(p)$ is determined essentially by the feedback function $K_2G_2(p)$, and therefore the deviations inflicted to the forward function $K_BG_B(p)$ by the exciting currents are usually negligible. However, with declining values of the feedback function $K_2G_2(p)$, the effect of the exciting currents becomes more prominent and with zero total feedback ($N_F=N_G$), the exciting currents become the decisive factor for the output voltage. In the following, the effect of the exciting currents will be added to the block diagram.

The exciting currents have a transfer function of the general character of equation 7. The voltage which produces the flux change is the voltage on the inductance E_X, which is obtained by multiplying equation 7 by pL. As a result, one obtains for the ratio of the voltage E_X to the applied voltage E_ϵ

$$\frac{\bar{E}_X}{\bar{E}_\epsilon}=\frac{pT_a}{1+pT_a} \tag{51}$$

where T_a is a quantity still to be determined. The voltage transfer function of

$\bar{I}_L$

Figure 15. Block diagram of series-connected saturable reactor with external gate current feedback, and with inductive d-c load. $K_2G_2(p)=0$ for amplistats with zero reverse-rectifier current

equation 20 becomes

$$\frac{\bar{E}_O}{\bar{E}_\epsilon}=4f\frac{N_G}{N_C}\frac{1}{p}\frac{pT_a}{1+pT_a} \tag{52}$$

$$K_E=4f\frac{N_G}{N_C}T_a \tag{53}$$

$$G_E(p)=\frac{1}{1+pT_a} \tag{54}$$

The voltage gain for $N_F=N_G$ can also be expressed

$$K_E=\frac{d(I_LR_O)}{d(I_CR_C)}=\frac{d(I_LN_G)}{d(I_CN_C)}\frac{R_ON_C}{R_CN_G}$$

$$=K_{AT_0}\frac{R_ON_C}{R_CN_G} \tag{55}$$

where K_{AT_0} is the ampere-turn gain for $N_F=N_G$ and often has magnitudes from 30 to 300. Equating equations 53 and 55, one obtains for T_a

$$T_a=\frac{1}{4f}\frac{R_O}{R_C}\frac{N_C^2}{N_G^2}K_{AT_0}=T_C K_{AT_0} \tag{56}$$

where T_C is the time constant of equation 14.

One arrives at the important conclusion that the time constant T_a can be determined from a static test.[16,17] For the special case of purely resistive load one obtains from Figure 15 and equation 8 for the time constant T

$$T=T_CK_{AT} \tag{57}$$

regardless of the amount of feedback or reverse current. Again, K_{AT} is determined by a static test and T_C is calculated from equation 14.

Conclusion

The saturable reactor with or without feedback and the amplistat circuits are represented in block diagram form in Figure 15. The load is either a purely resistive or an inductive d-c load. The transient response is obtained from the block diagram by a simple manipulation, equation 8. With inductive d-c load, the response of the load current may be oscillatory, Figure 13; as positive feedback is increased, the oscillatory character decreases and finally vanishes altogether.

The equations of this paper hold for the series-connected saturable reactor. The performance of the parallel-connected saturable reactor is ascertained by replacing N_G in all equations by $N_G/2$ (reference 4).

For amplistats, the feedback function $K_2G_2(p)=0$, provided boost-or-buck windings and rectifier reverse current are absent. Then the transfer function of the amplistate consists of the forward functions $K_EG_E(p)$ $K_LG_L(p)$ only; the response is always overdamped. With rectifier reverse current present, the feedback function reappears, being a function of the reverse to forward current ratio of the rectifiers, which ratio takes the place of the term $(1-N_F/N_G)$ in Figure 15. Again it is reiterated that when applying Figure 15 to the amplistat all terms containing N_G must be replaced by $N_G/2$.

The block diagram also permits the study of the effects of parameter variations on the operation of magnetic amplifiers, such as changes of line voltage, line frequency, load resistance, rectifier reverse resistance, core material, and so forth. It should be pointed out, however, that the transient response has been derived under the assumption of the control windings not producing transient currents in other windings, such as bias, feedback, gate windings, or in the laminations of the core (eddy currents). If such currents are induced, the total time constant of all currents involved enters into the calculation, and a considerable complication of the analysis results.

Discussion

M. Riaz (Massachusetts Institute of Technology, Cambridge, Mass.): The advantages of the block diagram have been clearly demonstrated by Dr. Storm in his analysis of the transient response of saturable reactors: not only does the technique offer a better insight into the physics of these devices but it also permits the systematic utilization of the methods of analysis and synthesis already developed for feedback control systems. The block-diagram representation has an added desirable feature in that it often discloses the similar dynamic properties of essentially different types of energy-conversion devices and thus provides a generalized approach based on analogy that is helpful in understanding the mechanics of operation of these devices. In this respect, the analogy between saturable reactors and metadynes is indeed very striking.

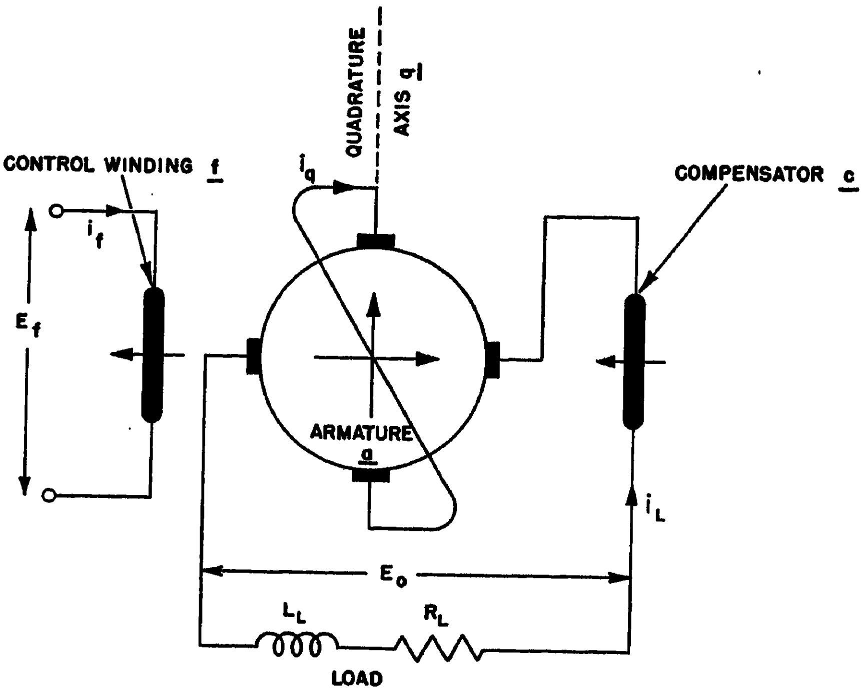

Figure 1. Schematic diagram of a simple metadyne generator supplying an inductive load

A simple metadyne generator with resistive-inductive load is shown schematically in Figure 1 of the discussion. A general transient analysis of the metadyne is given in reference 1. If we assume that the control field circuit has a very small time constant (or that it is energized from a large impedance constant-current source), and if we further neglect the mutual inductance effects, the differential equations governing the operation of the metadyne of Figure 1 of the discussion are

$$E_f = i_f R_f$$

$$E_O = K_a i_q = i_L R_O (1 + pT_L)$$

$$K_f i_f - (K_a - K_c) i_L = i_q R_q (1 + pT_q)$$

where

K = speed-voltage coefficient = knN
N = turns
n = speed of rotation
k = constant dependent upon number of conductors and permeance of the magnetic circuit

The block diagram representation of the metadyne generator shown in Figure 2 of the discussion is easily derived from these equations. It is similar to Figure 15 of the paper, which represents a saturable reactor, except for the fact that the forward gain of the saturable reactor is directly proportional to frequency, whereas the forward gain of the metadyne is proportional to the square of the speed. This squared-speed term appears in the transfer function of the metadyne because here we are essentially dealing with a 2-stage structure. It is interesting to notice the equivalence of the effects of exciting currents in both representations (the excitation field of the metadyne is produced by quadrature current i_q).

Because the same block diagram is applicable to both saturable reactor and metadyne, results obtained for one structure may also be derived for the other. Dynamically both devices are essentially similar.

The oscillatory character of the load current is a main feature of the metadyne (see Figure 13 of reference 1) whose inherent fast response makes it especially suited to its use as an exciter. This property known as field-forcing action, is a result of the constant-current characteristic of the machine produced by the negative feedback of the output. The metadyne may then be considered analogous to a series-connected saturable reactor.

As the degree of compensation is increased (feedback decreased), the oscillatory character lessens and finally vanishes in the case of perfect compensation ($N_a = N_c$) corresponding to amplidyne operation. However, the over-all amplification is increased with this reduction of scalar negative feedback. Amplidyne behavior is then dictated by its constant-voltage characteristic which accounts for the lack of field-forcing action in an inductive load; this behavior is analogous to that of a self-excited magnetic amplifier.[2]

Although block diagram techniques, often developed with electronic systems in mind, are very helpful in looking for means of improving the performance of feedback control systems, it must be remembered that they are based upon idealized conditions. Magnetic devices of both static and rotating types with their associated energy storages always introduce subsidiary effects (for instance, mutual inductances between windings) which greatly complicate the analysis and are therefore usually neglected. However, all final assessment must account for these effects, the importance of which may vary from case to case.

in connection with a computer for a large positive increase of control voltage provided that the nonlinear nature of the control characteristic is included.

Suppose in a voltage regulating system a magnetic amplifier is used as the pilot exciter for the main exciter of a synchronous generator. One may wish to determine the rate of rise of the exciter for a large error signal to the regulator caused by a large power system disturbance (such as switching out a line). The saturable reactor can no longer be considered a linear device since it goes to ceiling voltage quite rapidly. The resulting nonlinear effects can be handled if an analogue computer is available or step-by-step integration is employed. The following procedure will give the solution.

Refer now to Figure 15. The forward transfer function $K_EG_E(p)$ can be written as

$$\bar{E}_O=\left[4f\frac{N_G}{N_C}\bar{E}_\epsilon-\frac{\bar{E}_O}{T_CK_{AT_0}}\right]\frac{1}{p}$$

This is recognized as a forward transfer function and a feedback transfer function and the block diagram of Figure 15 becomes Figure 3 of the discussion.

Since K_{AT_0} is the slope of the control characteristic at any point and T_C is a constant determined from equation 14 of the paper, a curve relating θ_F to $\bar{E}_O$ can easily be drawn. A curve of $K_2G_2(p)$ of which $F'(a)$ is the only variable may be drawn as a function of $\bar{I}_L$. Nonlinear elements on the analogue computer will then permit a continuous solution. This sort of thing is done frequently to handle saturation in rotating machines. The block diagram makes the steps of analysis easier to visualize. When using a computer, the other restrictions of Dr. Storm's analysis can be obviated in the same manner.

H. F. Storm: The author wishes to thank R. A. Phillips and M. Riaz for their worthwhile discussions.

Extended Regulation Curves for 6-Phase Double-Way and Double-Wye Rectifiers

I. K. DORTORT
MEMBER AIEE

AS THE load on a rectifier increases from no load to short circuit, several modes of operation are encountered. The number and characteristics of these modes depend on the connection of the rectifier transformer and rectifying elements,[1,2] and the distribution of impedances in the coupled circuits.[3,4]

For the commonly used 6-phase double-way and double-wye rectifiers, the entire regulation curve has been worked out only for the special case of a rectifier having secondary reactance, no primary reactance, and infinite inductance in the d-c circuit.[1,2] These conditions are seldom approached in actual practice. The lack of information for the case of primary reactance has not been felt too severely because the first mode of operation is the same for rectifiers having primary reactance, secondary reactance, or both. The first mode will generally include the entire normal range of rectifier operation.

The value of the short-circuit current for the case of a rectifier with only primary reactance and no inductance in the d-c circuit is given in an AIEE report.[3] Formulas for the entire range of load on rectifiers with only primary reactance and having either infinite or zero d-c inductance were presented in a paper by the author[4] and later found to be in error in two areas. This paper presents the derivation of the regulation curve for the case of primary reactance only, and either infinite or zero inductance in the d-c circuit.

The definitions of primary and secondary reactance are important. For the purpose of this paper it is sufficient to

define primary reactance as reactance which produces equal voltage drops in diametrically opposite valve circuits. Secondary reactance produces a voltage drop in only one valve circuit. Generally, primary reactance will involve only alternating leakage fluxes, while secondary reactance involves only unidirectional leakage fluxes.

Definition of Symbols

As far as possible the legend of symbols has been made consistent with the nomenclature of the report on "Protection of Electronic Power Converters."[3] Subscript pu denotes per-unit quantities.

$e_{A,B,C}$ = instantaneous phase voltages
E = rms value of phase voltages
E_d = average direct voltage
ΔE_d = direct voltage drop $= E_{d0} - E_d$
E_{d0} = average direct voltage at no load
$E_{d\text{pu}} = E_d/E_{d0}$
$i_{1,2,3}$ = instantaneous valve currents
i_d = instantaneous direct current during single conduction (only one phase conducting in a given direction)
i_d'' = instantaneous direct current during overlap (two phases conducting in the same direction)
i_c = instantaneous commutating current
L_d = d-c inductance
L_p = primary inductance
I_d = average d-c load current
I_{dn} = rated d-c load current
N = turn ratio, secondary to primary
S = load factor $= X_{c\text{pu}}(I_d/I_{dn})$
F_x = reactance factor $= (I_dX_c)/E_s$
u = angle of overlap (double conduction)
α = angle of delay
γ = angle of double commutation
X_c = commutating reactance
$X_{c\text{pu}}$ = per-unit commutating reactance $= (\sqrt{2}X_cI_{dn})/(\sqrt{3}E)$

Equality of 6-Phase Double-Wye and Double-Way

It is well known that the 6-phase double-way and double-wye circuits exhibit similar characteristics during the first mode of operations. If it can be proved for the general case that both circuits behave in identically the same manner from no load to short circuit, the derivation of the extended regulation curve for one will hold for both.

Taking first the case of the 6-phase double-way rectifier, Figure 1(A) shows the actual diagram, 1(B) shows a functional diagram for the period of single conduction, when only one phase conducts in a given direction, and 1(C) is the functional diagram during a period of overlap, u when two phases are conducting in the same direction. Figure 2 shows the characterized voltage and current wave shapes.

Using the operator $D = d/dt$, the current i_d through the d-c load during the period of single conduction, Figure 1(B) is given by the generalized equation

$$[(2L_p + L_d)D + R]i_d = e_A - e_C \qquad (1)$$

When e_B becomes equal to $e_A - L_pDi_d$, valve *3* is free to conduct current and the period of overlap u begins. The build-up of current in valve *3* and the decay of current in valve *1* can be represented by a circulating current i_c. The two currents i_d'' and i_c during this period are represented by the simultaneous equations

$$[(2L_p + L_d)D + R]i_d'' - L_pDi_c = e_A - e_C \qquad (2)$$

$$-L_pDi_d'' + 2L_pDi_c = e_B - e_A \qquad (3)$$

Figure 3 shows the 6-phase double-wye circuit with interphase transformer. The magnetizing current of the interphase

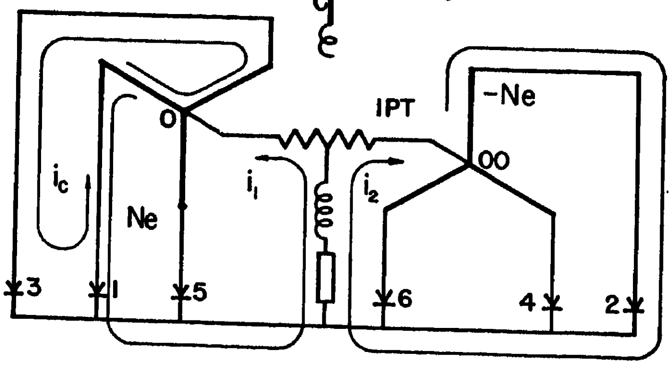

Figure 3. Diagram of 6-phase double-wye rectifier with interphase transformer IPT

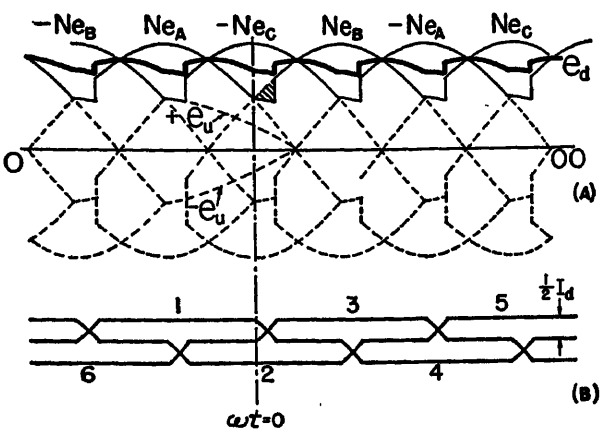

Figure 4. Voltage and current wave shapes of double-wye rectifier (characterized), first mode

A. Voltages
B. Currents

transformer is considered to be negligibly small, so that $i_1=i_2=i_d/2$.

During the period of single conduction

$$[(N^2L_p+L_d)D+R]i_1+[L_dD+R]i_2=Ne_A \tag{4}$$

$$[L_pD+R]i_1+[(N^2L_p+L_d)D+R]i_2=-Ne_C \tag{5}$$

Since $i_1+i_2=i_d$, equations 4 and 5 reduce to

$$[(N^2L_p+2L_d)D+2R]i_d=N(e_A-e_C) \tag{6}$$

To make the two cases directly comparable, let $N=2$ and e, L_p, R, L_d be the same for both connections. Then equation 6 reduces exactly to equation 1, proving the 6-phase double-way and double-wye equivalent during the period of single conduction.

The period of "single" conduction ends and the overlap u begins with the pick-up of valve *3* when Ne_B becomes equal to $Ne_A-N^2L_pDi_1$. Remembering that $N=2$ and $i_1=i_d/2$, this condition again duplicates the performance of the 6-phase double-way rectifier. When $N=2$, $i_c'=i_c/2$. This is to be expected, since in the double-way circuit i_d is commutated in total, while in the double-wye circuit only $i_d/2$ is commutated at any one time. During the commutation period u

$$[(N^2L_p+L_d)D+R]i_1+[L_dD+R]i_2-N^2L_pDi_c'=Ne_A \tag{7}$$

$$[L_dD+R]i_1+[(N^2L_p+L_d)D+R]i_2=-Ne_C \tag{8}$$

$$N^2L_pDi_1+2N^2L_pDi_c'=N(e_B-e_A) \tag{9}$$

Substituting $i_1+i_2=i_d$ and $N=2$ these equations reduce to

$$[(2L_p+L_d)D+R]i_d-2L_pDi_c'=e_A-e_C \tag{10}$$

$$-L_pDi_d+4L_pDi_c'=e_B-e_C \tag{11}$$

Substituting $i_c'=i_c/2$ these equations become identical to equations 2 and 3 for the double-way rectifier.

The value of i_d at the beginning of the period of single conduction must be the same as the value of i_d'' at the end of the preceding period of overlap. Under steady-state conditions, the value of i_d at the end of the period of single conduction must also be equal to the value of i_d'' at the beginning of the preceding period of overlap. These conditions uniquely determine the constants of integration of the preceding differential equations.

It can be seen in Figure 2(A) that during commutation between valves *6* and *2* of the double-way rectifier the terminal voltage of phase *B* is depressed along curve e_u and will remain negative with respect to the terminal voltage of phase *A* until the commutation *6-2* is completed. Valve *3* is therefore prevented from picking up at least until that time. Since this behavior is repeated at each of the six commutation periods per cycle, commutation is automatically limited to a maximum of 60 electrical degrees during the first and second modes of operation regardless of the load. When u reaches 60 degrees, a further increase of load current will cause a delay in pick-up resembling phase control.

The 6-phase double-wye circuit exhibits exactly the same property. Refer to Figures 4(A) and 4(B). During commutation between valves *6* and *2* the terminal voltage of d-c winding $-Ne_B$ with respect to neutral 00 is raised along curve e_u. This winding is closely coupled to winding $+Ne_B$ and their voltages must at

all times be equal and opposite. Therefore, during this period, the terminal voltage of winding Ne_B with respect to neutral 0 is depressed along line $-e_u$ and will remain negative with respect to the terminal voltage of phase Ne_A until the commutation *6-2* is completed. Again, valve *3* is prevented from conducting until that time.

Similarly, it can be shown that both circuits behave the same way during periods of double commutation, that is when two commutations occur at the same time. The third mode of operation with d-c inductance involves double commutation and the identity of the two circuits will become obvious during the derivation of the equations.

The preceding discussion presents the proof of the identity of the behavior of the two connections and sets down the equations and limits required in the derivation of the complete regulation curves. We can proceed, then, with the derivations for the case of the double-way circuit and by means of per-unit quantities make the formulas directly applicable to both circuits.

Highly Inductive Load

First Mode

At no load, there is of course no overlap and the direct voltage is the average difference between the positive and negative envelopes of the phase voltages.

$$E_{d0}=\frac{3}{1/f}\int_0^{1/2f}(e_B-e_A)dt=\frac{3}{\pi}\sqrt{6}E=2.34E \tag{12}$$

In the case of the double-wye circuit, the instantaneous direct voltage is the average of the instantaneous direct voltages of the two 3-phase systems. From considerations of symmetry, the average direct voltages of the two systems are equal and therefore each equal to the average combined direct voltage. Then

$$E_{d0}=\frac{3\sqrt{3}\sqrt{2}NE}{2/f}=\int_0^{1/2f}\sin\omega t\,dt$$
$$=\frac{3}{\pi}\sqrt{\frac{3}{2}}NE=1.17NE \tag{13}$$

which, again, becomes identical to equation 12 when $N=2$.

To determine the drop in direct voltage due to primary reactance, refer to Figure 2 and note that at each commutation we lose from the time integral of the direct voltage an area equal in volt-seconds to

$$\frac{\Delta E_d}{6f}=\int_a^b e_{\text{drop}}dt=n(\phi_b-\phi_a)10^{-8}$$
$$=L_p(i_b-i_a) \tag{14}$$

a fundamental relationship in which i_a and i_b are the values of the current through a primary reactance at the beginning and end of a commutating period, and $n(\phi_b-\phi_a)$ is the equivalent change of flux linkages.

In the limiting case of infinite load inductance, the valve and phase currents are flat-topped at the value I_d and $i_b-i_2=I_d$. Therefore

Solutions for equations 33, 34, 35 arranged in order of work.

$$\Delta E_d = 6fL_pI_d \tag{15}$$

The average drop during one cycle is therefore

$$\Delta E_d = \frac{3}{\pi}X_cI_d \tag{16}$$

Substituting

$$X_c = \sqrt{3}X_{cpu}E/\sqrt{2}I_{dn}$$

and

$$E = \pi E_{d0}/3\sqrt{6}$$

$$\frac{\Delta E_d}{E_{d0}} = \frac{1}{2}X_{cpu}\frac{I_d}{I_{dn}} = \frac{1}{2}S \tag{17}$$

SECOND MODE

Equation 17 holds from no load until the overlap u reaches 60 degrees. As the load is increased still further the terminal voltage of phase B remains depressed along e_u [Figure 2(A)], preventing the conduction of valve *3* until commutation *6-2* is completed and the terminal voltage returns to normal. This process is repeated at the end of each commutation period so that one begins where the preceding one ends, each lasting exactly 60 degrees and each delayed by an angle α, as shown in Figure 5(A).

L_d being very large, i_d and i_d'' are held constant at the value I_d and equation 3 reduces to

$$2L_pDi_c = e_B - e_A \tag{18}$$

$$i_c = \frac{\sqrt{6}E}{2X_c}[\cos\alpha - \cos\omega t] \tag{19}$$

At $\omega t = \alpha + u$, $i_c = I_d$ and equation 19 becomes

$$I_d = \frac{\sqrt{6}E}{2X_c}[\cos\alpha - \cos(\alpha+u)] \tag{20}$$

as can be seen by inspection of Figure 5(B).

The first mode ends and the second begins with α equal to zero and u equal to 60 degrees. Equations 16, 17, and 20 give us at this point $X_{cpu}I_d/I_{dn} = 1/2$ and $\Delta E_d/E_{d0} = 1/4$.

To obtain the regulation when the load increases beyond this value, the volt-seconds lost from the direct voltage due to the delay α must be added to the volt-seconds lost in L_p during commutation.

$$\int_0^{(\alpha+u)/\omega} e_{\text{drop}}dt = \sqrt{6}E\int_0^{\alpha/\omega}\sin\omega t\,dt + L_pI_d \tag{21}$$

This loss of area occurs six times a cycle and averaging the total lost area over the cycle

$$\Delta E_d = \frac{3}{\pi}[\sqrt{6}E(1-\cos\alpha) + X_cI_d] \tag{22}$$

which reduces to

$$\frac{\Delta E_d}{E_{d0}} = (1-\cos\alpha) + \frac{1}{2}S \tag{23}$$

Substituting for X_c and making $u = \pi/3$ in equation 20

$$S = \cos\alpha - \cos\left(\alpha + \frac{\pi}{3}\right)$$

or

$$\cos\alpha = \frac{1}{2}S - \frac{1}{2}\sqrt{3}\sqrt{1-S^2} \tag{24}$$

Replacing cos α in equation 23 the per-unit voltage drop during the second mode of operation with highly inductive load becomes

$$\frac{\Delta E_d}{E_{d0}} = 1 - \frac{1}{2}\sqrt{3}\sqrt{1-S^2} \tag{25}$$

The limit is reached when $\alpha = 30$ degrees and the third mode of operation begins. At $\alpha = 30$ degrees, $S = \sqrt{3}/2$ and $\Delta E_d/E_{d0} = 0.567$.

THIRD MODE

From Figure 5(C) it is seen that were α to increase beyond 30 degrees as the load increases, the potential of the positive terminal of the rectifier would decrease along e_u, the average voltage of valves *1* and *3*, and fall below the voltage of the negative terminal which is rising along e_C, the voltage of valve *2*. As there is no artificial blocking of the valves, this condition cannot exist: The a-c terminals of valves *1* and *4* are connected together and must always have the same potential so this mode of operation would require the existence of a voltage across valve *4* in the direction of current flow.

Valve *4*, therefore, picks up at the point of intersection, and for a time γ all three phases are involved in commutation, the net output voltage being zero for this period.

At first glance it appears valves *5* and *6* should also pick up and carry current during this interval. Current wave shapes can be constructed for simultaneous conduction of all valves, which will satisfy the conditions of a perfectly smooth d-c output and zero valve voltages, but only at complete short circuit. However, simultaneous conduction of only valves *1*, *3*, *2*, and *4* satisfies these conditions while approaching complete short circuit and produces a lower value of steady-state short-circuit current. Even in an ideal circuit the higher short-circuit current could only be initiated by a transient condition.

Figure 6(A) shows the voltage conditions in the rectifier as short circuit is approached and Figure 6(B) the output voltage of the rectifier for the same conditions. Figure 6(C) demonstrates the construction of the valve currents. It should be noted here that each valve carries current one-half cycle plus γ.

During the overlap between valves *1* and *4*, the time rate of change of the sum of these two currents must equal the time rate of change of the short-circuit current of phase A. There are no losses in the path of the commutating current, so we can say that the sum of the sinusoidal components of these currents must equal the short-circuit current of phase A and the voltage during that period will then be zero.

The lettered sections of the current curves in Figure 6(C) refer to the sinusoidal components which are displaced by a suitable d-c component from similarly lettered sections on the light sinusoidal curves. Adding up the height of each section between the limits indicated below the figure, we have

$$I_d = \frac{\sqrt{2}E}{X_c}\sin\left(\omega t - \frac{2}{3}\pi\right)\Bigg|_{\pi/6}^{\pi/6+\gamma} + \frac{\sqrt{6}E}{2X_c}\sin\left(\omega t - \frac{\pi}{2}\right)\Bigg|_{\pi/6+\gamma}^{\pi/2} + \frac{\sqrt{2}E}{X_c}\sin\left(\omega t - \frac{\pi}{3}\right)\Bigg|_{\pi/2}^{\pi/2+\gamma} \tag{26}$$

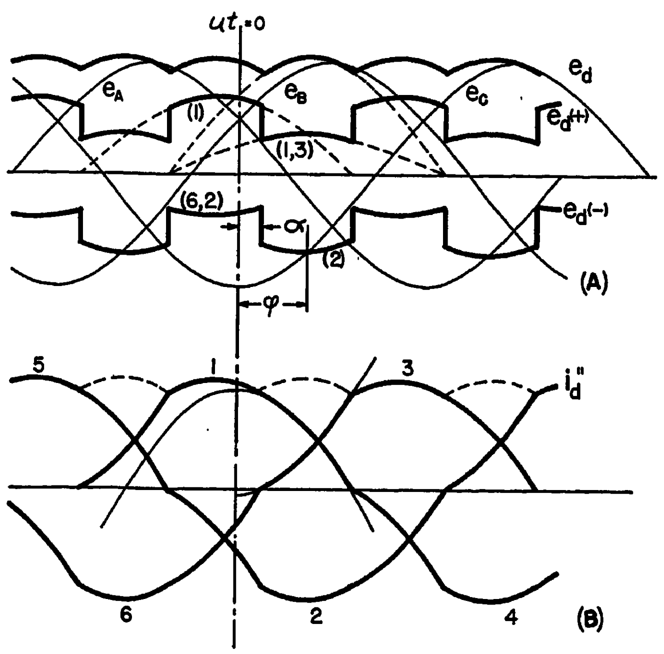

Figure 10. Double-way rectifier, noninductive load, second mode

A. Voltages
B. Currents

Evaluating the three terms and substituting for X_c

$$\sin\left(\gamma+\frac{\pi}{6}\right)=\sqrt{3}S-1 \qquad (27)$$

In evaluating the voltage drop during the third mode of operation, the reactance drop through the primary reactance is caused by the rise of current from 0 to I_d through, say valve *3*, and the final decay of current in valve *6* during the period γ.

$$\Delta E_d=6f\left[\frac{\sqrt{6}E}{\omega}\int_0^{\pi/6}\sin\omega t\,d\omega t+\frac{X_c}{w}\left\{I_d+\frac{\sqrt{2}E}{X_c}\sin\omega t\Big|_{\pi/6}^{\pi/6+\gamma}\right\}\right] \qquad (28)$$

With the help of equation 27, and making the necessary substitutions, this is reduced quite easily to

$$\frac{\Delta E_d}{E_{d0}}=1-\sqrt{3}+\frac{3}{2}S \qquad (29)$$

which is linear with respect to load.

At full short circuit $\Delta E_d/E_{d0}=1$, $S=2/\sqrt{3}$ and $\gamma=60$ degrees.

Noninductive Load

First Mode

Referring back to Figures 1(B) and 1(C), but eliminating the d-c inductance L_d, equations 1, 2, and 3 become

$$[2L_pD+R]i_d=\sqrt{6}E\sin\left(\omega t+\frac{2}{3}\pi\right) \qquad (30)$$

$$[2L_pD+R]i_d''-L_pDi_c=\sqrt{6}E\sin\left(\omega t+\frac{2}{3}\pi\right) \qquad (31)$$

$$-L_pDi_d''+2L_pDi_c=\sqrt{6}E\sin\omega t \qquad (32)$$

In this and what follows the single prime applies to quantities and functions during the period of single conduction and the double prime applies to the period of overlap u. Angles u and α are the same as in the treatment of the case for highly inductive load, α occurring here even in the first mode. σ is used for convenience to denote the start of the first single conduction period and is the correct sum of $u+\alpha$ in the step-by-step evaluation of the constants of integration in the solutions of the preceding equations.

The solutions for i_d, i_d'' and i_c take the form

$$i_d=\frac{\sqrt{6}E}{Z'}\sin\left(\omega t+\frac{2}{3}\pi-\phi'\right)+A\epsilon^{-\frac{R}{2X_c}\left(\omega t+\frac{\pi}{3}-\sigma\right)}\quad\left(\sigma-\frac{\pi}{3}<\omega t<\alpha\right) \qquad (33)$$

$$i_d''=\frac{3\sqrt{2}E}{2Z''}\sin\left(\omega t+\frac{\pi}{2}-\phi''\right)+B\epsilon^{-\frac{2R}{3X_c}(\omega t-\alpha)}\quad(\alpha<\omega t<\sigma) \qquad (34)$$

$$i_c=\frac{1}{2}i_d''-\frac{\sqrt{6}E}{2X_c}\cos\omega t+C\quad(\alpha<\omega t<\sigma) \qquad (35)$$

in which α is the angle of delay and $\sigma=\alpha+u$

$$Z'=\sqrt{R^2+(2X_c)^2},\qquad\tan\phi'=2X_c/R \qquad (36)$$

$$Z''=\sqrt{R^2+(3X_c/2)^2},\quad\tan\phi''=3X_c/2R \qquad (37)$$

It is interesting to note that even though the output is not constant and contains logarithmic terms, the equivalent circuit can be drawn as in Figures 7(A) and 7(B), with i_d'' and i_c determined independently of each other. The term $i_d''/2$ now disappears from the expression for i_c. The net valve currents of course remain exactly the same regardless of the method used.

Returning to equations 34 and 35, it is necessary to determine α, the point at which overlap begins. This can occur only where the terminal voltage of the rectifier intersects the terminal voltage of the next phase to conduct current as shown in Figures 8(A) and 8(B). In this the first mode of operation there is no current through L_p of that phase so that its terminal and induced voltages are equal. Except that u is not necessarily 60 degrees, the action is very similar to the behavior of the rectifier with d-c inductance during its second mode of operation. The necessary condition is expressed by

$$\sqrt{2}E\sin\left(\omega t+\frac{5}{6}\pi\right)-L_pDi_d=\sqrt{2}E\sin\left(\omega t+\frac{\pi}{6}\right) \qquad (38)$$

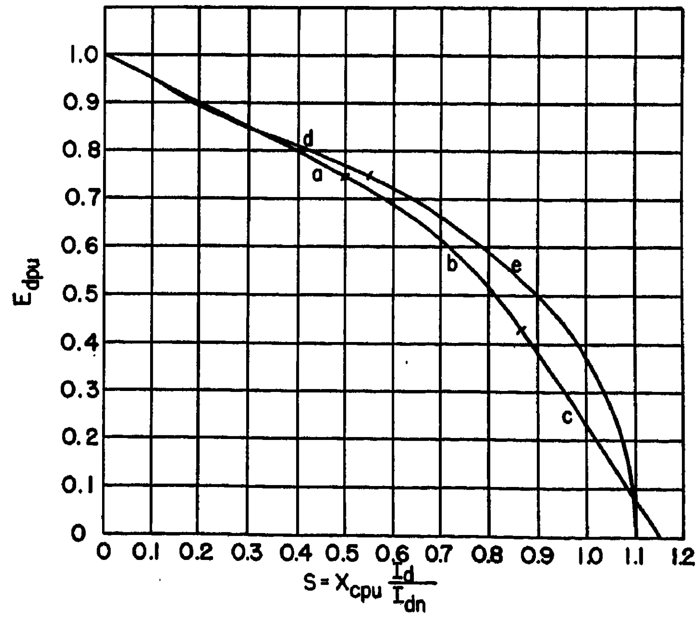

Figure 11. Regulation curves, no load to short circuit

A. Inductive load, first mode
B. Inductive load, second mode
C. Inductive load, third mode
D. Noninductive load, first mode
E. Noninductive load, second mode

which equation is satisfied at $\omega t=\alpha$. Making the necessary substitutions we obtain

$$\sin\alpha=\frac{X_c}{Z'}\sin\left(\frac{\pi}{6}+\alpha-\phi'\right)+\frac{AR}{2\sqrt{6}E}\epsilon^{-\frac{R}{2X_c}\left(\frac{\pi}{3}-u\right)} \qquad (39)$$

The constants of integrations A, B, and C and the angles α and u are best determined by successive approximations based on the necessary conditions that i_d at the beginning of single conduction is equal to i_d'' at the end of overlap, and i_d at the end of single conduction is equal to i_d'' at the beginning of overlap.

The average direct current I_d is obtained by integration of i_d and i_d'' (after substitution of constants in equations 33 and 34) over the limits already indicated and averaging over one-sixth of a cycle. The average direct voltage is then RI_d.

The results are given in Table I arranged in 5-degree intervals of ϕ''. $E_{d\text{pu}}$, u, and α are plotted against S in Figure 9. $E_{d\text{pu}}$ for an inductive load is also shown for comparison. The dotted line in this figure shows what the output voltage would be for a noninductive load if A and B of equations 33 and 34 were assumed to be zero throughout this mode of operation.

One of the surprising results is the inversion of α during the latter half of the second mode; that is, the start of commutation before the intersection of phase voltages. Also to be noted is the fact that u becomes practically 60 degrees considerably before the end of this mode of operation.

SECOND MODE

Since u must be equal to 60 degrees during the second mode, i_d'' must have the same value at the beginning and end of each period of overlap, there being no period of single conduction. Then substituting $\omega t=\alpha$ and $\omega t=\pi/3+\alpha$ in equation 34 and equating

$$\frac{3\sqrt{2}E}{2Z''}\sin\left(\frac{\pi}{2}+\alpha-\phi''\right)+B=\frac{3\sqrt{2}E}{2Z''}\sin\left(\frac{5}{6}\pi+\alpha-\phi''\right)+B\epsilon^{-\frac{2R}{3X_c}\frac{\pi}{3}} \qquad (40)$$

This condition is satisfied when $B=0$ and $\phi''-\alpha=30$ degrees.

Therefore

$$i_d''=\frac{3\sqrt{2}E}{2Z''}\sin\left(\omega t+\frac{\pi}{2}-\phi''\right)\quad\left(\phi''-\frac{\pi}{6}<\omega t<\phi''+\frac{\pi}{6}\right) \qquad (41)$$

The current in valve *1* during this period is

$$i_1=\frac{3\sqrt{2}E}{4Z''}\left[\sin\left(\omega t+\frac{\pi}{2}-\phi''\right)+\frac{1}{2}\sqrt{3}\right]+\frac{\sqrt{6}E}{2X_c}[\cos\omega t-\cos\alpha] \qquad (42)$$

The current in valve *3* during this same period is

$$i_3=\frac{3\sqrt{2}E}{4Z''}\left[\sin\left(\omega t+\frac{\pi}{2}-\phi''\right)-\frac{1}{2}\sqrt{3}\right]-\frac{\sqrt{6}E}{2X_c}[\cos\omega t-\cos\alpha] \qquad (43)$$

The construction of the currents and voltages is shown in Figure 10.

The average direct current is obtained by integrating and averaging i_d'' over the interval $\phi''-\pi/6$ to $\phi''+\pi/6$.

$$I_d=\frac{6f}{\omega}\int_{\phi''-\pi/6}^{\phi''+\pi/6} i_d''\,d\omega t=\frac{3}{\pi}\frac{3}{2}\frac{\sqrt{2}E}{Z''} \qquad (44)$$

Multiplying by $\sqrt{R^2+(3X_c/2)^2}=Z''$

$$\sqrt{(RI_d)^2+\left(\frac{3}{2}X_cI_d\right)^2}=\frac{3}{\pi}\frac{3}{2}\sqrt{2}E \qquad (45)$$

$RI_d=E_d$. Substituting for RI_d and X_c in equation 45 and dividing by E_{d0} we obtain by simple manipulation

$$E_{d\text{pu}}=\frac{E_d}{E_{d0}}=\frac{1}{2}\sqrt{3}\sqrt{1-\left(\frac{\pi}{2\sqrt{3}}S\right)^2} \qquad (46)$$

From equations 41, 42, and 43 and Figure 10 it is obvious that the instantaneous value of the direct current can never fall to zero in the second mode of operation and the terminal voltage of the rectifier cannot be zero during any part of the cycle unless $R=0$. Therefore, there can be no "double commutation" as occurred in mode *3* of the rectifier with highly inductive d-c load. Calling the terminal voltages with respect to neutral $e_d(+)$ and $e_d(-)$

$$e_{d(+)}=e_A-L_pDi_1 \qquad (47)$$

$$e_{d(-)}=e_C+L_pDi_d'' \qquad (48)$$

It must be shown that $e_{d(+)}-e_{d(-)}$ cannot be zero except when $R=0$. Substituting for i_1 and i_d'' in equations 47 and 48 and substracting we obtain after simplification

$$\tan\omega t\neq-\frac{1-\sin^2\phi''}{\sin\phi''\cos\phi''} \qquad (49)$$

Within the limits $\phi''-30$ degrees $<\omega t<\phi''+30$ degrees and 30 degrees $<\phi''<90$ degrees the two terms of equation 49 cannot be equal except for $R=0$, that is $\phi''=90$ degrees.

The second mode, thus ends at short circuit and $S=2\sqrt{3}/\pi$ at short circuit.

Conclusion

The complete regulation curves for rectifiers with primary reactance only, having either zero or infinite d-c inductance are shown in Figure 11. Equations similar to 1, 2, and 3 can, of course, be set up for the more general case of finite d-c inductance, but no attempt has been made to obtain a general solution. There is no reason to believe the curves will not fall between the two limiting cases presented here.

The case for mixed primary and secondary reactance presents much greater difficulty and from the work done so far it appears that specific solutions for particular problems will be in order for some time unless investigation is being carried on in other quarters.

As previously mentioned, the author's earlier paper[4] contained two errors which can now be corrected. The first mode of operation for the case with noninductive d-c load was given as a straight line; the resulting error in computation is not great. The second error occurred in the omission of mode *3* in the case of a rectifier with highly inductive d-c load. Short-circuit computations based on that paper will probable remain valid since losses in the rectifier unit depress the regulation curve so that the third mode of operation is almost entirely eliminated.

Discussion

R. L. Witzke, J. V. Kresser, and J. K. Dillard (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The question of voltage regulation of rectifiers operating at large angles of overlap is becoming increasingly important; two papers on this subject were given at the meeting. Mr. Dortort's paper is more general since it covers the case of a noninductive as well as an inductive load. Taking slightly different analytical approaches, both papers reach the same conclusions with respect to

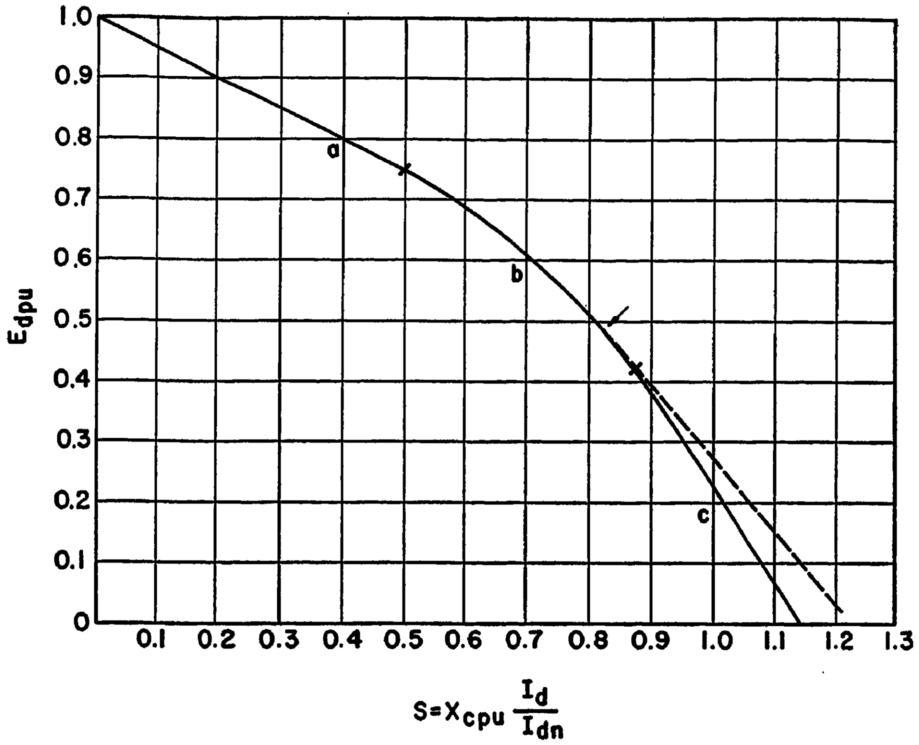

Figure 1. Voltage regulation curve showing effect of leakage between transformer secondary windings

—— $X_{ss}=0$
- - - - $X_{ss}=0.25\ X_c$

cases treated in both papers, and our paper[1] contains laboratory data to substantiate the calculated curves. Neither paper treats extensively the case for mixed primary and secondary reactance which occurs where the leakage reactance between the secondary windings of the double-wye transformer is not negligible. Knowledge of the effect of leakage reactance is essential, however, if the curves based on negligible leakage are to be used with confidence in practical cases.

The regulation curve for inductive load from Figure 11 of the Dortort paper, derived for zero reactance between secondary windings, is reproduced by the solid line of Figure 1 of the discussion. The first mode of operation is along curve *a* out to $S=0.500$; the second mode is along curve *b* out to $S=0.866$; the third mode is along curve *c* out to short circuit at $S=1.15$. Taking leakage reactance into account, equations for the regulation curve are derived and given later. The first and second modes of operation are the same as for the case of negligible leakage reactance X_{ss}, except that the second mode terminates not at 30 degrees delay but at some smaller angle determined by equation 14 of the discussion. In general, the reactance between secondary windings on the same core will be in the range of 0.5 to 2.0 per cent on the a-c winding kilovolt-ampere base.[3] Taking the upper limit, the leakage reactance might be of the order of 25 per cent of the commutating reactance. In this case, $\alpha_m=25.9$ degrees and the second mode terminates at $S=0.827$, the point designated by the arrow in Figure 1 of the discussion. The third mode of operation exists along the dashed curve of the figure, rather than along curve *c*, ending just short of short circuit at $S=1.21$. The lower limit of leakage reactance would give a curve between the solid and dashed lines of Figure 1. There follows a fourth mode of operation, which does not exist where $X_{ss}=0$, during which simultaneous commutations occur within the same wye. Equations for the fourth mode were not derived since, for practical limits of leakage reactance, the third mode of operation carries almost to short circuit.

One other point is of interest. If X_{ss} is negligible, $\alpha_m=30$ degrees and equations 22 and 24 of the derivations given here reduce to

$$\frac{I_cX_c}{E_s}=\frac{\sqrt{2}}{2}+\frac{\sqrt{6}}{4}\sin u-\frac{\sqrt{2}}{4}\cos u$$

$$\frac{E_d}{E_{d0}}=\frac{\sqrt{3}}{2}\,1-\sin(u-30°)$$

These are the equations given for the third mode of operation in our paper.[1] Therefore, if the reactance between secondary windings can be neglected, the operation of a 6-phase double-wye rectifier is identical to that of a 6-phase double-way rectifier.

Derivation of Equations

Transformers used in 6-phase double-wye rectifier circuits usually have a single primary winding and two secondary windings displaced by 180 degrees. The circuit is easier to analyze if the transformer leakage reactance is represented by the conventional equivalent circuit of a 3-winding transformer external to an ideal transformer as shown in Figure 2 of the discussion. Ideal transformers permit the use of two separate primary windings. The reactances X_{ps} and X_{ss} are the actual leakage reactances between primary and each secondary winding and between secondary windings respectively. The turns ratio is taken as $\sqrt{3}$ in order to make the ratio of transformation between primary and secondary line-to-line voltages unity. The derivations are based on a highly inductive load.

Line-to-neutral voltages behind source reactance are E_a, E_b, E_c, defined by the phases of Figure 2(B). Commutation from phase 1 to phase 3 occurs when $E_1=E_3$. If $E_a=\sqrt{2}\ E_s\cos(\omega t+\pi/2)$, where E_s is the rms value of transformer secondary no-load line-to-neutral voltage, commutation from phase 1 to phase 3 normally starts when $t=0$. This fact may be deduced from the phase diagram of Figure 2 of the discussion, which takes cognizance of the phase shift through the delta-wye transformer bank.

First Mode of Operation

During a phase 1 to phase 3 commutation, if $L_c=L_s+L_{ps}$ and $p=d/dt$

$$E_{ab}=-\frac{3}{2}L_cpi_1+E_{a'b'}$$

$$E_{bc}=E_{b'c'} \tag{1}$$

$$E_{a'b'}=E_{c'a'}=-\frac{E_{bc}}{2}$$

The last equation arises from the consideration that $E_3=E_1$ and the sum of the voltages around the delta is zero.

The solution of equation 1 gives

$$pi_1=-\left[\frac{2E_{ab}+E_{bc}}{3L_c}\right]\doteq-\frac{E_a}{L_c} \tag{2}$$

The commutating angle is obtained by integrating equation 2 over the commutating interval and evaluating the integral at the boundaries $\omega t=0$ at which the current $i=0$ and $\omega t=u$ at which $i=I_d/\sqrt{3}$. The latter value is obtained from the fact that $i_{cc}=i\sqrt{3}/2$ and the final value of $i_{cc}=I_d/2$. This is shown in Figure 2 of the discussion. After integrating and rearranging

$$\cos u=1-\frac{I_dX_c}{\sqrt{6}E_s} \tag{3}$$

The average direct voltage may be obtained by averaging the instantaneous voltages during the period of symmetry which is 120 degrees. The instantaneous direct voltage is given by

$$e_d=E_3=-\frac{E_{a'b'}}{\sqrt{3}} \tag{4}$$

During the commutation interval, which lasts from $\omega t=0$ to $\omega t=u$, from equation 1, $E_{a'b'}=-E_{bc}/2=-\sqrt{3}/2\ E_s\cos\omega t$. During the noncommutation interval, $\omega t=u$ to $\omega t=2\pi/3$, from Figure 2, $E_{a'b'}\doteq E_{ab}=\sqrt{3}\ \sqrt{2}\ E_s\cos(\omega t+2\pi/3)$. Therefore, integrating equation 4 over these limits, the average direct voltage is

$$E_d=\frac{3\sqrt{6}}{2\pi}E_s\left(\frac{1+\cos u}{2}\right) \tag{5}$$

Neglecting arc drop each 3-phase rectifier group has this average output voltage which is also the average direct voltage across the load. The system is equivalent to two 3-phase rectifiers in parallel with 60 degrees shift between the voltages, the difference between the two sets of instantaneous voltages being absorbed by the interphase transformer.

The no-load direct voltage E_{d0} is obtained from equation 5 with $u=0$. Substituting 3 into 5 and dividing by E_{d0}

$$\frac{E_d}{E_{d0}}=1-\frac{I_dX_c}{2\sqrt{6}E_s} \tag{6}$$

For the double-wye circuit $X_c=\frac{\sqrt{6}E_s}{I_{dn}}X_{cpu}$.

Therefore

$$\frac{E_d}{E_{d0}}=1-\frac{1}{2}\frac{I_d}{I_{dn}}X_{cpu}=1-\frac{1}{2}S \tag{7}$$

which corresponds to equation 17 of the Dortort paper. This shows that operation during the first mode is unaffected by leakage reactance between the secondary windings.

SECOND MODE OF OPERATION

As Mr. Dortort points out, and as also derived in our paper,[1] when the overlap angle reaches 60 degrees, commutations are delayed by an angle α. For this condition, the average direct voltage is obtained from equation 5 of the discussion, with the limits of integration being α to $\alpha+\pi/3$ for the first integral, and $\alpha+\pi/3$ to $\alpha+2\pi/3$ for the second integral. Performing the integration between the indicated limits, combining terms, reducing, and dividing by $E_{d0}=3\sqrt{6}\ E_s/2\pi$

$$\frac{E_d}{E_{d0}}=\frac{\sqrt{3}}{2}\cos(\alpha+30\text{ degrees}) \tag{8}$$

The commutating angle is obtained from equation 2 with the limits of integration $\omega t=\alpha$ to $\omega t=\alpha+\pi/3$. Performing the integration between these limits and combining terms, similar to the derivation of equation 3

$$\frac{I_dX_c}{E_s}=\sqrt{6}\sin\ (\alpha+30\text{ degrees}) \tag{9}$$

Substituting equation 9 into 8

$$\frac{E_d}{E_{d0}}=\sqrt{\frac{3}{4}-\frac{1}{8}\left[\frac{I_dX_c}{E_s}\right]^2}=\frac{\sqrt{3}}{2}\sqrt{1-S^2} \tag{10}$$

which corresponds to equation 25 of the Dortort paper. If leakage reactance between secondary windings is negligible, the limit is reached when $\alpha=30$ degrees and the third mode of operation begins. Considering leakage, the limit is reached at $\alpha<30$ degrees as shown now.

Following the same reasoning used in writing equation 1, the voltages in the other delta during a phase 1 to phase 3 commutation are found to be

$$E_{bc}=E_{b''c''}$$

$$E_{ca}=\frac{3}{2}\left(L_c-\frac{L_{ss}}{2}\right)pi_1+E_{c''a''} \tag{11}$$

From Figure 2 of the discussion it can be seen that commutation from phase 1 to phase 3 is followed by commutation from phase 2 to phase 4. Defining E_2' and E_4' as the values of E_2 and E_4 respectively during the phase 1 to phase 3 commutation

$$E_2'=\frac{E_{b''c''}}{\sqrt{3}}=\frac{E_{bc}}{\sqrt{3}}$$

$$E_4'=\frac{E_{c''a''}}{\sqrt{3}}=\frac{1}{\sqrt{3}}\left[E_{ca}-\frac{3}{2}\left(L_c-\frac{L_{ss}}{2}\right)pi_1\right] \tag{12}$$

Substituting equation 2 into 12

$$E_2'=\frac{E_{bc}}{\sqrt{3}}$$

$$E_4'=\frac{1}{\sqrt{3}}\left[E_{ca}+\frac{3}{2}\left(\frac{2X_c-X_{ss}}{2X_c}\right)E_a\right]$$

$$=\frac{1}{\sqrt{3}}\left[E_{ca}+\frac{6X_c-3X_{ss}}{4X_c}E_a\right] \tag{13}$$

No-load values of these voltages are $E_2=E_{bc}/\sqrt{3}$ and $E_4=E_{ca}/\sqrt{3}$. Therefore, E_2 is unchanged but E_4 is reduced in magnitude and shifted back in phase angle while there is a phase 1 to phase 3 commutation in the other wye.

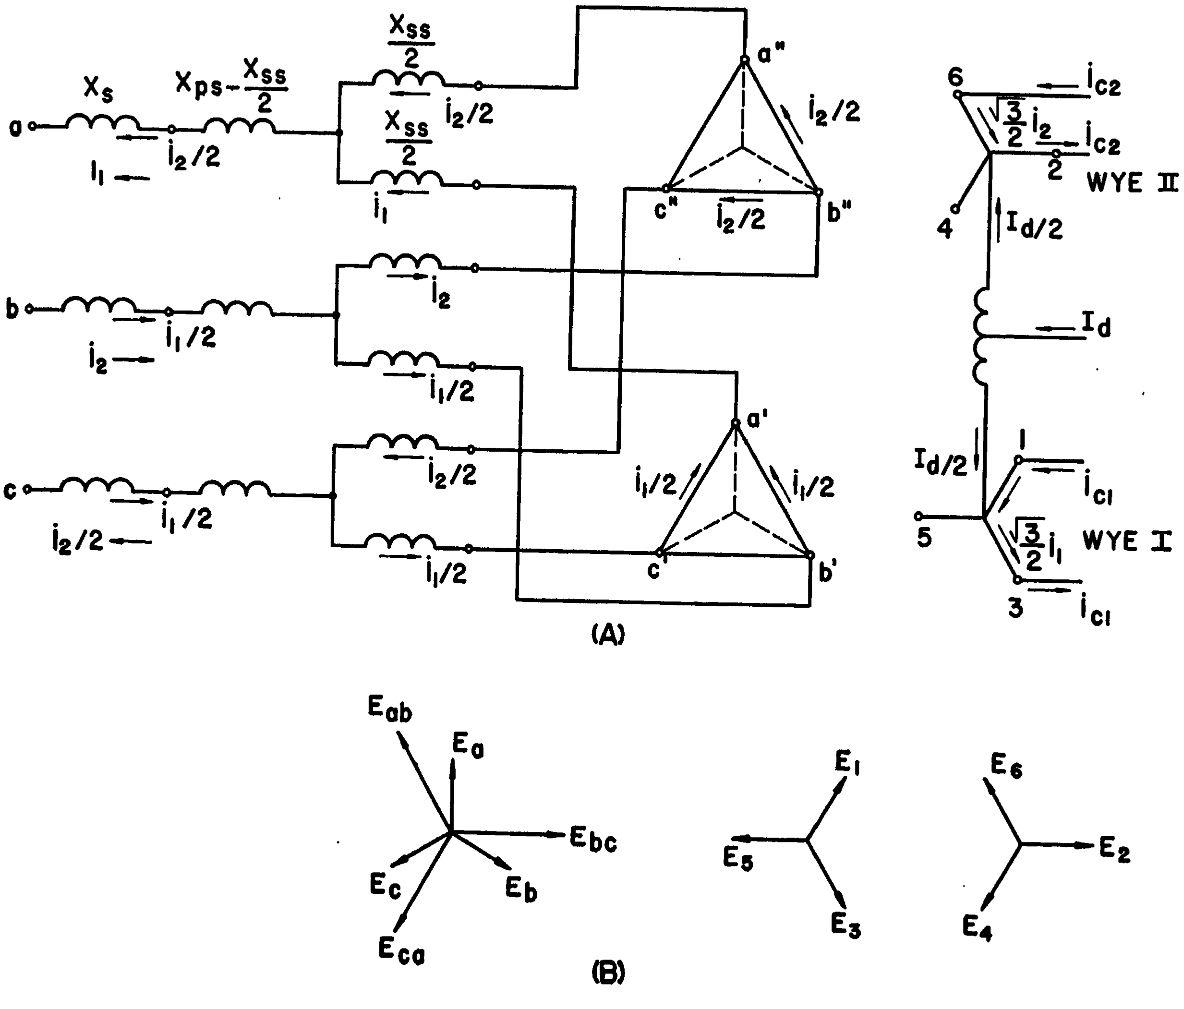

Figure 2 (A). Circuit diagram for double-wye circuit. (B) Voltage phase diagrams at no load

The maximum value of α for which equation 10 is valid is determined from 13 by equating E_2' and E_4' for the instant $\omega t=\pi/3+\alpha_m$ since the normal start of commutation is $\omega t=\pi/3$. Rewriting the voltages of 13 in accordance with the phase diagram of Figure 2, substituting $\omega t=\pi/3+\alpha_m$, equating the two equations of 13, expanding, and collecting terms

$$\tan \alpha_m=\left[\frac{2X_c-X_{ss}}{6X_c+X_{ss}}\right]\sqrt{3} \qquad (14)$$

where X_c is the commutating reactance and X_{ss} is the leakage reactance between secondary windings.

THIRD MODE OF OPERATION

When the forced delay angle reaches α_m as determined by equation 14 of the discussion, commutations will start in the second wye since the voltages E_2' and E_4' become equal. Hence, there will be a time when both wyes will commutate simultaneously. Because of the symmetry of operation, the simultaneous commutation interval δ is the same at the end as at the start of the commutating period. Since a new commutation starts every 60 degrees, the total commutating period is 60 degrees+δ, as shown in Figure 3 of the discussion. However, in each wye commutations must start 120 degrees apart, making the angle of symmetry 120 degrees. This mode of operation continues until $\delta=60$ degrees.

The 120-degree angle of symmetry is composed of four distinct intervals as shown in Figure 3. During the first interval, $\omega t=\alpha_m$ to $\omega t=\alpha_m+\delta$, simultaneous commutations exist from phase 6 to 2 and from phase 1 to 3. In the second interval, $\omega t=\alpha_m+\delta$ to $\omega t=\alpha_m+60$ degrees, the only commutation is from phase 1 to 3. During the third interval, $\omega t=\alpha_m+60$ degrees to $\omega t=\alpha_m+\delta+60$ degrees, there are simultaneous commutations from phase 1 to 3 and from phase 2 to 4. In the fourth interval, $\omega t=\alpha_m+\delta+60$ degrees to $\omega t=\alpha_m+120$ degrees, the only commutation is from phase 2 to 4.

Referring to Figure 2, the current i_2 is shown for the phase 6 to 2 commutation. For the phase 2 to 4 commutation, i_2 flows into terminal c and $i_2/2$ flows out terminals a and b. Bearing this fact in mind, the following equations apply for the 120-degree period beginning at the start of the phase 1 to 3 commutation illustrated in Figure 3

First Interval, Where $L_c=L_s+L_{ps}$ and $L=L_c-L_{ss}/2$

$$E_{ab}=-\frac{3}{2}L_cpi_1-\frac{3}{2}Lpi_2+E_{a'b'}=-\frac{3}{2}Lpi_1-\frac{3}{2}L_cpi_2+E_{a''b''}$$

$$E_{bc}=\frac{3}{2}pi_2+E_{b'c'}=\frac{3}{2}L_cpi_2+E_{b''c''} \qquad (15)$$

$$E_{ca}=\frac{3}{2}L_cpi_1+E_{c'a'}=\frac{3}{2}Lpi_1+E_{c''a''}$$

$$E_{a'b'}=E_{c'a'}=-\frac{1}{2}E_{b'c'} \text{ and}$$

$$E_{a''b''}=E_{b''c''}=-\frac{1}{2}E_{c''a''}$$

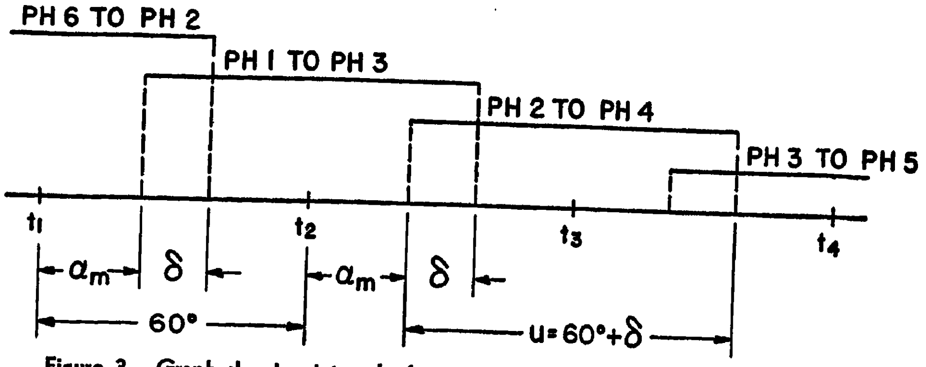

Figure 3. Graph showing interval of commutations in the third mode of operation

Solving equation 15

$$pi_1=-2\left[\frac{2L_cE_a+LE_b}{4L_c^2-L^2}\right]$$

$$pi_2=2\left[\frac{LE_a+2L_cE_b}{4L_c^2-L^2}\right] \qquad (16)$$

Second Interval

The equations are given by 1 and the solution by 2.

$$pi_1=-\frac{2E_{ab}+E_{bc}}{3L_c}=-\frac{E_a}{L_c}$$

$$pi_2=0 \qquad (17)$$

Third Interval

$$E_{ab}=-\frac{3}{2}L_cpi_1+E_{a'b'}=-\frac{3}{2}Lpi_1+E_{a''b''}$$

$$E_{bc}=-\frac{3}{2}Lpi_2+E_{b'c'}=-\frac{3}{2}L_cpi_2+E_{b''c''} \qquad (18)$$

$$E_{ca}=\frac{3}{2}L_cpi_1+\frac{3}{2}Lpi_2+E_{c'a'}=\frac{3}{2}Lpi_1+\frac{3}{2}L_cpi_2+E_{c''a''}$$

$$E_{a'b'}=E_{c'a'}=-\frac{1}{2}E_{b'c'} \text{ and}$$

$$E_{b''c''}=E_{c''a''}=-\frac{1}{2}E_{a''b''}$$

Solving equation 18

$$pi_1=-2\left[\frac{2L_cE_a+LE_c}{4L_c^2-L^2}\right]$$

$$pi_2=2\left[\frac{LE_a+2L_cE_c}{4L_c^2-L^2}\right] \qquad (19)$$

Fourth Interval

In this interval the only commutation is from phase 2 to 4. By following the same procedure used in obtaining equation 2

$$pi_1=0$$

$$pi_2=\frac{E_c}{L_c} \qquad (20)$$

The instantaneous commutation current, $i_{c1}=\sqrt{3}\,i_1/2$, increases from zero at the start of the first interval to its final value, $I_c=I_d/2$, at the end of the third interval.

Using equations 16, 17, and 19 and integrating between the limits of the intervals

$$I_c=-\frac{\sqrt{3}}{2}\left[\int_{\alpha m}^{\alpha_m+\delta}\frac{4X_cE_a+2XE_b}{4X_c^2-X^2}d(\omega t)+\int_{\alpha_m+\delta}^{\alpha_m+60}\frac{E_a}{X_c}d(\omega t)+\int_{\alpha_m+60}^{\alpha_m+\delta+60}\frac{4X_cE_a+2XE_c}{4X_c^2-X^2}d(\omega t)\right] \qquad (21)$$

where $X_c=X_s+X_{ps}$ and $X=X_c-X_{ss}/2$.

As shown on Figure 2, the reference voltage $E_a=\sqrt{2}E_s\cos(\omega t+90\text{ degrees})$ and from Figure 3, $\delta=u-60$ degrees. Evaluating the integrals, collecting terms, combining, and multiplying by X_c/E_s

$$\frac{I_cX_c}{E_s}=\left[\sqrt{6}\cos\left(\frac{u}{2}+30\text{ degrees}\right)+\frac{6\sqrt{2}X_c}{2X_c+X}\sin\left(\frac{u}{2}-40\text{ degrees}\right)\right]\times\sin\left(\frac{u}{2}+\alpha_m\right) \qquad (22)$$

The instantaneous direct voltage is obtained from equation 4 with $E_{a'b'}$ determined from the previously given circuit equations for each particular interval. This will give the following for the successive intervals:

From equations 15 and 16

$$e_{d1}=-\frac{E_{a'b'}}{\sqrt{3}}=\frac{1}{\sqrt{3}}\times\left[\frac{2(L_c^2-L^2)E_a+(4L_c^2-3L_cL-L^2)E_b}{4L_c^2-L^2}\right]$$

From 17 which came from 1

$$e_{d2}=-\frac{E_{a'b'}}{\sqrt{3}}=\frac{E_{bc}}{2\sqrt{3}}$$

From 18 and 19

$$e_{d3}=-\frac{E_{a'b'}}{\sqrt{3}}=\frac{1}{\sqrt{3}}\times\left[\frac{2(L_c^2-L^2)E_a+(4L_c^2-3L_cL-L^2)E_c}{4L_c^2-L^2}\right]$$

From equation 20 and Figure 2

$$e_{d4}=-\frac{E_{a'b'}}{\sqrt{3}}=-\frac{E_{ab}}{\sqrt{3}}$$

The average direct voltage is the average of the voltages above over a 120-degree period.

$$E_d=\frac{3}{2\pi}\left[\int_{\alpha_m}^{\alpha_m+\delta} e_{d1}\,d(\omega t)+\int_{\alpha_m+}^{\alpha_m+60} e_{d2}\,d(\omega t)+\int_{\alpha_m+60}^{\alpha_m+\delta+60} e_{d3}\,d(\omega t)+\int_{\alpha_m+\delta+60}^{\alpha_m+120} e_{d4}\,d(\omega t)\right] \quad (23)$$

Evaluating the integrals with $\delta=u-60$ degrees, collecting terms, reducing, and dividing by $E_{d0}=3\sqrt{6}/2\pi E_s$

$$\frac{E_d}{E_{d0}}=\sqrt{3}\cos\left(\frac{u}{2}+30\right)\cos\left(\frac{u}{2}+\alpha_m\right)+\frac{2}{\sqrt{3}}\left[\frac{X_c-X}{2X_c+X}\right]\sin\left(\frac{u}{2}+\alpha_m\right)\times\sin\left(\frac{u}{2}-30\right) \quad (24)$$

Operation during the third mode is given by equations 22 and 24 where α_m is determined by equation 14.

1. INFLUENCE OF A-C REACTANCE ON VOLTAGE REGULATION OF 6-PHASE RECTIFIERS, R. L. Witzke, J. V. Kresser, J. K. Dillard. *AIEE Transactions*, volume 72, part I, 1953 (*Paper 53-54*).

2. RECTIFIER TRANSFORMER CHARACTERISTICS, AIEE Committee Report. *AIEE Transactions*, volume 68, part II, 1949, pages 1305-11.

I. K. Dortort: In their discussion Witzke, Kresser, and Dillard have taken a long step toward the completely general treatment of 6-phase double-way and double-wye rectifiers. It is evident that the subject of mixed primary and secondary reactances received a great deal of thought during the preparation of their own paper.[1]

Equation 14 of their discussion

$$\tan\alpha_m=\left[\frac{2X_c-X_{ss}}{6X_c+X_{ss}}\right]\sqrt{3}$$

defines a point of particular interest. When $X_{ss}=2X_c$ all primary reactance has been eliminated and the two 3-phase systems are completely isolated from each other; α_m becomes zero. The second mode of operation disappears and the first mode continues until

$$E_d/E_{d0}=1/2(\sqrt{3}-1) \text{ and } S=3-\sqrt{3}$$

If the current increases still further another mode of operation occurs, described in the early literature on rectifiers. The overlap increases until each anode conducts a full 360 degrees. The regulation curve is another straight line reaching short circuit at $S=2\sqrt{3}$.

The third mode is presented in the discussion as a straight line although this is not obvious from equation 24. It will be interesting (academically) to see if this mode stretches out as primary reactance decreases until it is transformed into the second mode of the classical 3-phase case. Or perhaps the second and third modes of mixed case both shrink and are replaced by the fourth mode (not described) which then transforms into the second mode of the classical case.

Of more practical interest, work remains to include the effect of losses, finite inductance in the load circuit, back electromotive force, and particularly the response of the rectifier under transient conditions.

Nondestructive Testing of Insulation

EMANUEL L. BRANCATO
MEMBER AIEE

THE USER of electrical apparatus is constantly in need of information concerning the condition of the insulation. This information, at the present time, is supplied by such tests as insulation resistance, power factor, capacitance, or by more severe tests such as "high-pot." Unfortunately, none of these tests give a true indication of the "health" of the dielectric but rather indicate its present condition—a condition that may exist only temporarily and can be corrected by suitable action. It is, of course, important to have this information; however, it is of equal importance in many applications to have an indication of the useful life than can be expected from the dielectric at any time during its use.

The user, as well as the designer, of electrical apparatus can predict the minimum useful life of the insulation in such equipment when operated under an assumed set of conditions by referring to appropriate thermal aging curves for the insulation. However, after the equipment has been in operation for a period of time, the post operation will influence the future life and these thermal aging curves are no longer useful. It becomes necessary then to be able to measure some property of the dielectric that is related to this thermal aging process and which takes into consideration the deterioration.

Several methods of nondestructive testing have been outlined or proposed;[1,2] however, for reasons of impracticability, or lack of sufficient evidence of reliability, these cannot be adopted. During early studies on various insulation measurements the electrical properties revealed a correlation with thermal aging. Further studies were then made on Formex-insulated magnet wire to verify these observations. These results are reported herein.

Experimental Procedure

Based on modern concepts of dielectrics[3-8] instrumentation was set up to measure capacitance, dielectric losses, and insulation resistance at suitable intervals during an aging cycle. A General Radio Company Schering Bridge, type *716-B* was employed in the measurement of capacitance and dielectric loss. This bridge is direct reading in capacitance at all audio frequencies, and in dissipation factor at frequencies of 1 kilocycle.

The bridge error signal is amplified by a General Radio Company type *814* amplifier to increase the balancing sensitivity. The balance is achieved on the fundamental by means of an appropriate filter. Detection of the unbalance is obtained with a Dumont *304H* cathode-ray oscilloscope. The null is sharply defined by a Lissajous pattern formed by the error and generated signals. The over-all sensitivity permits detection to within 0.02 per cent for capacitance, and 0.3 per cent for dissipation factor.

A test specimen was selected which would reflect the configuration of an electrical apparatus; this is shown in Figure 1. The specimen consists of a metal spool of $1^3/_{16}$ inches diameter wound with about 120 turns of number 26 Formex-insulated wire. Its capacitance to ground is approximately 1,000 micromicrofarads.

Time Variation of Dielectric Properties

Utilizing this experimental technique, the time variations in several of the elec-

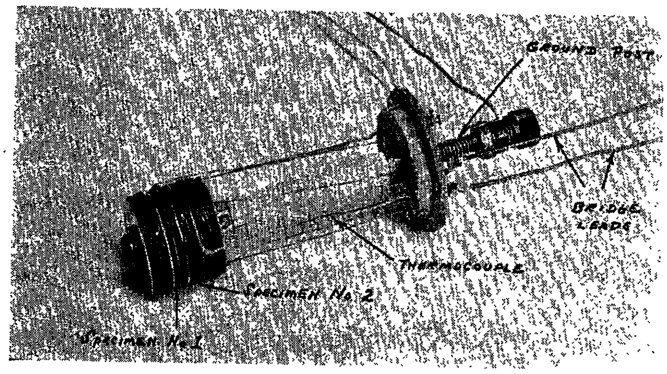

Figure 1 (above). Test specimen

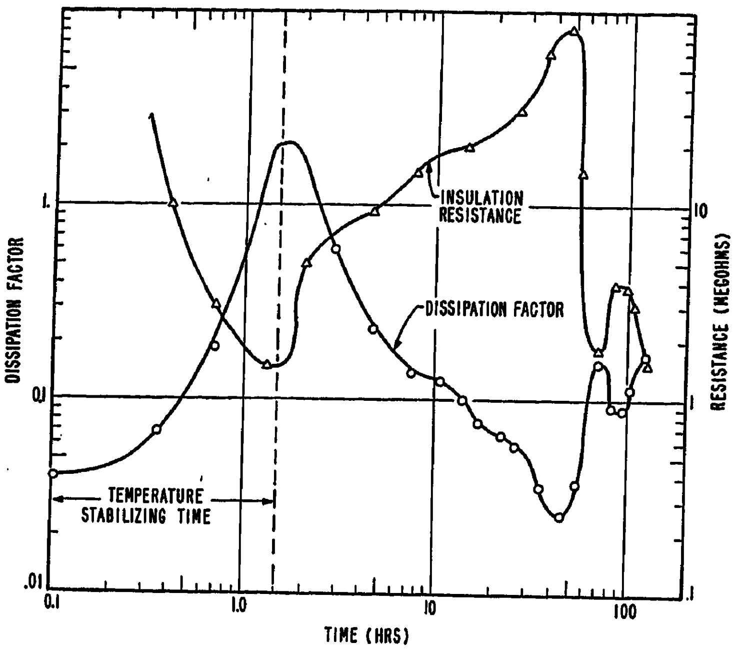
Figure 3 (right). Time variations in dissipation and insulation resistance of Formex at 220-degree-centigrade aging temperature. Bridge measurements at 1,000 cycles per second



trical properties of the dielectric were obtained. Figure 2 is representative of the effects of time and temperature on capacitance. It will be observed that the capacitance rises as the coil is being heated. This rise reflects the bulk expansion of the coil which tends to increase the area and decrease the dielectric spacing. Later in time the plasticizer begins to evaporate and aging effects become evident. As a result of shrinkage during this latter period, capacitance begins to fall with time. Although there is no regular plasticizer in Formex wire enamel, there are high boiling point ingredients, for example, cresol which acts like a plasticizer, and following volatilization a loss of weight by the insulant can be measured. For brevity these ingredients are referred to as plasticizers.

Tracing the effects of temperature and time on dielectric loss, it is observed in Figure 2 that the dissipation factor increases sharply as the specimen temperature rises. Before stabilized conditions are reached, the loss factor curve effectively indicates a temperature dependence starting with room temperature and assuming aging effects are negligible. Increased losses are due, in part, to further decreases in viscosity of the plasticizer which allows greater freedom to the permanent dipolar molecules to move in the presence of an alternating field. As the temperature rises further it will be noticed (at the point where a decrease in capacitance is observed) that the dissipation begins to diminish as a consequence of the inability of the dipoles to follow the field due to thermal agitation resulting in a decrease of frictional losses. The decline in this loss function at these high temperatures is modified by the motion of ions which contribute additional losses. After temperature stabilization at 180 degrees centigrade the loss factor curve is effected by aging time. Essentially, there is a decrease in the loss factor maximum (high temperature absorption peak) with a shift of the peak to higher temperatures, while the temperature of the minimum loss factor point rises indicating that the material remains in the embrittled state at high temperature.[9] At a constant aging temperature, loss of plasticizer continues which increases the viscosity of the dielectric restricting the vibration of the dipoles and ion migration. The decrease in dielectric loss continues with time and reaches a minimum at about 270 hours. This minimum in dissipation factor denotes embrittlement. The loss curve begins to rise again due to decomposition of the material.

The variation in dissipation, during an aging cycle, has been ascribed to variations in the mobility of dipoles and ions. It is conceivable, therefore, that a measure of d-c losses, essentially due to ion migration, should reveal similar behavior. Continuous measurements of d-c resistance was obtained on Formex specimens concurrently with capacitance and dissipation measurements. The results indicated that insulation resistance varied with aging time as an inverse function of the dissipation. This is shown in Figure 3.

Having established the behavior of the dielectric loss, due to ion migration, in Formex, it becomes of interest to obtain a comparative measure of a-c and d-c losses with aging time. These losses are presented as equivalent parallel resistances; the a-c resistance is obtained by calculating a relation incorporating the values of capacitance and dissipation obtained from bridge measurements while the d-c resistance represents the insulation resistance measured during the aging cycles. Examination of the two resistance charac-

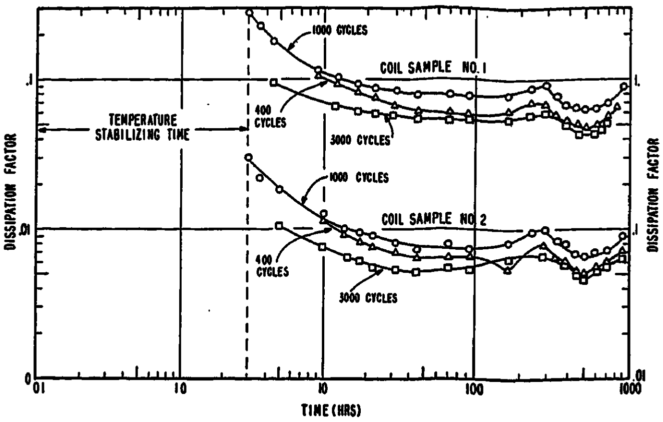

Figure 6 (right). Time variations in dissipation of Formex at 200-degree-centigrade aging temperature. Bridge measurements at 400, 1,000, and 3,000 cycles per second

teristics, in Figure 4, indicates a distinct similarity between the two, the magnitude of the a-c effective parallel resistance naturally being the smaller. At a point beyond embrittlement, the insulation resistance characteristics merge with the a-c resistance characteristics suggesting a disappearance of dipolar losses leaving the losses resulting essentially from ion migration.

Effect of Frequency on Dielectric Measurements

Measurements were made to discover the effect of frequency on the variations of the dielectric characteristics with age. While the capacitance range of the bridge is unaffected by frequency, the dissipation factor range is directly proportional to frequency. Thus, the dissipation factor range is 3 per cent at 50 cycles and 560 per cent at 10 kilocycles. It was found that 400 cycles was the minimum frequency required to provide the bridge with sufficient range to measure the loss in Formex insulation. As the frequency was increased, the bridge was found to be insensitive beyond 3,000 cycles.

Employing this range, data are presented in Figures 5 and 6 of the variations in capacitance and dissipation of two specimens of several, simultaneously aged at 200 degrees centigrade. Comparison of data reveals no distinct shifts in characteristics with frequency suggesting independency of frequency within this frequency spectrum. Furthermore, the corresponding characteristics of the two samples are, for practical purposes, superimposable; thus, one sample is sufficient to furnish representative data. All subsequent tests are conducted at 1,000 cycles.

In view of the limited frequency range of the present instrumentation, no attempt was made to measure relaxation time.

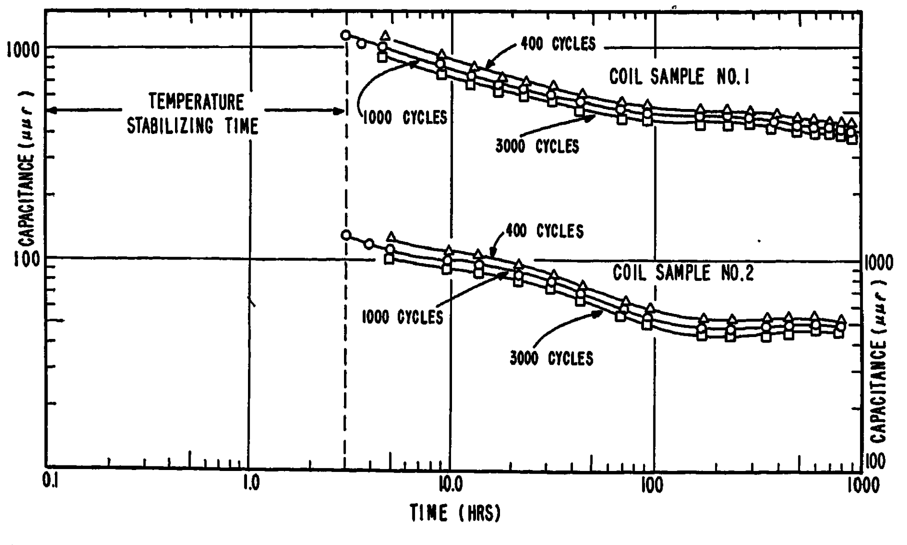

Figure 5. Time variations in the effective capacitance of Formex at 200-degree-centigrade aging temperature. Bridge measurements at 400, 1,000, and 3,000 cycles per second

Effect of Humidity on Dielectric Measurements

Insulation resistance measurements reflect conduction through insulation, as well as conduction over the surface, due to humidity. Correspondingly, dissipation is a measure of all the losses in the material, as well as that loss due to adsorbed humidity. The validity of this is established with the presentation of Figure 7. This figure represents graphically the variations in insulation resistance and dissipation with temperature and humidity. The coil was cycled in temperatures from 30 to 160 degrees centigrade and the measurements of the parameters obtained at suitable intervals. Upon completion of this cycle the specimen was immersed in water for a period of 1/2 hour. Upon removal, the coil was heated and the same measurements were taken. Below 100 degree centigrade no measurements could be obtained because the insulation resistance was very low (the bridge cannot be balanced), but beyond 100 degrees the insulation resistance and dissipation recuperated and the values returned to "dry" magnitudes corresponding to the temperature.

Correlation with Life-Temperature Data

Using the criterion of minimum dissipation as an index of embrittlement, a number of specimen coils were aged, each at a different temperature level ranging from 180 to 260 degrees centigrade. The embrittlement characteristics obtained are plotted in Figure 8. Since embrittlement represents the initial condition preceding the end-of-life of the insulation, this characteristic represents, in reality, the life temperature characteristics of the insulation. This conclusion is supported by the comparison of the life tempera-

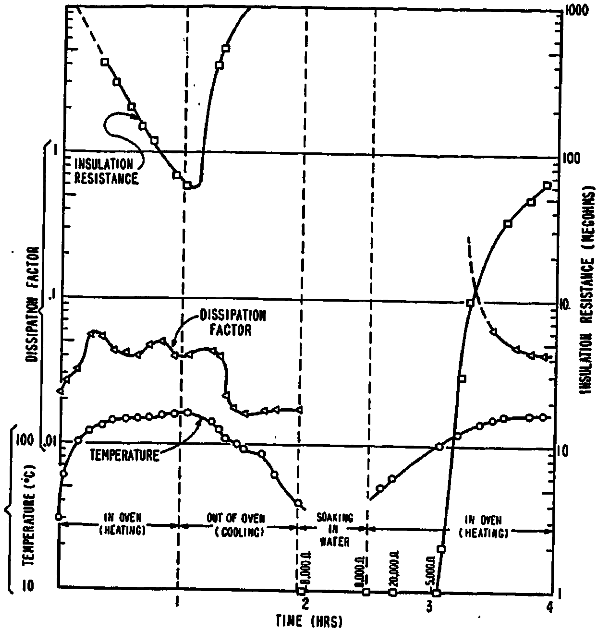

Figure 7 (left). Effects of humidity on insulation resistance and dissipation factor

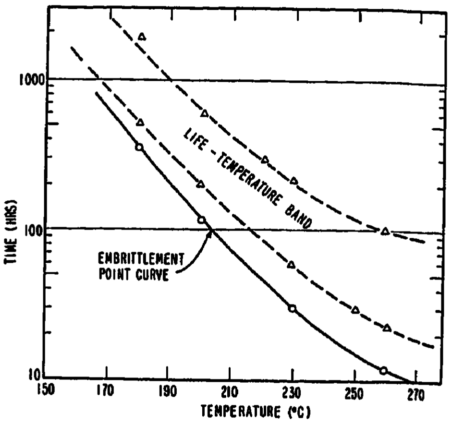

Figure 8 (right). Embrittlement characteristics of Formex

ture characteristics, also in Figure 8, obtained for the same size and type of wire by an earlier investigation.[10] The aging band represents the first and last failure of 20 specimen coils subjected to the stresses experienced by a continuously operating electric motor.

Comparison of the embrittlement curve to the minimum life curve of the aging data reveals that the former is similar in trend but lower in magnitude. This difference is expected because dielectric dissipation is a sensitive function of embrittlement and registers the effect before the cracking of insulation sheathing becomes apparent. Percentagewise, the time elapsed between embrittlement and flaking is greatest at the higher temperature, due to an apparent elasticity resulting from high temperature operation which keeps the insulation or its disintegrated products in literally molten state.

Conclusions

The dielectric properties of Formex insulation undergo a change during thermal aging. This is particularly evident in the dielectric loss and in the insulation resistance. The variations in these values during aging tests can be correlated with the mechanical properties of the materials making it possible to establish the time at which the plasticizer has been removed and embrittlement exists. This point of embrittlement correlates with minimum point on the normal life temperature curves for Formex insulation.

The usefulness of these changes in dielectric properties during thermal aging in determining the true picture of life remaining in insulation can be determined only through further studies of other insulations with dipolar as well as those with nonpolar groups. An investigation of the effects of environment and conditions of contamination would be desirable.

It is important that studies be made of the change in properties of insulated structures which are composed of two or more dielectrics, as is found in machinery construction. It is expected, too, that further work will reveal the effects of temperature cycling on these dielectric properties; this is particularly desirable information at the higher temperatures.

Discussion

F. S. Oliver (Doble Engineering Company, Belmont, Mass.): The author presents the results of some laboratory tests on Formex insulation. The title of his paper however indicates a more general coverage and he dismisses as impractical several test methods which have been proved by years of trial and experience to produce valuable information concerning the suitability for continued service of electrical power apparatus insulation. Moreover the author does not appear to present a test program which can be used to determine the suitability for service of such insulation.

A recent AIEE questionnaire[1] clearly showed that insulation test programs at nondestructive voltages are used with good results by a large number of utilities. On the insulation of apparatus such as bushings, circuit breakers, transformers, and so forth, 60-cycle power-factor testing has been used with eminent success. Some of the many papers presented on the subject are listed at the end of this discussion.[2–5]

In any insulation test program it should be borne in mind that it is most important to be able to locate the presence of contaminants such as moisture or the results of mechanical injury both of which may be serious failure hazards.

It appears evident that the author carried out his tests on small samples in the laboratory with the ultimate destruction of the sample. I would like to ask the author if the techniques described could be practically applied to nondestructively testing the insulation of all types of power apparatus.

I would also like to ask what tests the author used to determine when embrittlement occurred and when such embrittlement was sufficient to cause insulation failure under normal operating conditions.

In conclusion I would like to emphasize the fact that test methods have been developed and are in wide spread use which have given well documented proof of their worth in evaluating the suitability of insulation for continued service. Such methods cannot be summarily dismissed as the introduction of this paper appears to indicate.

T. W. Dakin (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Mr. Brancato has demonstrated in his paper a means of indicating the aging of a particular wire enamel in a coil system. This method may also in some cases be able to predict the failure. Its generality or limitation in this latter respect needs to be tested more extensively since, if it does prove more generally applicable, it merits considerable attention on the part of engineers who must maintain the insulation in such apparatus. It would serve as a monitoring method for inspecting the degree of aging in service of motors, magnet coils, and so forth. A general decline in dissipation factor of motor insulation with aging at elevated temperatures based on a study of two systems of varnished impregnated enamel wire motor insulation has been reported. This decline was similar to the declining dissipation factor observed by Mr. Brancato. I do think, however, that previous investigators have also noted in some cases declining dissipation factor with aging of insulation, although the reason for the declining dissipation factor may have varied from the present case.

Several effects coincident with aging in different varnishes will produce a decreasing ionic conductivity. One of these effects is the slow loss of solvent, or of plasticizer as mentioned by the author. This increases the internal viscosity. Oxidative reactions which crosslink and further polymerize the varnish also will increase the internal viscosity. All of these lead to a decreased ionic conductivity and dissipation factor or increased resistance.

The increased internal viscosity also affects the position of the dissipation factor maximum due to dipolar rotation in the varnish by shifting this maximum toward higher temperatures. An examination of the data published by T. D. Callinan[1] on the dissipation factor of formvar resin would seem to indicate that this maximum occurs at a considerably lower temperature than was used by Mr. Brancato in the present aging studies. After temperature stabilization, his measurements were probably made on a part of the curve where the power factor was increasing with temperature due to increasing ionic conductivity with temperature. As the aging proceeded, the ionic conduction decreased with the hardening of the resin. As the aging proceeds still further, the dipolar dissipation factor maximum which was originally at lower temperatures would shift upward toward the measuring temperature and cause an increasing trend in power factor leading to a minimum. However, such a minimum would not be associated with a maximum d-c resistance followed by a sharply declining value such as the author found. Therefore, we must conclude that the rising dissipation factor following the minimum value and the declining resistance is due not to dipoles but to an increasing ionic conduction, possibly increased ionic concentration, as a result of oxidation or decomposition. It is not readily apparent, however, why such a minimum should necessarily be associated with embrittlement, unless at this point cracking has already started to occur and conduction starts to occur within and on the surface of the cracks. A microscopic examination of the wire just following this point might reveal the cracks. The discusser feels that more evidence and study should be made before there is justification for concluding that such a dissipation factor minimum as the author observed is unequivocally associated with embrittlement of the resin.

In Figure 8, the author has plotted the time to reach the "embrittlement point" and the range of life on a logarithmic scale versus temperature on a linear scale. If the same data are plotted with the temperature on a reciprocal absolute temperature scale, it becomes almost linear and is thereby easier to extrapolate. This indicates that the aging follows a single chemical reaction rate mechanism.

REFERENCE

1. See reference 9 of the paper.

B. P. Kang (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): First of all, the author must be complimented for his accomplishments in this timely and important investigation. The experimental results are what should be normally expected from both theoretical standpoint and past experience. A few remarks may be in order in regard to the explanations of some of the phenomena.

On Figure 2, the shape of the dissipation factor versus aging time curve is quite a common one. The rise on dissipation factor from 0.1 to 0.5 hour is due to the rise of temperature within this period of time. From 0.5 to about 350 hours, the curve declines first rapidly and then slowly. This seems due to the driving off of the volatile constituents of the insulation; therefore the viscosity is increased. The final rise in dissipation factor from 350 to 600 hours is due to the thermal deterioration of the material. This is a well-known phenomenon and a well-accepted explanation, and the author has confirmed it with his results.

The correlation between insulation resistance and dissipation factor as shown in Figure 3 is generally true. A material with higher insulation resistance generally has a low dissipation factor. However, no exact function can be established to express the relationships between the two properties of even a single material. Most of the commonly used insulating materials have a maximum point on the dissipation factor versus frequency curve, and this maximum point is shifted to the higher frequency region with a higher testing temperature. Murphy and Morgan have shown these facts.[1] Such a correlation, when it exists, therefore, may hold for a particular frequency at a particular temperature, but no generalization should be proposed.

This leads to the discussion on Figure 4. Since the d-c insulation resistance must be supposed to have been taken at the usual 1-minute electrification time and the a-c insulation resistance was computed by the data from the 1-kilocycle measurement, no exact correlation should exist except by coincidence. In order to make a dependable comparison, oscillographic observation on d-c and Schering Bridge measurements on a-c must be taken simultaneously, and the Whitehead-Bannos analysis must be applied. It can be assured that by using the method developed by J. B. Whitehead, all the losses from an a-c measurement can be accounted for.

REFERENCE

1. See reference 3 of the paper.

Emanuel L. Brancato: In closing the discussion, the author wishes to express his appreciation of the interest shown in the subject and of the comments presented by Dr. Dakin, Dr. Kang, and Mr. Oliver.

Unfortunately, the introduction to this investigation has justifiably disturbed Mr. Oliver in that it appeared to condemn all existing nondestructive testing as impractical. This, of course, was not intended. A careful reading of the paper would reveal the purpose of the study to be directed towards the development of a technique capable of predicting expected life of insulation in contradistinction to the objective of existing nondestructive testing which is to determine the present condition of insulation. To offer an analogy, the dielectric measurements have been currently used as a physician uses a thermometer to determine whether or not the patient is fit to work. Continuing with this analogy, the dielectric measurements, in this paper, are used in the same manner an insurance man employs a calendar to predict the expected life.

Dr. Dakin presents an interesting interpretation of the mechanism of the dielectric changes during an aging period of insulation. In the continuation of the experimental work further study will be made to determine the respective contribution of the dipolar and ionic motion to the variation of over-all loss with time.

The author concurs with Dr. Kang's observation relative to the absence of exact relationship between insulation resistance and dissipation factor and is grateful for the offered suggestion on a method of simultaneously measuring the a-c and d-c resistance.

Mr. Oliver and Dr. Dakin question the degree of aging when the insulation reflected a minimum loss. Though it was not indicated in the body of this paper, the insulation specimens were examined for embrittlement at the minimum dissipation point. In all cases a gentle bending of the wire resulted in flaking of insulation demonstrating the embrittlement of the resin.

A question has been raised as to the generality of the reported findings and their applicability to insulation structures employed in existing electrical apparatus. At this point of the study no attempt is made to generalize; the conclusions are based entirely on the properties of Formex. Other insulations of dipolar and nonpolar nature as well as insulation structures of composite dielectric are being studied at present to determine if a similar correlation will be exhibited between dielectric properties and insulation age.

A New Method for Treating Electron Tubes when Used as Superregenerative Detectors

Part I. Superregenerative Circuits Under No-Signal Condition

ABD EL-SAMIE MOSTAFA
NONMEMBER AIEE

M. EL-SHISHINI
NONMEMBER AIEE

Synopsis: This paper is the first of a series of papers dealing with a comprehensive study of superregenerative detection. It deals with superregenerative circuits under no-signal condition; the second paper[1] deals with the same circuits under signal condition, and the third paper[2] is an experimental investigation and verification for the theoretical analysis of papers 1 and 2.

A new theoretical analysis based on treating the electron tube as a periodically varying element is given herein. The methods of superposition and successive approximation are applied to the solution of circuits having periodically varying resistances and the results are directly applied to the present nonlinear problem.

Multiple resonance, the characteristic noise, the building up of oscillation (to an amplitude depending fundamentally on the quenching source and the nonlinearity of the tube characteristic), and the condition of stability of superregeneration are clearly shown. In superregeneration, both the amplitude and frequency of oscillation are modulated; however, the amount of frequency modulation is small. The degree of modulation depends not only on the amplitude and frequency of the quenching voltage, but also on the nonlinearity of the tube characteristic as well as on other circuit parameters. Numerical examples are given to clarify the theoretical predictions.

SUPERREGENERATIVE receiving circuits have become of increasing importance due to their extension into many war-time applications. Accordingly, a need is felt for a rigorous treatment of these circuits.

Several prewar and after-war papers[3–7] dealing, theoretically and experimentally, with superregenerative circuits have been published. In all of these publications, the circuits were treated as if they were linear, and therefore a clear and complete explanation could not be given regarding most superregeneration phenomena.

Theoretical Analysis

As a considerable improvement in performance can be obtained by using a separate tube to produce the required quenching voltage, the following analysis will be confined to a separately quenched superregenerative detector.

A schematic diagram for a separately quenched superregenerative detector is shown, see Figure 1. The losses in the circuit are represented by a shunt arm of conductance G in order to simplify the analysis, and the results obtained apply as well to the more usual case where the losses are associated with the inductance. A sinusoidal quenching voltage $v_q(=N\times \cos pt)$ is applied in the plate circuit of the detector; if it were applied in the grid circuit, it could be very approximately transferred to the plate circuit with its amplitude only multiplied with the amplification factor μ. The automatic bias which is developed under working conditions is represented by a constant bias E_C plus a periodic part of fundamental periodicity equal to the frequency of the quench source and which can be transferred to the plate circuit and then included in v_q. This implies that with a constant quench signal, v_q may vary with different oscillating conditions, variable M for example. This also applies to E_C. Applying Kirchhoff's first law for the currents meeting at the point P we get

$$i_C+i_G+i_p+i_L=0$$

giving after differentiation,

$$d^2v/dt^2+(1/C)\{G\,dv/dt+di_p/dt\}+\omega_0^2v=0 \quad (1)$$

where i_C, i_L, and i_G represent the alternating components of the currents in the capacitive inductive and conductive branches respectively. i_p represents the deviation of the plate current from its steady value, which latter corresponds only to the polarizing potential $(E_b-\mu E_C)$ (plate side), and therefore i_p includes the variation due to the quenching voltage v_q. v is the voltage across the tuned circuit, and $\omega_0^2=1/LC$. i_p can be represented as a power series of the lumped voltage ϵ' as follows

$$i_p=\alpha\epsilon'+\beta\epsilon'^2+\gamma\epsilon'^3\,*$$

where

$$\epsilon'=(1-\mu M/L)v+v_q$$

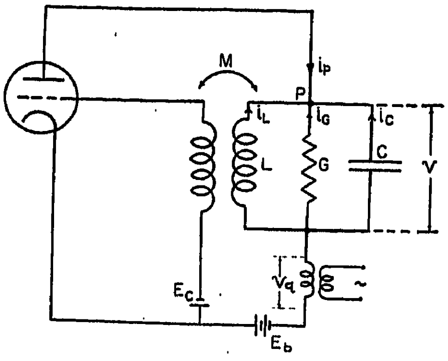

Figure 1. Separately quenched superregenerative detector

* For very small amplitudes, $i_p\approx\alpha\epsilon'=\epsilon'/\rho$ and $\alpha=1/\rho$, where ρ = plate resistance of tube.

Paper 53-158, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted March 1, 1950; made available for printing December 3, 1952.

ABD EL-SAMIE MOSTAFA is with Alexandria University, Alexandria, Egypt. M. EL-SHISHINI is a member of the Egyptian Senate, Cairo, Egypt.

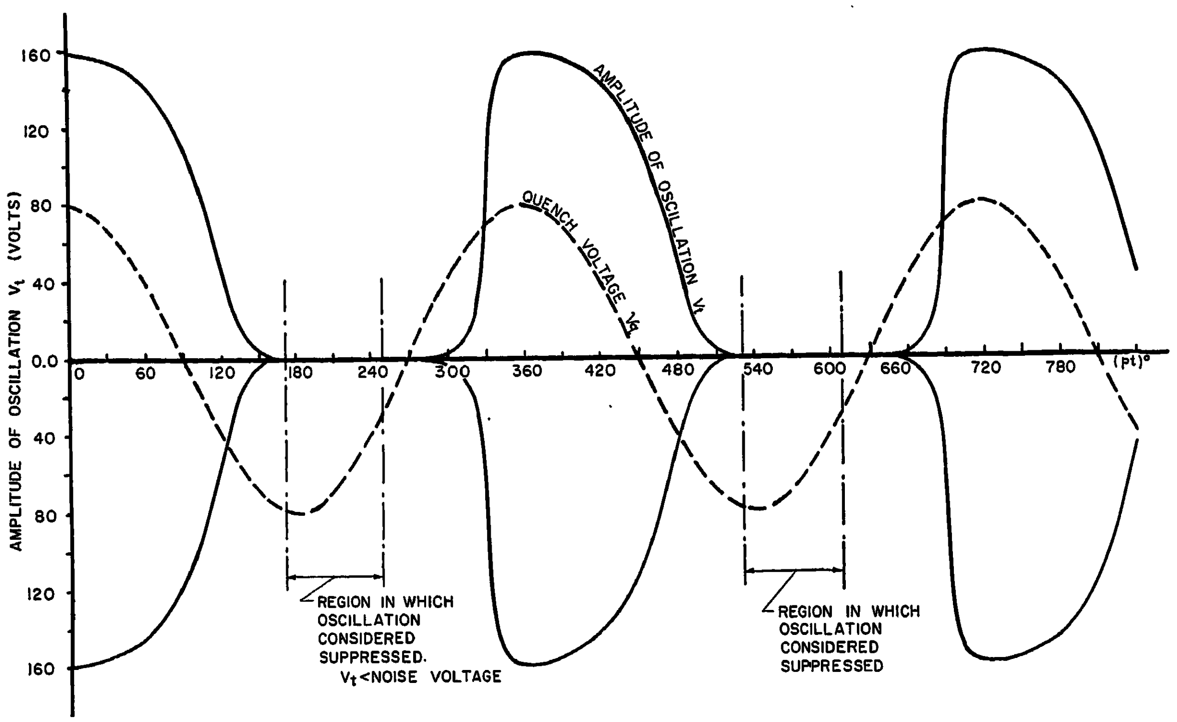

Figure 2. Envelope of oscillation, quench frequency = 100 kilocycles per second

giving

$$dip/d\epsilon' = \alpha + 2\beta\{(1-\mu M/L)v + v_q\} + 3\gamma\{(1-\mu M/L)^2 v^2 + 2(1-\mu M/L)vv_q + v_q^2\}$$

and

$$d\epsilon'/dt = (1-\mu M/L)dv/dt + dv_q/dt$$

If the frequency $p/2\pi$ of the quench source is much less than $\omega/2\pi$ which is usually the case in superregeneration, dv_q/dt can be neglected compared with dv/dt, and

$$d\epsilon'/dt \approx (1-\mu M/L)dv/dt$$

giving

$$dip/dt = (dip/d\epsilon')d\epsilon'/dt = \{\alpha(1-\mu M/L) + 2\beta(1-\mu M/L)^2 v + 2\beta(1-\mu M/L)v_q + 3\gamma(1-\mu M/L)^3 v^2 + 6\gamma(1-\mu M/L)^2 v\, v_q + 3\gamma(1-\mu M/L)v_q^2\}dv/dt \quad (2)$$

The output voltage v can be assumed to be of the form

$$V_t \cos\omega t + V_{t2}\cos(2\omega t + \theta_{t2}) + V_{t3}\cos(3\omega t + \theta_{t3}) + \ldots,$$

where V_t, V_{t2}, V_{t3}, θ_{t2}, θ_{t3}, and ω are slowly varying with time. For the solution of equation 1 to the first power of the tube parameters (α, β, and γ), it is sufficient to substitute $V_t \cos\omega t$ for v in the coefficient of dv/dt of equation 2. Equation 1 therefore reduces to

$$d^2v/dt^2 + (G_t/C)(1 + h_{p_t}\cos pt + h_{2p_t}\cos 2pt + h_{1_t}\cos\omega t + h_{2_t}\cos 2\omega t)dv/dt + \omega_0^2 v = 0 \quad (1A)$$

where

$$G_t = G + \alpha(1-\mu M/L) + (3\gamma/2)\times(1-\mu M/L)^3 V_t^2 + (3\gamma/2)\times(1-\mu M/L)N^2$$

$$h_{p_t} = (1/G_t)2\beta(1-\mu M/L)N$$

$$h_{2p_t} = (1/G_t)3\gamma(1-\mu M/L)(N^2/2)$$

$$h_{1t} = (1/G_t)(2\beta + 6\gamma N\cos pt)(1-\mu M/L)^2 V_t$$

and

$$h_{2t} = (1/G_t)3\gamma(1-\mu M/L)^3(V_t^2/2).$$

In this way, the nonlinear differential equation 1 has been transformed to a linear one with periodically varying coefficients.

In the present analysis, it is assumed that each of $(G_t/\omega C)$, $(G_t/\omega C)h_{1_t}$, and $(G_t/\omega C)h_{2_t}$ is much less than unity (this is equivalent to saying that the present work is limited to small signals).

For the solution of equation 1(A), the methods of superposition and successive approximation will be adopted. Although these methods can be applied directly to equation 1(A), a misunderstanding may result due to the fact that the amplitudes of variation h_{1_t}, h_{2_t} and so forth are functions of the required amplitude of oscillation V_t. Moreover, the coefficient of v in equation 1(A), namely, "ω_0^2" is constant which is not the case under signal condition; therefore the general case where such a coefficient is variable with time should be treated. Again, as a series circuit is usually preferred to its dual parallel one, the former will be chosen for the solution of equation 1(A). Consider a series $L-C_t-R_t$ circuit, where R_t is a function of time and given by

$$R_t = R_{0t}\left\{1 + \sum_{m=1}^{\infty} h_{mp_t}\cos mpt + \sum_{n=1}^{\infty} h_{nt}\cos n\omega t\right\}$$

R_{0t}, h_{mp_t}, and h_{n_t} are slowly varying with time; C_t is also a slow function of time and the inductance L is constant, and $p << \omega$. The differential equation for the charge Q across capacitor C_t is given by

$$d^2Q/dt^2 + (R_{0t}/L)\left(1 + \sum_{m=1}^{\infty} h_{mp_t}\cos mpt + \sum_{n=1}^{\infty} h_{nt}\cos n\omega t\right)dQ/dt + \omega_{0t}^2 Q = 0 \quad (3)$$

where

$$\omega_{0_t}^2 = 1/LC_t$$

Although successive approximation can be applied to equation 3, the amount of work can be reduced by the transformation $Q = q\epsilon^F$, where F is a function of time. Substitution in equation 3 gives

$$d^2q/dt^2 + \{2dF/dt + R_t/L\}dq/dt + \{d^2F/dt^2 + (dF/dt)^2 + (R_t/L)dF/dt + \omega_{0t}^2\}q = 0 \quad (4)$$

F is so chosen that the coefficient of dq/dt in equation 4 vanishes; therefore

$$F = -\int(R_t/2L)dt = -\int(R_{0t}/2L)\times\left\{1 + \sum_{m=1}^{\infty} h_{mp_t}\cos mpt + \sum_{n=1}^{\infty} h_{nt}\cos n\omega t\right\}dt$$

Coefficient of q in equation 4 is given by

$$\omega_{0t}^2\left[1 - (1/2\omega_{0t}^2 L)(d/dt)\left\{\sum_{m=1}^{\infty} R_{0t}h_{mp_t}\times\cos mpt + \sum_{n=1}^{\infty} R_{0t}h_{nt}\cos n\omega t\right\} - (R_{0t}/2\omega_{0t}L)^2\left\{1 + \sum_{m=1}^{\infty} h_{mp_t}\cos mpt + \sum_{n=1}^{\infty} h_{n_t}\cos n\omega t\right\}^2\right]$$

Now, if $(R_{0t}/2\omega_{0t}L)$ is much less than unity and ω is near ω_{0t}, both assumptions being satisfied in the present nonlinear problem, terms containing $(R_{0t}/2\omega_{0t}L)^2$ can be neglected. Again, as R_{0t}, h_{nt}, ω, and h_{mp_t} are very slow functions of time, that is, their variation in one cycle of the frequency $\omega/2\pi$ can be neglected, and also as $p\ll\omega$, coefficient of q will be given approximately by

$$\omega_t^2\left\{1+(R_{0t}/2\omega_tL)(\omega/\omega_t)\sum_{n=1}^{\infty} nh_{nt}\sin n\omega t\right\}$$

where

$$\omega_t^2=\omega_{0t}^2-(1/2L)(d/dt)\sum_{m=1}^{\infty} R_{0t}h_{mp_t}\cos mpt$$

Equation 4, therefore, becomes

$$diq/dt+\omega_t^2\left\{1+(R_{0t}/2\omega_tL)(\omega/\omega_t)\sum_{n=1}^{\infty}\times nh_{nt}\sin n\omega t\right\}\int iqdt=0 \quad (5)$$

where $iq=dq/dt$, and where R_{0t}, ω, ω_t, and h_{nt} are very slow functions of time; therefore, for a small interval of time t_1, corresponding to several cycles of oscillations, they can be considered constants and equal R_0, ω, ω_0, and h_n respectively. Equation 5 then becomes

$$diq/dt+\omega_0^2\left\{1+(R_0/2\omega_0L)(\omega/\omega_0)\sum_{n=1}^{\infty}\times nh_n\sin n\omega t\right\}\int iqdt=0 \quad (5A)$$

The current iq of 5(A) to a good degree of approximation, so long as each of $(h_1R_0/\omega L)$, $(h_2R_0/\omega L)$, and so forth is much less than unity, will be given by (see Appendix I):

$$\begin{aligned}iq=B_1\epsilon^{\sqrt{a}t}[&-(R_0/2\omega L)h_1\cos(\phi'-\theta')/\times\\&2\{(\sqrt{a}/\omega)+\omega/\sqrt{a}\}\sqrt{1+a/\omega^2}+\\&\sin(\omega t+\phi')-\{\sqrt{M_2^2+N_2^2}\omega^2\times\\&\sqrt{4+a/\omega^2}/2\sqrt{a^2+9\omega^4+10a\omega^2}\}\times\\&\sin(2\omega t+\theta_2+\theta_2'-\psi_2)-\\&\{\sqrt{M_3^2+N_3^2}\omega^2\sqrt{9+a/\omega^2}/2\times\\&\sqrt{a^2+64\omega^4+20a\omega^2}\}\sin(3\omega t+\\&\theta_3+\theta_3'-\psi_3)-\ldots]\end{aligned} \quad (6)$$

where

$$\sqrt{a}=(\omega/4)\sqrt{(h_2R_0/\omega L)^2-4(2d+d^2)^2},$$
$$\tan\phi'=2(2d+d^2)/\{(4\sqrt{a}/\omega)+(h_2R_0/\omega L)\},\ \tan\theta'=\omega/\sqrt{a}$$

$$M_2=(1/\sqrt{1+a/\omega^2})(h_1+3h_3)(R_0/2\omega L)\times\sin(\phi'-\theta')$$

$$N_2=-(1/\sqrt{1+a/\omega^2})(h_1-3h_3)\times(R_0/2\omega L)\cos(\phi'-\theta')$$

$$\tan\theta_2=N_2/M_2,\quad \tan\theta_2'=2\omega/\sqrt{a},\quad \tan\psi_2=4\omega\sqrt{a}/(a-3\omega^2)$$

$$M_3=(1/\sqrt{1+a/\omega^2})(h_2+2h_4)\times(R_0/\omega L)\sin(\phi'-\theta')$$

$$N_3=-(1/\sqrt{1+a/\omega^2})(h_2-2h_4)\times(R_0/\omega L)\cos(\phi'-\theta')$$

$$\tan\theta_3=N_3/M_3$$

$$\tan\theta_3'=3\omega/\sqrt{a}$$

and

$$\tan\psi_3=6\omega\sqrt{a}/(a-8\omega^2)$$

The charge

$$\begin{aligned}q=\int i_qdt=(B_1/\omega)\epsilon\sqrt{a}t[&-\{\cos(\phi'-\theta')/2\times\\&(1+a/\omega^2)^{3/2}\}(h_1R_0/2\omega L)+\\&\sin(\omega t+\phi'-\theta')/\sqrt{1+a/\omega^2}-\\&\{\omega^2\sqrt{M_2^2+N_2^2}/2\times\\&\sqrt{a^2+9\omega^4+10a\omega^2}\}\sin(2\omega t+\\&\theta_2-\psi_2)-\{\omega^2\sqrt{M_3^2+N_3^2}/2\times\\&\sqrt{a^2+64\omega^4+20a\omega^2}\}\sin(3\omega t+\\&\theta_3-\psi_3)-\ldots]\end{aligned} \quad (6A)$$

The charge q given by equation 6(A) is true for the small time interval t_1 which contains several cycles of oscillations. For a general solution at any time t, $\sqrt{a}t$ should be replaced by $\int\sqrt{a}\,dt$ and ωt by $\int\omega dt$. Charge q will be given by

$$\begin{aligned}q=(B_1/\omega)\epsilon^{\int\sqrt{a}dt}[&-\{\cos(\phi'-\theta')/2\times\\&(1+a/\omega^2)^{3/2}\}(h_{1t}R_{0t}/2\omega L)+\\&\sin(\textstyle\int\omega dt+\phi'-\theta')/\sqrt{1+a/\omega^2}-\\&\{\omega^2\sqrt{M_2^2+N_2^2}/2\times\\&\sqrt{a^2+9\omega^4+10a\omega^2}\}\sin(\textstyle\int 2\omega dt+\\&\theta_2-\psi_2)-\{\omega^2\sqrt{M_3^2+N_3^2}/2\times\\&\sqrt{a^2+64\omega^4+20a\omega^2}\}\sin(\textstyle\int 3\omega dt+\\&\theta_3-\psi_3)-\ldots]\end{aligned}$$

The charge Q of equation 3 will, therefore, be given by

$$\begin{aligned}Q&=\epsilon^{\int[\sqrt{a}-(R_{0t}/2L)\{1+\sum_{m=1}^{\infty}h_{mp_t}\times\cos mpt+\sum_{n=1}^{\infty}h_{n_t}\cos n\omega t\}]dt}q\\&\approx(B_1/\omega)\epsilon^{\int(\sqrt{a}-R_{0t}/2L)dt}[-h_{1t}(R_{0t}/\times 2\omega L)\cos(\phi'-\theta')+\sin(\textstyle\int\omega dt+\\&\quad\phi'-\theta')+(h_{1t}R_{0t}/6\omega L)\cos(\textstyle\int 2\omega dt+\phi'-\theta')+(h_{2t}R_{0t}/16\omega L)\times\\&\quad\cos(\textstyle\int 3\omega dt+\phi'-\theta')+\ldots]\end{aligned} \quad (7)$$

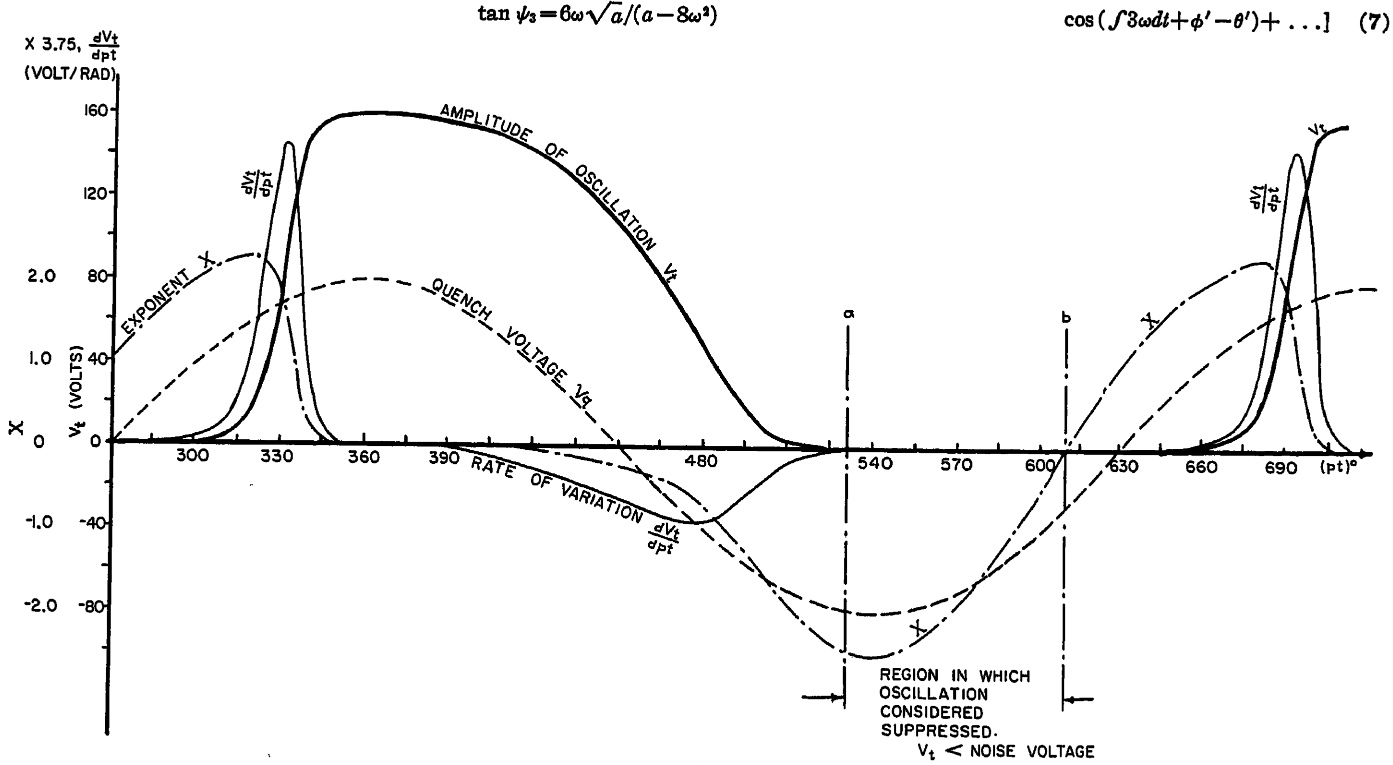

Figure 3. Amplitude of oscillation V_t, rate of variation dV_t/dpt, and exponent X, quench frequency = 100 kilocycles per second

V_t (at a) = V_t (at b) = noise voltage

The amount of detune d is obtained from the relation $\omega_t = \omega(1+d)$ where

$$\omega_t = \omega_{0t} \times \sqrt{1-(1/2\omega_{0t}^2 L)(d/dt)\sum_{m=1}^{\infty} R_{0t} h m_{p_t} \cos mpt}$$

$$\approx \omega_{0t}\left\{1-(1/4\omega_{0t}^2 L)(d/dt)\sum_{m=1}^{\infty} \times R_{0t} h_{mpt} \cos mpt\right\}$$

and

$$\omega_{0t}^2 = 1/LC_t$$

Now, equation 3 is similar to 1(A) with the substitution of Q, R_{0t}, L, and C_t for v, G_t, C, and L respectively. Also the assumptions made for the solution of equation 3 are satisfied in equation 1(A). However, the voltage v must be of the same form as assumed and which is $v = V_t \cos \omega t + \ldots$. Therefore, a possible solution of 1(A) can be obtained from equation 7 provided $\phi' - \theta' = \pi/2$, giving $d \approx -(1/8)(G_t/\omega C)^2 h_{2t}^2 \approx 0$, and hence

$$\omega \approx \omega_t = \omega_0\left\{1-(1/4)(1/\omega_0^2 L)(d/dt)\sum_{m=1}^{\infty} \times R_{0t} h_{mpt} \cos mpt\right\}$$

where

$$\omega_0^2 = 1/LC$$

Therefore, the output voltage v of equation 1(A) is given by

$$v = A_s \epsilon^{\int X dt}\{\cos(\omega_0 t+\Delta\omega)-(1/6\omega C)\times (2\beta-6\gamma' N\cos pt)(1-\mu M/L)^2 \times V_t \sin 2(\omega_0 t+\Delta\omega)-(\mu M/L-1)^3 \times (1/8\omega C)(3\gamma' V_t^2/4)\times \sin 3(\omega_0 t+\Delta\omega)-\ldots\} \quad (8)$$

where

$V_t = A_s \epsilon^{\int X dt}$

A_s = a constant depending on initial conditions = amplitude of oscillation at start

$X = (1/2C)[\alpha' - G - (3\gamma'/4)(\mu M/L-1)^3 \times V_t^2 - (3\gamma'/2)(\mu M/L-1)N^2 + (\mu M/L-1)\{2\beta N \cos pt - (3\gamma'/2)N^2 \cos 2pt\}]$

$\Delta\omega = -\{(\mu M/L-1)/4\omega_0 C\}\{-2\beta N \cos pt + (3\gamma'/2)N^2 \cos 2pt\}$

$\alpha' = \alpha(\mu M/L-1)$, and $\gamma' = -\gamma$

It should be noted that the system is, in general, oscillating in the absence of the quenching voltage and hence $\mu M/L > 1.0$. Also, for all practical cases, γ is negative and β is positive. It is clear from equation 8 that both the amplitude and frequency of oscillation are modulated. The fundamental frequency of modulation equals the quenching voltage frequency. The amount of modulation depends not only on the amplitude and frequency of the quenching voltage, but also on the nonlinearity of the tube characteristic as well as other circuit parameters.

ENVELOPE OF OSCILLATION V_t AND THE RATE OF VARIATION OF THE AMPLITUDE OF OSCILLATION dV_t/dpt

The amplitude of oscillation V_t is given by, $V_t = A_s \epsilon^{\int X dt}$ giving

$$dV_t/dpt = XV_t/p = (\epsilon/2)(\omega/p)\times [1-(V_t^2/V_0^2)-\{3\gamma'(\mu M/L-1)/\times 2(\alpha'-G)\}N^2(1+\cos 2pt)+ \{2\beta(\mu M/L-1)/(\alpha'-G)\}N \cos pt]V_t \quad (9)$$

where

$X = (1/2C)\{\alpha_{eq}' - G - (3\gamma'/4)(\mu M/L-1)^3 V_t^2\}$

$\epsilon = (\alpha' - G)/\omega C$

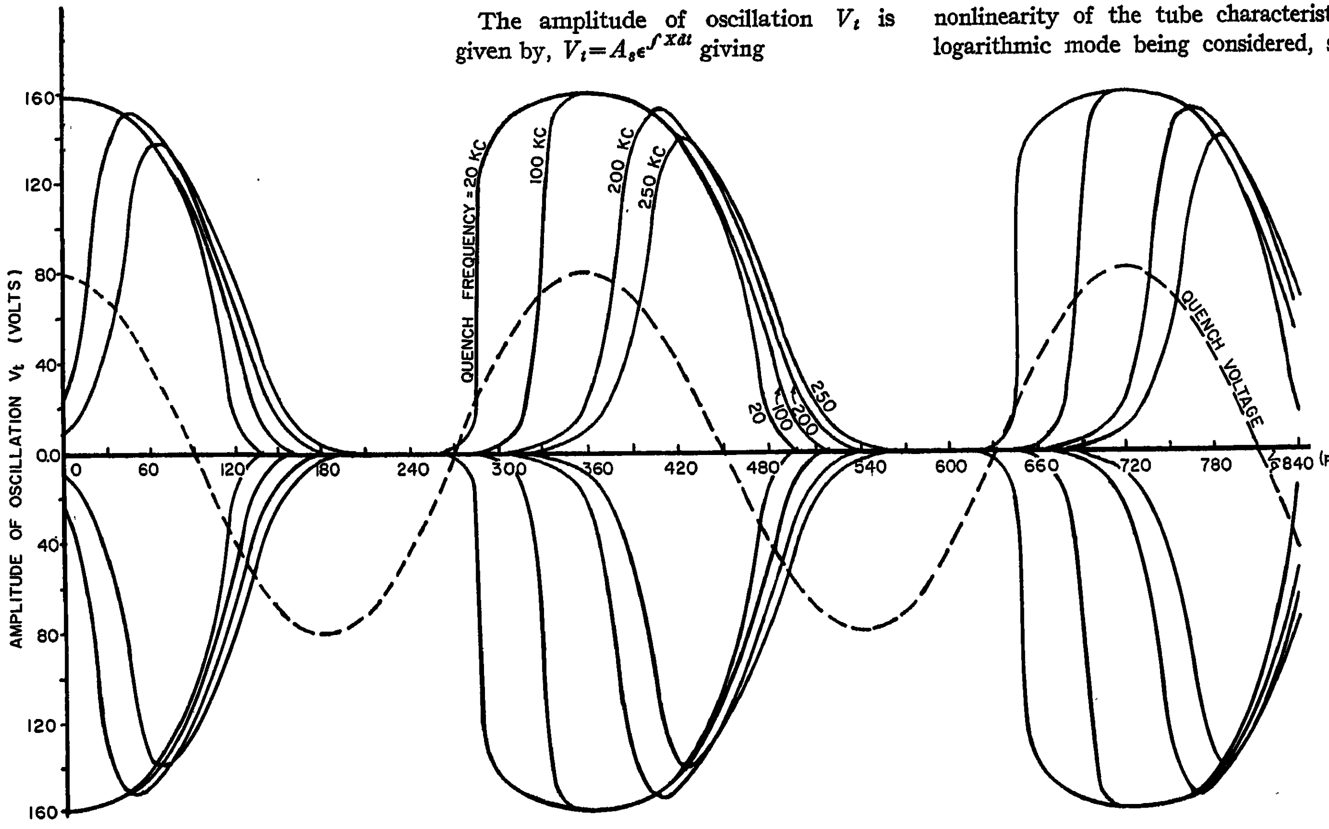
and as the amount of nonlinearity is assumed small, $\epsilon << 1$

$\alpha_{eq}' = (\mu M/L-1)\{(1/\rho)-(3\gamma'/2)N^2 + 2\beta N \cos pt - (3\gamma'/2)N^2 \cos 2pt\}$

and $V_0 = \sqrt{(\alpha'-G)/(3/4)\gamma'(\mu M/L-1)^3}$ is the amplitude of free oscillation if the quench voltage were absent. Comparing X with the corresponding exponent of a free oscillator,[8] it is concluded that a superregenerative detector can be considered as an ordinary oscillator with periodically variable regeneration. The exponent X depends not only on the amplitude N and the frequency $p/2\pi$ of the quench source, but also on the nonlinearity of the tube characteristic and the amplitude of oscillation, Figure 3.

In superregeneration, the amplitude N and the frequency $p/2\pi$ of the quench source are in general so adjusted that the exponent X during a quench cycle decreases, reaches zero, and reverses its sign, see Figure 3. During a part of the quench cycle, X is positive and oscillation builds up exponentially to an amplitude which is generally limited by N and the nonlinearity of the tube characteristic, logarithmic mode being considered, see

Figure 4. Envelope of oscillation at different quench frequencies



Figures 2 and 3. At the other part of the quench cycle, X is negative and oscillation dies down to an amplitude of the order of the internal tube and external circuit noise voltages, at which interval the oscillation can be considered suppressed, see Figures 2 and 3. During the interval at which $(\alpha_{eq}'-G)$ is positive, the system works as an oscillator with variable regeneration. When $(\alpha_{eq}'-G)$ is negative, the oscillation will be damped to practically zero amplitude and remaining practically suppressed till $(\alpha_{eq}'-G)$ becomes positive, and the system starts oscillating again. The same process is repeated for each cycle of quench voltage.

It is clear from equation 9 that the effect of increasing the quench frequency $p/2\pi$ is to reduce the rate of variation dV_t/dpt. If $p/2\pi$ is increased beyond a certain value, the amplitude of oscillation cannot attain the saturation value and the detector will operate in the linear mode instead of the logarithmic mode as shown in Figure 4 (characteristics with $p/2\pi$ equal to 200 and 250 kilocycles per second).

THE CHARACTERISTIC NOISE

It should be noted that if there were not any electromotive force impressed upon the circuit, the oscillation could not start even if $(\alpha_{eq}'-G)$ became positive. But when no signal is applied to the detector, a number of random electromotive forces act upon the oscillatory circuit from various internal and external sources such as the shot effect, the flicker effect, and thermal agitation. The oscillation is therefore initiated by an impulse corresponding to the value of the random electromotive forces at the instant when the operating conditions favor oscillation, that is, at the instant when $(\alpha_{eq}'-G)$ becomes positive. Owing to the irregularities in the initiating electromotive force the oscillation starts at random and thus leads to the characteristic noise of superregenerative circuits with no applied signal.

CONDITION OF STABILITY OF OSCILLATION

The amplitude V_t of the fundamental of oscillation at any instant is given by

$$V_t=A_s\epsilon^{\int X dt}$$

and

$$X=(1/2C)[(\mu M/L-1)\{(1/\rho)-(3\gamma'/4)\times (\mu M/L-1)^2V_t^2-(3\gamma'/2)N^2+ 2\beta N\cos pt-(3\gamma'/2)N^2\cos 2pt\}-G]$$

For small values of V_t, X is positive and the oscillation builds up from the small starting value A_s which corresponds to the noise voltage. As time goes on, $\int X dt$ increases and hence V_t increases; however, at the same time, X reduces. Therefore $\int X dt$ tends towards a maximum value, at which instant V_t becomes maximum and equals V_m. Therefore, V_t is maximum when $\int X dt$ is maximum and equals V_m/A_s, that is, when $X=0$. Alternatively, V_t is maximum when $dV_t/dt=0$, but $dV_t/dt=XV_t$; thus, V_t is maximum when $X=0$. Maximum values of V_t can therefore be obtained from the following relation

$$(X)_{V_t=V_m}=(1/2C)[(\mu M/L-1)/\rho-G- (3\gamma'/4)V_m^2(\mu M/L-1)^3-(\mu M/ L-1)\{(3\gamma'/2)N^2-2\beta N\cos pt+ (3\gamma'/2)N^2\cos 2pt\}]=0 \quad (10)$$

Equation 10 as it is, gives one value for V_m, this is because the tube characteristic was represented by three terms only for simplicity. But, if more terms were taken, equation 10 would yield more than one value for V_m. Whether these maximum values occur in practice or not depends on their stability.

If there is a slight increase δV in the possible maximum amplitudes V_m given by equation 10, then the increase δX in $(X)_{V_t=V_m}$ must be negative, that is, X must be reduced from its zero value to a negative one, otherwise $\epsilon^{\int X dt}$ would increase beyond V_m/A_s and hence the maximum amplitude would rise indefinitely which is contrary to the fact. Therefore the condition for stability is, $(dX/dV_m)<0$, that is

$$(d/dV_m)\{(\mu M/L-1)/\rho-G-(3\gamma'/4)\times (\mu M/L-1)^3V_m^2\}<-(d/dV_m)\times \{(\mu M/L-1)(2\beta N\cos pt_m- (3\gamma'/2)N^2\cos 2pt_m-(3\gamma'/2)N^2)\}$$

where t_m is the instant at which $V_t=V_m$. If there were no quenching voltage, the system would represent a simple free oscillator and if having a stationary amplitude $=V_m$, the condition of stability would be

$$(d/dV_m)\{(\mu M/L-1)/\rho-G- (3\gamma'/4)(\mu M/L-1)^3V_m^2\}<0$$

Therefore, a stable system in the superregenerative state may be unstable in the free state for the same maximum amplitude of oscillation.

MULTIPLE RESONANCE

Usually, the amplitudes of the harmonics obtained from equation 8 are very small, and therefore they can be neglected when discussing multiple resonance. The fundamental of the output voltage is

$$v=V_t\cos\{\omega_0t-(1/4\omega_0C)(\mu M/L-1)\times (-2\beta N\cos pt+(3\gamma'/2)N^2\cos 2pt)\}$$

The amplitude of oscillation V_t is given by

$$V_t=A_s\epsilon^{\int X dt}$$

$$=A_s\epsilon^{\int (1/2)\{m_0+pm_1\cos pt+ 2pm_2\cos 2pt-(3\gamma'/4C)(\mu M/L-1)^3V_t^2\}}$$

giving

$$(d/dt)(1/V_t^2)+(m_0+pm_1\cos pt+2pm_2\times \cos 2pt)(1/V_t^2)=(3\gamma'/4C)(\mu M/L-1)^3$$

and

$$1/V_t^2=\epsilon^{-(m_0t+m_1\sin pt+m_2\sin 2pt)}\times \{B+(3\gamma'/4C)(\mu M/L-1)^3\times \int\epsilon^{(m_0t+m_1\sin pt+m_2\sin 2pt)}dt\}$$

$$=B\epsilon^{-m_0t}\{A_0+A_1\cos pt+A_2\cos 2pt+ \ldots -B_1\sin pt-B_2\sin 2pt-\ldots\}+ (3\gamma'/4C)(\mu M/L-1)^3[(A_0/m_0)+ \{(m_0A_1-pB_1)/(p^2+m_0^2)\}\cos pt+ \{(m_0A_2-2pB_2)/(4p^2+m_0^2)\}\cos 2pt+ \ldots+\{(m_0B_1+pA_1)/(p^2+m_0^2)\}\times \sin pt+\{(m_0B_2+2pA_2)/(4p^2+m_0^2)\}\times \sin 2pt+\ldots]\{A_0+A_1\cos pt+ A_2\cos 2pt+\ldots-B_1\sin pt- B_2\sin 2pt-\ldots\} \quad (11)$$

This gives the transient and the steady-state solutions respectively where $B=$a constant depending on initial conditions.

$$m_0=(1/C)\{\alpha'-G-(3\gamma'/2)(\mu M/L-1)N^2\}$$

$$m_1=(2\beta/pC)(\mu M/L-1)N$$

$$m_2=-(3\gamma'/4pC)(\mu M/L-1)N^2$$

$$A_0=I_0(m_1)I_0(m_2)-2\sum_{n=1}^{\infty}I_{8n-4}(m_1)I_{4n-2}(m_2)+ 2\sum_{n=1}^{\infty}I_{8n}(m_1)I_{4n}(m_2)$$

$$A_1=2\sum_{n=1}^{\infty}I_{8n-7}(m_1)I_{4n-3}(m_2)- 2\sum_{n=1}^{\infty}I_{8n-5}(m_1)I_{4n-3}(m_2)- 2\sum_{n=1}^{\infty}I_{8n-3}(m_1)I_{4n-1}(m_2)+ 2\sum_{n=1}^{\infty}I_{8n-1}(m_1)\ I_{4n-1}(m_2)$$

$$A_2=-2I_2(m_1)I_0(m_2)+2\sum_{n=1}^{\infty}I_{8n-6}(m_1)\times I_{4n-2}(m_2)+2\sum_{n=1}^{\infty}I_{8n-2}(m_1)I_{4n-2}(m_2)- 2\sum_{n=1}^{\infty}I_{8n-2}(m_1)I_{4n}(m_2)- 2\sum_{n=1}^{\infty}I_{8n+2}(m_1)I_{4n}(m_2)$$

$$B_1=2I_1(m_1)I_0(m_2)-2\sum_{n=1}^{\infty}I_{8n-5}(m_1)\times I_{4n-2}(m_2)-2\sum_{n=1}^{\infty}I_{8n-3}(m_1)I_{4n-1}(m_2)+ 2\sum_{n=1}^{\infty}I_{8n-1}(m_1)I_{4n}(m_2)+ 2\sum_{n=1}^{\infty}I_{8n+1}(m_1)I_{4n}(m_2)$$

$$\begin{aligned} B_2 = 2\sum_{n=1}^{\infty} & I_{8n-8}(m_1)I_{4n-3}(m_2) - \\ & 2\sum_{n=1}^{\infty} I_{8n-4}(m_1)I_{4n-3}(m_2) - \\ & 2\sum_{n=1}^{\infty} I_{8n-4}(m_1)I_{4n-1}(m_2) + \\ & \qquad 2\sum_{n=1}^{\infty} I_{8n}(m_1)I_{4n-1}(m_2) \end{aligned}$$

and I_n=modified Bessel function of order n.[9] As stated before, in some parts of the quench cycle, the oscillation can be considered suppressed, in which part the amplitude of oscillation is less than the internal tube noise and external circuit noise voltages. Therefore, in each quench cycle, the oscillation is started by an amplitude due to the noise voltage, and therefore both the steady and transient solutions exist.

Now, if steady state only is considered

$$\begin{aligned} v = (& A_0' + A_1' \cos pt + A_2' \cos 2pt + \ldots + \\ & B_1' \sin pt + B_2' \sin 2pt + \ldots) \times \\ & \cos \{\omega_0 t - ((\mu M/L - 1)/4\omega_0 C) \times \\ & \quad (-2\beta N \cos pt + (3\gamma'/2)N^2 \cos 2pt)\} \end{aligned}$$

where A_0', A_1', $A_2' \ldots$ and B_1', $B_2' \ldots$ are functions of m_0, p, A_1, $A_2 \ldots$, B_1, $B_2 \ldots$ Therefore

$$\begin{aligned} v = (& A_0' + A_1' \cos pt + A_2' \cos 2pt + \ldots + \\ & B_1' \sin pt + B_2' \sin 2pt + \ldots) \times \\ \Bigg[\!\Bigg[& (\cos \omega_0 t)\Bigg[\Bigg\{ J_0(m_1 p/4\omega) + (-1)^n \times \\ & \sum_{n=1}^{\infty} J_{2n}(m_1 p/4\omega) \cos 2npt \Bigg\} \times \\ & \Bigg\{ J_0(m_2 p/4\omega) + (-1)^n 2\sum_{n=1}^{\infty} \times \\ & J_{2n}(m_2 p/4\omega) \cos 4npt \Bigg\} - \\ & \Bigg\{ (-1)^{n+1} 2\sum_{n=1}^{\infty} J_{2n-1}(m_1 p/4\omega) \cos npt \Bigg\} \times \\ & \Bigg\{ (-1)^{n+1} 2\sum_{n=1}^{\infty} J_{2n-1}(m_2 p/4\omega) \times \\ & \cos npt \Bigg\}\Bigg] + (\sin \omega_0 t)\Bigg[\Bigg\{ (-1)^{n+1} 2 \times \\ & \sum_{n=1}^{\infty} J_{2n-1}(m_1 p/4\omega) \cos npt \Bigg\} \times \\ & \Bigg\{ J_0(m_2 p/4\omega) + (-1)^n 2\sum_{n=1}^{\infty} \times \\ & J_{2n}(m_2 p/4\omega) \cos 4npt \Bigg\} + \\ & \Bigg\{ J_0(m_1 p/4\omega) + (-1)^n 2\sum_{n=1}^{\infty} \times \\ & J_{2n}(m_1 p/4\omega) \cos 2npt \Bigg\}\Bigg\{ (-1)^{n+1} 2 \times \\ & \quad \sum_{n=1}^{\infty} J_{2n-1}(m_2 p/4\omega) \cos 2npt \Bigg]\Bigg\} \Bigg]\!\Bigg] \end{aligned}$$

where J_n is a Bessel function of order n.[9]

But, as p/ω is $<<1$, therefore terms containing $J_n(mp/4\omega)$ can be neglected and the term $J_0(mp/4\omega)$ can be considered unity. Therefore, the voltage v, to a good degree of approximation, may be given by

$$\begin{aligned} v \approx (& A_0' + A_1' \cos pt + A_2' \cos 2pt + \ldots + \\ & B_1' \sin pt + B_2' \sin 2pt + \ldots) \cos \omega_0 t \\ = & A_0' \cos \omega_0 t + (A_1'/2)\{\cos(\omega_0 + p)t + \\ & \cos(\omega_0 - p)t\} + (A_2'/2)\{\cos(\omega_0 + 2p)t + \\ & \cos(\omega_0 - 2p)t\} + \ldots + (B_1'/2) \times \\ & \{\sin(\omega_0 + p)t - \sin(\omega_0 - p)t\} + \\ & (B_2'/2)\{\sin(\omega_0 + 2p)t - \\ & \qquad \sin(\omega_0 - 2p)t\} + \ldots \end{aligned}$$

This shows that the resonance curve of the circuit represents a major resonance at $\omega_0/2\pi$, plus resonances of diminishing importance at $(\omega_0 \pm np)/2\pi$, clarifying that multiple resonance is intrinsically a part of superregeneration. It is clear that such multiple resonance is mainly due to amplitude modulation.

Numerical Examples

In order to clarify the foregoing theoretical predictions, several examples will be calculated. Let

$\omega/2\pi = 75$ megacycles per second

$\epsilon = (\alpha' - G)/\omega C = 0.01$

$V_0 = 100$ volts

$\{3\gamma'(\mu M/L - 1)/2(\alpha' - G)\} N^2 = 0.5$

$\{2\beta(\mu M/L - 1)/(\alpha' - G)\} N = 2.5$

Substitution in equation 9 gives

$$\begin{aligned} dV_t/dpt = & \{3.75 \times 10^5/(p/2\pi)\}\{0.5(1 + \\ & 5 \cos pt - \cos 2pt) - V_t^2/10^4\} V_t \qquad (12) \end{aligned}$$

Although there is a complete solution given by equation 11 for the determination of V_t, yet it is easier to obtain V_t graphically from equation 12 using the step-by-step method. As stated before, both the transient and steady states exist and therefore the solution depends on the initial conditions, namely, the amplitude due to the impulse of the noise voltage at the instant at which the exponent X starts to be positive and which will be assumed to be 0.1 volt.

For a quench frequency of 100 kilocycles per second, the envelope of oscillation is shown in Figure 2, the quench voltage is also shown. The oscillation builds up from an amplitude=0.1 volt (assumed noise voltage) at the instant of the quench cycle corresponding to (250°+m×360°), that is at the instant at which the exponent X starts to be positive; the oscillation dies down to the same amplitude at the instant corresponding to (170°+m×360°), where m is an integer. In the interval (170°+m×360°) up to (250°+m×360°), the oscillation is considered suppressed. Figure 3 shows the amplitude of oscillation V_t, the rate of amplitude variation dV_t/dpt and the exponent X, quench frequency being 100 kilocycles per second. Figure 4 shows the effect of the quench frequency on the envelope of oscillation. It is clear that at the quench frequencies 200 and 300 kc per second, the detector operates in the linear mode. At 20 and 100 kc per second, it operates in the logarithmic mode.

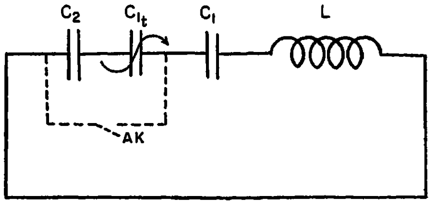


Figure 5. Connection diagram for equation 5(A)

Appendix I. Determination of the Current *iq* of Equation 5(A)

Let $\omega_0 = \omega(1+d)$ where d=amount of detune (a small fraction). The connection diagram giving the current iq of equation 5(A) will be as shown, see Figure 5, where

$1/C_1 = \omega^2 L$

$1/C_2 = (2d + d^2)/C_1$

and

$$1/C_{1t} = (1/C_1)(R_0/2\omega L)\sum_{n=1}^{\infty} nh_n \sin n\omega t$$

According to the well-known compensation theorem, if C_2 and C_{1t} are short-circuited by closing the artificial key (a.k.) and replaced instead by a generator of zero internal impedance and having an electromotive force $-\{(1/C_2) + (1/C_{1t})\}\int iq\,dt$ where iq is the actual current flowing in the circuit, iq would be unchanged; but the actual current flowing is unknown. Successive approximations will be adopted as follows.

Closing the a.k., the current would be given by, $i_1 = A \sin(\omega t + \phi)$, where A and ϕ are constants to be determined from initial conditions; the condenser is assumed to be initially charged. i_1 gives the first approximation for the current iq.

For a second approximation, replace C_2 and C_{1t} by a generator of zero internal impedance and having an electromotive force

$$\begin{aligned} v_1 = & -\{(1/C_2) + (1/C_{1t})\}\int i_1 dt \\ & = A\{(2d + d^2)/\omega C_1\} \cos(\omega t + \phi) + \\ & (A/2\omega C_1)(R_0/2\omega L) \times \\ & [h_1\{\sin(2\omega t + \phi) - \sin\phi\} + \\ & 2h_2\{\sin(3\omega t + \phi) + \sin(\omega t - \phi)\} + \\ & 3h_3\{\sin(4\omega t + \phi) + \sin(2\omega t - \phi)\} + \\ & \qquad \ldots] = v_{10} + v_{1w} + v_{2w} + v_{3w} + \ldots \end{aligned}$$

The voltage v_1 consists of components of frequencies zero (that is, d-c component), $\omega/2\pi$, $2\omega/2\pi$, $3\omega/2\pi$, and so forth.

It should be noted that the voltage component $v_{1\omega}$ is of the same frequency as the natural frequency of the $L-C_1$ circuit. Therefore, if this component were applied to the $L-C_1$ circuit, the resulting current would increase indefinitely. In fact, it is this component which has the most important effect in producing current.

To get the effect of $v_{1\omega}$, close the a.k. of Figure 5 and apply such a voltage, other generators being short-circuited, the current is given by

$$i_2 = -(A/2)\omega^2[2(2d+d^2)\{-(t/2\omega)\times \cos(\omega t+\phi)+(1/4\omega^2)\sin(\omega t+\phi)\} - (R_0/\omega L)h_2\{(t/2\omega)\sin(\omega t-\phi)+ (1/4\omega^2)\cos(\omega t-\phi)\}]$$

The components of i_2 whose amplitudes do not contain the time t can be included in $i_1(=A\sin(\omega t+\phi))$ in which case A and ϕ will be different, but yet depend on initial conditions. Therefore, the components whose amplitudes contain the time t will only be considered. The effects of the components of v_1 of frequencies other than $\omega/2\pi$ on the current fundamental can be neglected so long as each of $(R_0/\omega L)h_1$, $(R_0/\omega L)h_2$, $(R_0/\omega L)h_3$, and so forth is much less than unity; conditions which are satisfied in the present nonlinear problem.

Therefore, the fundamental component of the current iq to a second degree of approximation may be given by, $i_1+i_2=A\times \{\sin(\omega t+\phi)+(2(2d+d^2)/4)\omega t\cos(\omega t+\phi)+ (R_0/\omega L)h_2(\omega/4)t\sin(\omega t-\phi)\}$. Following the same lines, other approximations can be obtained and which may be given by

$$i_3 = A[\{(R_0/\omega L)h_2(\omega/4)\}^2 - \{2(2d+d^2)/4\}^2\omega^2](t^2/2!)\sin(\omega t+\phi)$$

$$i_4 = A[\{(R_0/\omega L)h_2(\omega/4)\}^2 - \{2(2d+d^2)\omega/4\}^2](t^3/3!)\times \{(2(2d+d^2)\omega/4)\cos(\omega t+\phi)+ (R_0/\omega L)h_2(\omega/4)\sin(\omega t-\phi)\}$$

$$i_5 = A[\{(R_0/\omega L)h_2(\omega/4)\}^2 - \{2(2d+d^2)\omega/4\}^2]^2(t^4/4!)\times \sin(\omega t+\phi)\ldots$$

Therefore, if each of $2(2d+d^2)\omega/4$, $(R_0/\omega L)h_1$, $(R_0/\omega L)h_2$, and so forth is very small compared with unity, the fundamental of the current iq, to a satisfactory degree of approximation, is given by

$$\begin{aligned} iq_{\text{Fund.}} &= i_1+i_2+i_3+i_4+i_5+\ldots \\ &= A\{1+(\sqrt{a})^2(t^2/2!)+(\sqrt{a})^4(t^4/4!)+ \ldots\}\sin(\omega t+\phi)+A\{2(2d+d^2)\omega/4\}\times (1/\sqrt{a})\{\sqrt{a}t+(\sqrt{a})^3(t^3/3!)+ \ldots\}\cos(\omega t+\phi)+A\{(R_0/\omega L)\times (h_2\omega/4)(1/\sqrt{a})\{\sqrt{a}t+(\sqrt{a})^3\times (t^3/3!)+\ldots\}\sin(\omega t-\phi) \end{aligned}$$

$$iq_{\text{Fund.}} = A[\cosh(\sqrt{a}t)\sin(\omega t+\phi)+ \{(\sinh(\sqrt{a}t))/\sqrt{a}\}\{(2(2d+d^2)\times \omega/4)\cos(\omega t+\phi)+(R_0/\omega L)\times (h_2\omega/4)\sin(\omega t-\phi)\}]$$

where

$$\sqrt{a} = (\omega/4)\sqrt{(h_2R_0/\omega L)^2 - \{2(2d+d^2)\}^2}$$

The current $iq_{\text{Fund.}}$ can be written as

$$iq_{\text{Fund.}} = B_1\epsilon^{\sqrt{a}t}\sin(\omega t+\phi')+B_2\epsilon^{-\sqrt{a}t}\times \sin(\omega t+\phi'')$$

where

$$\tan\phi' = 2(2d+d^2)/\{(4\sqrt{a}/\omega)+(R_0h_2/\omega L)\}$$

and

$$\tan\phi'' = -2(2d+d^2)/\{(4\sqrt{a}/\omega) - (h_2R_0/\omega L)\}$$

The angles ϕ' and ϕ'' are independent of initial conditions, they depend only on the amplitude of variation h_2 and the amount of detune d. However, B_1 and B_2 can be considered as constants depending on initial conditions. As $\sqrt{a}$ is real, which is the case of interest at present, the term containing $\epsilon^{-\sqrt{a}t}$ can be neglected, as it is a highly damped one, and $iq_{\text{Fund.}}$ can be satisfactorily given by

$$iq_{\text{Fund.}} = B_1\epsilon^{\sqrt{a}t}\sin(\omega t+\phi')$$

The harmonics other than the fundamental as well as the zero-frequency component can be obtained as follows.

Replace C_2 and C_{1t} by a generator of zero internal impedance and having an electromotive force equal to

$$\begin{aligned} &-\{(1/C_2)+(1/C_{1t})\}\int iq_{\text{Fund.}}dt \\ &= -\{B_1\epsilon^{\sqrt{a}t}/\sqrt{1+a/\omega^2}\}[\{2(2d+ d^2)/2\omega C_1\}\sin(\omega t+\phi'-\theta') - (h_1R_0/ 2\omega L)(1/2\omega C_1)\{\cos(2\omega t+\phi'-\theta') - \cos(\phi'-\theta')\} - (2h_2R_0/2\omega L)\times (1/2\omega C_1)\{\cos(3\omega t+\phi'-\theta') - \cos(\omega t-\phi'+\theta')\} - (3h_3R_0/2\omega L)\times (1/2\omega C_1)\{\cos(4\omega t+\phi'-\theta') - \cos(2\omega t-\phi'+\theta')\} - \ldots] \\ &= v_{0h}+v_{1h}+v_{2h}+v_{3h}+\ldots \end{aligned}$$

where $\tan\theta' = \omega/\sqrt{a}$.

This voltage consists of components of frequencies zero, $\omega/2\pi$, $2\omega/2\pi$, $3\omega/2\pi$, and so forth, being equal to v_{0h}, v_{1h}, v_{2h}, v_{3h}, and so forth, respectively.

The effect of the component of frequency $\omega/2\pi$ is included in the predetermined fundamental.

The effects of components of frequencies zero, $2\omega/2\pi$, $3\omega/2\pi$, and so forth, give the zero-frequency, second, third, and so forth harmonic current components respectively to a good degree of approximation so long as each of $h_1R_0/\omega L$, $h_2R_0/\omega L$, $h_3R_0/\omega L$, and so forth is much less than unity. Therefore, the current iq will be given by equation 6 in the text.

Sensitivity and Output Formulas for the Resistance Bridge

PHILIP M. ANDRESS
ASSOCIATE MEMBER AIEE

IN EITHER the design or the application of a resistance bridge circuit, it may be necessary to calculate the output of the bridge in terms of input or vice versa. The purpose of the calculation may be to establish the required sensitivity of a galvanometer, meter, or of any other null detector or output device, which is to be energized by a resistance change in the bridge, or it may be necessary to determine the input voltage or current required for minimum operation. Upon occasion, an exact calculation may be required to calibrate the output indicator, as in the deflection types of resistance thermometer or strain-gauge bridges. The formulas and correction factors presented in Table I were developed by the author for convenience in performing such calculations.

Paper 53-1, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted March 25, 1952; made available for printing October 7, 1952.

Philip M. Andress is with the Rubicon Company, Philadelphia, Pa.

The author wishes to express thanks to Dr. Frank Wenner of the National Bureau of Standards and to Norman E. Bonn and other members of the Rubicon Company staff for their invaluable help and suggestions during preparation of this material.

Table I. Sensitivity and Bridge Output Formulas*

Output	Input			Correction Factor for $p=\pm\Delta X/X$†
				
	(1A) $e=\frac{VCp}{T}$	(1B) $e=\frac{IBXp}{T}$‡	(1C) $e=\frac{EBXp}{T(D+L)}$	$1/(1+pw)$
	(2A) $i=\frac{Vp}{T}$	(2B) $i=\frac{IDp}{T}$	(2C) $i=\frac{Ep}{T(1+L/D)}$	$1/(1+py)$
	(3A) $i_G=\frac{Vp}{T(1+G/C)}$	(3B) $i_G=\frac{IBXp}{T(C+G)}$	(3C) $i_G=\frac{Ep}{T(1+G/C)(1+L/D)}$	$1/(1+pz)$

* Error of uncorrected formulas is less than p-proportional parts, hence is negligible for near balance calculations.

† Exact formula = uncorrected formula × correction factor.

Auxiliary Equations:

1. $e=Vp/4$ when $A=B=X=R$ (see item 5, Appendix)
2. $V=ID$
3. $CD=BX=AR$
4. $\sqrt{CD}=\sqrt{BX}=\sqrt{AR}$
5. $e=iC$
6. $w=[X+AD/(D+L)]/T$**
7. $y=[X+R+AD/(D+L)]/T$**
8. $z=[X+RC/(C+G)+AD/(D+L)]/T$**

** If the input is a constant regulated voltage, or if V is the voltage across the unbalanced bridge, then the value of L in the correction factors is zero; if a constant regulated current, or if I is the input current to the unbalanced bridge, then L is infinite and the fractions having $(D+L)$ in the denominator disappear from those expressions. The linear equations 1(C), 2(C), and 3(C) have no significance in these two special cases:

1. If $L=0$, then $w=(X+A)/T$; $y=(X+R+A)/T$; and $z=[X+RC/(C+G)+A]/T$.
2. If $L=\infty$, then $w=X/T$; $y=(X+R)/T$; and $z=[X+RC/(C+G)+A]/T$.

‡ See also item 6, Appendix.

These formulas can be used in essentially three types of applications:

1. The calculation of sensitivity of the balanced or near-balanced bridge in terms of the required precision of measurement or test (examples 1, 2, and 3).
2. The close approximation of the bridge output for moderate unbalances because of resistance changes in one or more arms.
3. The calculation of the exact output for any degree of unbalance because of a change in the X arm (examples 4 and 5).

It will be noted that if the uncorrected formulas are considered only as approximations, the other uncorrected formulas can be derived from equation 1(A) and auxiliary equations 2 and 3. These formulas can also be applied to the double, or Kelvin bridge circuit, except that CD must be substituted for BX where applicable, and T is the sum of the resistances of the six arms consisting of the two double-ratio arms plus the standard and unknown arms. However, they are particularly convenient for the single or Wheatstone bridge and have been developed primarily for application to the latter circuit.

Formula 1(A) is equivalent to the equation given by Wenner.[1] Formulas 3(A) and 3(C) have been previously published.[2] Formula 3(C) with correction factor is the equivalent of the so-called classical solution of the Wheatstone bridge, which because of its complexity is of historical rather than of practical value.[1] Auxiliary equation 1 has been in previous use for some time. Here it is presented as a special case of equation 1(A).

Nomenclature and Definitions Used in Table I

e = available electromotive force output
i = available current output
i_G = current through galvanometer branch (output)
V = input voltage to the balanced bridge
I = input current to the balanced bridge
E = battery electromotive force
C = resistance of the balanced bridge as viewed by the galvanometer (output bridge resistance)
D = resistance of the balanced bridge as viewed by the battery (input bridge resistance)
p = proportional-parts unbalance (see definition following) of the bridge, or the required proportional-parts precision
A, B, R, and X = resistances of the four arms of the balanced bridge, taken in rotation (B and X being opposite arms)
T = total additive resistance of all arms ($T=A+B+R+X$)
L = resistance of the battery branch (or limiting resistance); in general, the resistance looking from bridge toward power source
G = resistance of the galvanometer branch; in general the resistance looking from bridge toward the output
Available electromotive force = open circuit output electromotive force (see item 2, Appendix)
Available current = short-circuit output current (available electromotive force divided by output resistance) (see item 2, Appendix)

Galvanometer branch = galvanometer plus auxiliary series or parallel resistance, if used (output branch)

Battery branch = battery plus limiting resistance (input branch).

Balanced bridge = bridge in which the relationship $A/B = X/R$ holds, hence in which the output is zero, or null. Otherwise the bridge is said to be unbalanced.

Proportional-parts unbalance = the proportional-parts change of resistance in one arm (as $p = \Delta X/X$) to produce the unbalance, or in general the algebraic sum of the proportional parts changes where more than one arm is involved, that is, $p = \Delta X/X - \Delta R/R + \Delta B/B - \Delta A/A$.

Bridge sensitivity = least value of p to produce a detectable output, or alternatively, output for a specified value of p.

Examples

1. A 300-ohm galvanometer is to be used as the null detector for 0.1-per-cent measurements with a Wheatstone bridge. At balance, the resistances of the unknown and rheostat arms are $X = 200{,}000$ ohms and $R = 2{,}000$ ohms. The total resistance of the two ratio arms, $A+B$, is 1,000 ohms. What current will pass through the galvanometer corresponding to an 0.1-per-cent unbalance, if input voltage V is 10 volts, and if the galvanometer is in parallel with $A+B$?

Answer: $V = 10$, $p = 0.1$ per cent $= 0.001$, $T = 203{,}000$ ohms, $G = 300$ ohms (assuming that no dummy resistance is used), and $C = 1{,}000$ ohms. Substituting these values into formula 3(A) gives

$$i_G = (10\times 0.001)/(203{,}000\times 1.3) = 0.04\times 10^{-6} \text{ ampere}$$

2. If a galvanometer having an external critical-damping resistance of 10,000 ohms and an electromotive force sensitivity (see item 3, Appendix) of 100 microvolts per millimeter is to be used across this bridge, together with dummy series resistance to adjust the damping to critical, what deflection will correspond to 0.1-per-cent unbalance?

Answer: From formula 1(A) for available electromotive force

$$e = (10\times 1000\times 0.001)/203{,}000 = 50\times 10^{-6} \text{ volts} = 50 \text{ microvolts}$$

Since this available electromotive force is unaffected by the series resistance, the deflection is 50 microvolts ÷ 100 microvolts/millimeter = 1/2 millimeter.

3. Again referring to the same bridge, but assuming that a galvanometer with an electromotive force sensitivity of 4.5 microvolts per millimeter and an external critical damping resistance of 45 ohms is to be used with dummy parallel resistance for adjustment to critical damping, what deflection will correspond to 0.1-per-cent unbalance?

Answer: From formula 2(A) the available, or short-circuit current is

$$(10\times 0.001)/203{,}000 = 0.05 \text{ microampere}$$

Since this available current is unaffected by parallel resistance, the available electromotive force is $0.05\times 45 = 2.25$ microvolts (auxiliary equation 5). Dividing by the electromotive force sensitivity of 4.5 microvolts per millimeter gives 0.5-millimeter deflection.

4. The output electromotive force of a 120-ohm strain-gauge bridge is measured by means of an accurate potentiometer. Assuming that three arms of the bridge remain constant and that the resistance L in the battery branch can be neglected (see footnote** to Table I), what potentiometer reading will correspond to a 20-per-cent increase in resistance of the strain gauge when the input voltage is 1 volt?

Answer: Use formula 1(A) or auxiliary equation 1 with correction factor for available electromotive force. $V = 1$, $p = 0.2$. Hence the uncorrected value is $Vp/4 = 0.05$ volt. $w = [X + AD/(D+L)]/T = [120 + 120\times 120/(120)]/480 = 0.5$. Hence the correction factor is $1/(1+pw) = 1/(1+0.2\times 0.5) = 1/1.1$. The product is the exact value: $0.05\times(1/1.1) = 0.045$ volt.

5. What is the potentiometer reading in this setup for a 20-per-cent decrease in the resistance of the strain gauge?

Answer: Here uncorrected value and the value of w remain unchanged, and p is unchanged except for sign. The correction factor for $p = -0.2$ is $1/(1-0.2\times 0.5) = 1/0.9$; hence the potentiometer reading is $0.05\times(1/0.9) = 0.0555$ volt, with polarity reversed from that of example 4.

The correction factors are also useful to determine the error or nonlinearity of the uncorrected values, again where $p = \Delta X/X$. This error is, as applicable, pw, py, or pz proportional parts of the exact value and since neither w, y, or z can exceed 1.0, the limit of error of any uncorrected equation value where p is small compared to 1.0 is simply p-proportional parts (see item 1, Appendix). To illustrate, in examples 1 through 3, the limit of error is 0.1 per cent. It should be noted that this error represents a change in output corresponding to (0.1 per cent)^2, or to a resistance change of 1 part per million in the X arm, and that the actual error is probably less than this amount. On the other hand, where a calibrated unbalance of more than a few per cent is involved, the nonlinearity of the uncorrected formula may be significant, as in example 4 where the difference between the uncorrected and the exact value is 0.0045 ohm or 9 per cent, and in example 5 is 0.0055 ohm or $11\frac{1}{9}$ per cent.

Preferred Location of Galvanometer Branch in the Balanced Bridge

This is a modification of the rule previously presented by Kotter[3] which, contrary to the traditional rule,[5] takes into account both the distribution of wattage in the four arms and the damping of the galvanometer: "Connect the galvanometer across the higher or the lower bridge resistance depending on whether the specified external damping resistance of the galvanometer is higher or lower respectively than the mean bridge resistance."

The mean bridge resistance is defined as the geometric mean between the bridge resistances viewed by the battery and galvanometer branches. Numerically, this is the same as the geometric mean between either pair of opposite arms (auxiliary equation 4). The specified external damping resistance may be taken as the external critical-damping resistance, a published galvanometer characteristic (see item 4, Appendix).

The galvanometer is across the higher bridge resistance when it connects the junction of the two highest resistance arms with the junction of the two lowest resistance arms; otherwise it views the lower bridge resistance.

6. A galvanometer having an external critical damping resistance of 1,000 ohms is to be used at critical damping across a bridge whose arm resistances at balance taken in rotation are 90, 900, 100,000, and 10,000 ohms. Which is the preferred galvanometer connection?

Answer: The mean resistance between a pair of opposite arms is $\sqrt{90\times 100{,}000}$, or 3000 ohms. Since the external critical damping resistance is less than this value,

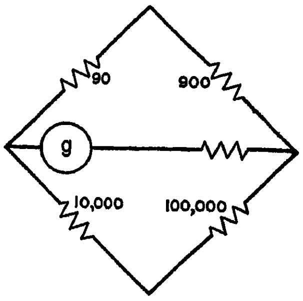

Figure 1

the better connection is across the lower bridge resistance as shown in Figure 1. In this case, the traditional rule would have called for the alternate arrangement, assuming that resistance is higher in the galvanometer branch than in the battery branch.[5]

Appendix

1. In the strictest sense, the limit of error of the uncorrected solution for any value of p, whether large or small and irrespective of sign, is p-proportional parts of the exact solution. However, it may also be considered as p-proportional parts of the uncorrected solution provided the unbalance is small say where p is less than 10 per cent. This over-all limit applies whether the unbalance is due to a resistance change in one arm only, or to a combination of changes in more than one arm.

2. The designations 'available electromotive force' and 'available current' were suggested to me by Dr. Frank Wenner of the National Bureau of Standards.

3. The electromotive force sensitivity of a galvanometer is defined as that electromotive force which produces unit deflection when it is introduced into a series circuit consisting of the galvanometer and its external critical-damping resistance. This electromotive force is also the potential difference appearing across the open circuit produced when the galvanometer is disconnected from this circuit, and is herein designated as the available electromotive force. It is often convenient to consider the electromotive force sensitivity of the galvanometer in the latter sense, as is illustrated by examples 2 and 3.

4. The galvanometer operates at highest efficiency at near-critical damping, hence it should be selected for a match between its external critical-damping resistance and the bridge resistance, rather than between its internal resistance and bridge resistance, as is sometimes recommended. Specifically, efficiency is usually highest when relative damping is between 0.6 and 0.8. Harris[4] gives a detailed presentation of this subject.

5. More generally $e=Vp/4$ when two arms adjacent to the galvanometer branch points are equal even though all four arms are not equal. Another useful equation, which can be derived from equation $2(B)$, is $i=Ip/4$ when two arms adjacent to the battery branch points are equal. When $A=B=X=R$ both $e=Vp/4$ and $i=Ip/4$.

6. It should be noted that formula $1(B)$ may be also conveniently written $e=(Ip)/S$, where S is the sum of the conductances of the four arms, that is, $S=1/A+1/B+1/R+1/X$. The relationship between equation $2(A)$ and this expression of equation $1(B)$ is an interesting illustration of the principal of duality.[6] Equivalent dual relationships apply to the other equations as well.

Discussion

F. Wenner and **F. K. Harris** (National Bureau of Standards, Washington, D. C.): The concepts of open-circuit voltage and short-circuit current (referred to in the present paper as available electromotive force and available current respectively) are, of course, well known in the solution of network problems. It has not been nearly so generally recognized that in the solution of the unbalanced Wheatstone bridge they are extremely valuable in that they permit the network and the detector to be considered as separate entities. The simplification that results from this separation and individual consideration of cause and effect is very well illustrated in Mr. Andress' collection of equations, and he is to be congratulated for carrying this work through to its logical conclusion. It should be pointed out that because of space limitations the development of these equations was omitted from the present paper, but we are glad to learn that this development is set forth in detail elsewhere.[1]

In the paper Mr. Andress has tabulated nine different expressions for the output of an unbalanced Wheatstone bridge in terms of its input, its circuit constants, and its proportional unbalance. Some cases also involve constants of either the input or detector branch of the bridge, or both. Each of these nine expressions involves a first-order approximation and a correction term which, taken together, constitute an exact expression. In the form stated, each is new, whether we think of the approximation or of the complete expression. Since the first-order approximations are simpler and serve nearly all needs, we shall limit further consideration to them.

We will recall Mr. Andress' statement of the order of approximation, that the proportional error resulting from use of the approximate expression is no greater than the proportional unbalance of the bridge (that is, no more than a 1-per-cent error results from using the approximate equations if the bridge is out of balance by 1 per cent). Obviously, then, if adjustments are being made to establish balance, the approximate expressions approach exact expressions. Furthermore, this is true even if certain liberties are taken with the expressions: V may represent the potential drop across the bridge whether it is precisely or only approximately balanced; I may represent current through the bridge for an exact or an approximate balance; and C may represent the bridge resistance seen from the galvanometer position for an exact or an approximate balance. Furthermore, it is necessary to know the bridge output in a form that can be used in stating galvanometer sensitivity so that, while it is customary to state galvanometer sensitivity in terms of the relation between its steady deflection and the current in its winding, it is proper and may be more convenient to use the available electromotive force or the available current rather than the current in the winding.

Taking into account the possibility that each of the nine first-order approximations may be stated in other forms, and accepting the modifications stated above for V, I, and C, Andress' equation $1(A)$ has been used by each of us, while equation $3(B)$ has been used by Jaeger. Equations $2(A)$, $2(B)$, and $2(C)$ are definitely new. Presumably equations $1(B)$ and $1(C)$ are also new. Whether $3(A)$ and $3(C)$ are new would be difficult to say, since many writers have derived more or less similar equations.

However, what is important is not the novelty of these expressions either in form or in substance but rather their convenience in use. The input, which we will need to know, may be measured with a voltmeter or an ammeter, or we may use simply the rated electromotive force of the battery. The constants of the circuit can usually be calculated from readings of the various bridge dial settings. An additional condition that must be met is that the resistance of the bridge circuit as seen from the position of the galvanometer must be appropriate for proper damping. Furthermore there must be an appropriate limit on the power dissipated in the bridge arms. These additional conditions may be stated explicitly or implicitly.

Andress' nine approximate expressions involve the three ways of expressing input and the three ways of expressing output, and constitute a complete assembly of bridge solutions. There are, of course, many other expressions stating the relations between the input, the circuit constants, and the output of a bridge, but most of these other expressions are more complicated than the simpler of the nine expressions under consideration here. It seems probable that in one way or another equations $1(A)$ and $2(B)$ of the paper will largely replace the more complicated expressions presently available as well as those which have been in general use since before the turn of the century.

Cathode-Ray Synchroscope and Automatic Synchronizer

M. ABDEL-HALIM AHMED
MEMBER AIEE

Synopsis: Two new electronic apparatus are introduced, in which the main element is a cathode-ray tube. The first is a synchroscope. The bus-bar voltage causes the beam to trace a circle, while the incoming machine voltage gives a pulse every cycle. The pulse is either applied to the *Y*-deflection plates or to the grid of the tube. In the first case it appears as a "pip" rotating round the circle, while in the latter case a luminous spot is seen to trace a circle. The behavior of both the pip and the spot is similar to that of the pointer of an ordinary synchroscope. The second apparatus is an automatic synchronizer. It is based on the same principle as the synchroscope, but uses a special cathode-ray tube in which the fluorescent screen is replaced by two collecting electrodes. When the pulse is applied to the grid of the tube, the beam current flows to one electrode or the other, and when it flows to the proper electrode, it causes a relay to operate which in turn causes the synchronizing circuit breaker to close. Both apparatus are discussed, and a description including the design data of an actual experimental synchroscope is given.

IN ALL branches of industry, a modern industrial tool is forging a silent evolution. This tool is electronics. Today there is scarcely a field of industry where electronic equipment is not speeding production, refining the process of manufacture, improving quality, doing efficiently what before had not been done at all, and making possible accurate and reliable measurements where other instruments or apparatus cannot be used or are unreliable. Above all, electronic control equipment has become versatile in all fields. Therefore, the modern tendency in power generating stations is to have the control gear operating electronically whenever possible.

Although the synchroscope is an essential part of a power station, yet synchronizing equipment has not followed the recent rapid developments in science and industry, and electronics has not yet invaded that field.

The cathode-ray synchroscope is the first developed type of electronic synchroscope. It is used in the Communications Laboratories of the Faculty of Engineering at Fouad I University.

The new cathode-ray automatic synchronizer exhibits the main features of an automatic synchronizing equipment, making use of the general principles underlying the cathode-ray synchroscope. It involves a new application of the phenomenon of commutating a cathode-ray beam by means of electrodes replacing the normal screen of a cathode-ray tube.

The Cathode-Ray Synchroscope

General Principle

The idea of this synchroscope lies in having a cathode-ray tube in which the beam traces a circle (or an ellipse) by the use of a conventional phase-splitting resistance-capacitance circuit, giving two voltages with a 90-degree phase difference which are applied to the *X* and *Y* plates of the cathode-ray tube; see Fig. 1. The voltage applied to the phase-splitting circuit is derived from the bus-bar voltage of the power station through an isolating line transformer of a suitable ratio.

The voltage of the incoming line is used to give a pulse at a certain defined instant of its cycle. This pulse is superimposed on the *Y*-plate deflecting voltage obtained from the phase-splitting circuit. Actually two pulses (displaced by 180 degrees) are obtained in each cycle, and therefore the circle traced on the screen of the cathode-ray tube will now have two pips, one positive and the other negative, displaced by 180 degrees, and their position relative to the circle depends on the instantaneous phase difference between the bus bar and incoming line voltages.

When these two voltages have exactly the same frequency, the pips will always occur when the beam is tracing two definite points of the circle, and the trace will be a circle with two stationary pips. If the frequencies of the bus bar and incoming line are different, the two pips will be seen to move round the circle, in the same manner as the pointer of an ordinary synchroscope rotates. The direction of the motion depends on which frequency is greater, and the speed of motion depends on the amount of difference between the two frequencies.

When the two voltages are exactly in phase, the two pips will be at two certain points on the screen; if the two frequencies are equal, the two pips will be stationary at these two points, which indicates the right instant for synchronizing; see Fig. 2(*A*). The two positions of the pips can be adjusted to occur exactly on the *Y* axis of the tube, Fig. 2(*B*), by means of a suitable arrangement of the circuit.

Generation of Pulse

The easiest method for obtaining a pulse, which occurs only twice per cycle and at definite instants in the cycle, is by the use of a saturated transformer, which serves at the same time for the isolation of the cathode-ray tube deflection system from the incoming voltage system.

The sine-wave input voltage is applied to the primary of the transformer through a suitable high resistance, Fig. 3, which ensures that the magnetizing current flowing in the primary winding of the transformer is very nearly sinusoidal. It was found that a transformer with only one or two laminations of good-quality core material gives satisfactory results.

Assuming an ideal magnetization curve for the core material as shown in Fig. 4(*A*), the voltage induced in the secondary winding of the transformer would be as shown in Fig. 4(*B*). The pulses occur at the instants when the primary voltage is zero.

However, due to the effects of the hys-

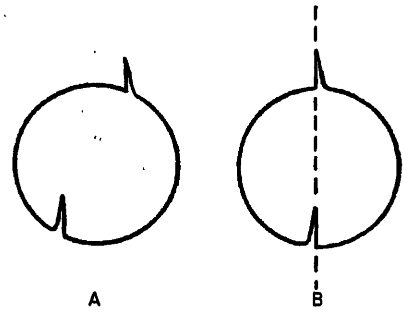
Paper 53-128, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted April 28, 1952; made available for printing November 28, 1952.

Dr. M. Abdel-Halim Ahmed is with Fouad I University, Giza, Cairo, Egypt.



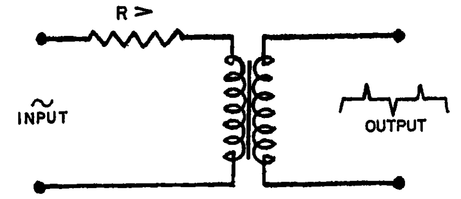


Figure 2 (left). Circular trace appearing on screen of cathode-ray synchroscope

Figure 3 (above). Circuit for pulse generation

teresis and eddy-current losses and the curvature of the magnetization curve of the core, there will be a time-lag displacement in the positions of the pulses as well as a distortion in their shape, and the secondary voltage wave form will be as shown in Fig. 4(*C*), which shows that the voltage rises rather slowly but decays sharply. The two peaks occur at 180 degrees, but lag a certain angle (about 30 degrees in the actual transformer used) behind the zero points of the original sine wave. Adjustment of the synchronization instant can evidently be made more accurately on the sharp side of the pulse.

It is evident that a magnetic-core material having an almost rectangular hysteresis loop with high permeability and low coercive force will give pulses approximating the desired ideal shape. To obtain pulses of good shape and sharp peaks, the number of the necessary ampere-turns should be more than about 10 times the ampere-turns necessary for producing the maximum flux density in the usual design of a normal power transformer using the same magnetic-core material.

When the two pips appear on the cathode-ray tube, confusion may result, especially when they are of large amplitudes, and it is preferable to suppress one of them. This can easily be done by any of the conventional methods, such as connecting a copper-oxide rectifier element across the secondary of the pulse transformer. The proper synchronization instant will then be when the remaining pip is on the Y axis in the upper part of the circle.

Adjustment of Correct Positions of Pips

If, at the correct instant for synchronization, the pips are required to be on the Y axis, a correction must be effected for the transformer time lag, in addition to the time advancement of the X-plate voltage ahead of the bus-bar voltage, which is inevitably produced by the phase-splitting circuit. A total correction angle of about 75 degrees is required. This is easily done by applying phase-shifting circuits before the phase-splitting circuit, and actually the phase-splitting circuit itself could be designed to incorporate the necessary correction. Many circuits have been successfully used, and the circuit shown in Fig. 5 was adopted in the final design of the apparatus. It has the following features:

1. Gives good wave forms of the voltages applied to the deflection plates. The resistance-capacitance circuit acts as a filter for the harmonics, if any.
2. It is easy to adjust the amount of phase-angle correction, and hence the correct position of the pips, without appreciably affecting the size of the trace, merely by varying resistance R.
3. It is easy to adjust the size and shape of the trace, without affecting the phase-angle correction appreciably, merely by varying R_3.

Power Supply for Cathode-Ray Tube

The power supply for the cathode-ray tube is obtained from the existing or bus-bar voltage, which is the one to be connected first to the apparatus; thus the circle would appear first. A conventional power supply circuit is used, employing a half-wave rectifier.

The high-tension secondary of the cathode-ray tube mains transformer may be used also for feeding the phase-splitting circuit. The phase-shifting circuit will also correct for any phase shift between the secondary and primary voltages of this transformer.

Rotating-Spot Principle

The pulse signals, instead of being applied to the Y plates of the cathode-ray tube, may be applied to the grid of the tube, and the grid bias is adjusted so that the beam disappears when the pulse voltage falls a few volts below the positive peak value. In this case, instead of having two rotating pips, we get one rotating illuminated point, and the original circle will not be visible. The proper instant for synchronization is when the spot lies on the upper part of the Y axis.

Frequency of Generating Station

If the synchroscope is adjusted for, say, 50-cycle operation, it will be found that it works well with 40 and 60 cycles. The only discrepancy that may appear is that the circle becomes an ellipse. This does not affect the operation of the apparatus in the least.

The characteristics of the pulse transformer may vary with frequency, giving different time-lag angles. This was found to be almost exactly compensated with the variation of the phase shift produced by the phase-shifting circuit. However, if greater accuracy is desired, one may vary the value of resistance R, Fig. 5.

The Experimental Synchroscope

The connection diagram for the developed experimental synchroscope is shown in Fig. 6. Switch S_1 is a 6-pole double-throw switch used to change the operation of the synchroscope from rotating pips (position 1) to rotating spot (position 2). Switch S_2 is a single-pole 3-way switch provided to enable the use of the synchroscope on either 40, 50, or 60 cycles. Both switches are added only for demonstration purposes and may be dispensed with in commercial apparatus.

Terminals 1 and 2 are for connection to the bus-bar voltage (110 volts), while terminals 1′ and 2′ are for connection to the incoming line. Both pairs should be connected to identical phases. Terminals 2*a* and 2′*a* are provided for use with 220 volts.

The cathode-ray tube is shielded against external electrostatic and magnetic effects. The experimental synchroscope is shown in Fig. 7.

Calibration of Synchroscope

The calibration of the apparatus is done most easily by connecting terminals 1 and 1′ together, and terminals 2 and 2′ together, to one supply. Stationary pips or spot will thus appear, giving the exact positions for correct synchronization.

This procedure is also used when it is required to adjust the circuit elements to bring these positions of correct synchronization exactly on the Y axis.

Features of the New Synchroscope

1. Easy to make.
2. Easy to adjust and operate.
3. Cheap and durable.
4. More convenient; can be installed on the control desk.
5. Accuracy is the same as in normal synchroscopes, or better.
6. Not liable to errors, sticking, damage, etc.

The Cathode-Ray Automatic Synchronizer

The cathode-ray synchroscope is used when manual synchronizing of generators is desired. However where automatic synchronization is preferable, the cathode-ray automatic synchronizer will be found a simple and reliable gear.

The main parts of a cathode-ray automatic synchronizer are:

1. A cathode-ray synchroscope identical to that described previously and working on the rotating spot principle discussed before. The normal cathode-ray tube of the synchroscope is dispensed with, as it is replaced in the automatic synchronizer by a special tube. However, the normal cathode-ray tube may be used with the special tube, to serve as a visual monitor on the automatic synchronizer, or for manual synchronization when necessary.
2. A special cathode-ray tube, in which the beam current, as it traces the ellipse, is commutated by two electrodes replacing the screen of a normal tube. The idea of collecting a cathode-ray beam by such electrodes, instead of by the accelerating anode of the tube after having traced the desired phenomenon on the screen, was first suggested in 1938 by Colebrook,[1] who discussed a new principle for the generation of ultrashort waves, and since that time many devices have been suggested or utilized incorporating the same feature, but all were concerned with applications in the ultrashort wave field.

   The application of this principle in the field of electronic measuring instruments and apparatus was proposed by the author in 1947;[2] several new types of electronic measuring instruments were presented, some of which used cathode-ray commutation. The application of the cathode-ray commutation principle in this field did not remain a mere proposal, but has been successfully verified experimentally during the past few years in our university.
3. Normal electromagnetic relays, which are actuated by the commutating-electrode currents of the cathode-ray tube, and which in turn cause the operation of the synchronization circuit breaker.

General Principle

A cathode-ray tube of the commutating-electrode type is used. The tube has two commutating electrodes *A* and *B*, Fig. 8, replacing the fluorescent screen. Through the use of circuits similar to those associated with the cathode-ray synchroscope, deflection voltages derived from the bus bars are applied to the *X*- and *Y*-deflection plates, while the pulses derived from the incoming line are applied to the grid of the tube.

In the absence of the pulses, the beam will trace a circle (or an ellipse) every cycle, and will be intercepted by electrode *A*, which subtends a very small angle θ, during a very small part of the cycle. The time of interception is equal to $(\theta/2\pi)T$, T being the time period of a cycle.

For the operation of the tube as a synchronizer, the tube is biased beyond cutoff, the beam current in this case will be zero, and we can only imagine a beam with zero current tracing a circle.

When the pulses are applied, the negative pulse will have no effect, but the positive pulse (occurring once every cycle) will cause a current to flow, provided the pulse has a sufficient peak value. This current will be collected by either electrode *A* or *B*, depending on the instant in which the positive pulse occurs; and the duration of the current will depend on the pulse width.

Assuming that the bus bar and incoming voltages are in phase and of equal frequencies (which are the required conditions for correct synchronizing), the positive pulse will occur whenever the beam traces electrode *A*. Hence electrode *A* will receive all the pulse currents, while the current in electrode *B* is always zero. Use is made of the current in electrode *A* to operate a relay which will cause the synchronizing circuit breaker to close.

If the two voltages are of equal frequencies but of different phase angles and the phase difference is greater than $\pm(\theta/2)$, all the pulse currents will fall on electrode *B* (assuming a very narrow pulse width), while the current in electrode *A* will be zero; therefore the relay incorporated with its circuit will not operate.

However, the relay will operate if the phase difference is less than $(\theta/2)$, and this is always allowable if the angle θ is small, as the incoming machine will be

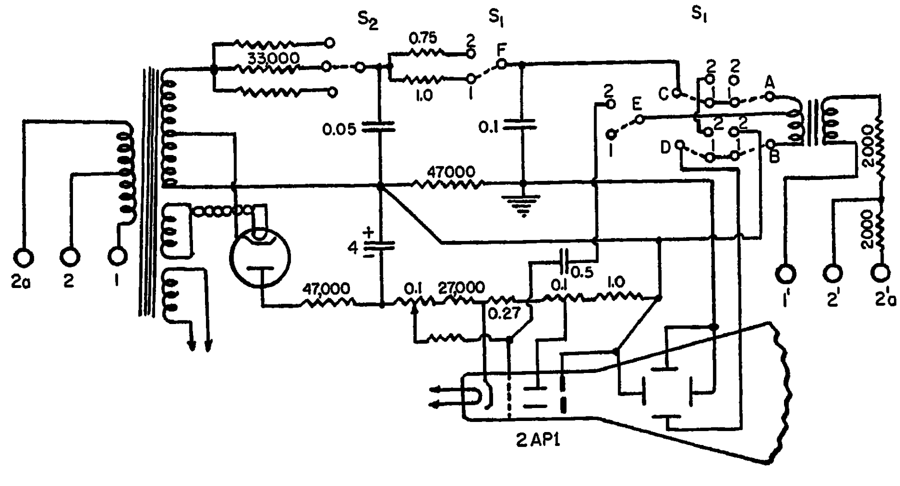

Figure 6. Connection diagram of experimental synchroscope (for demonstrations)

able to step into synchronism with the bus bars. It is therefore necessary that the angle θ should not be larger than what the synchronization conditions permit.

Now, if the two voltages are of different frequencies, the pulse will not occur when the beam is tracing a definite point of the circle, but the interception point will be moving forward or backward according to whether the frequency of the incoming voltage is smaller or larger. It will therefore be evident that only a few pulses fall on electrode A, while the majority will fall on electrode B. Bearing in mind that only one pulse occurs per cycle, the general shape of the currents in the electrodes will be as shown in Fig. 9.

Since it is required that the relay incorporated with the circuit of electrode A must not operate in this case, this relay must not be a quick-operating one, that is to say, it must not operate as it receives one pulse but will remain unoperated till it receives a second pulse following the first by a time interval equal to the period of a cycle. This will happen only if the frequencies are equal or different by a very small amount, such that every cycle the pulse position moves forward or backward by an angle less than θ.

Assuming the duration of the pulse to be negligibly small, it is evident that two (or more) consecutive pulses will be received by electrode A if the frequency difference (δ) is less than $[(\theta/2)/2\pi]f$, where f is the bus-bar frequency. If δ lies between $[(\theta/2)/2\pi]f$ and $(\theta/2)\pi f$, electrode A might receive one pulse or two consecutive pulses, according to the position of the first pulse on electrode A. For larger frequency differences only one pulse is received.

And it is always possible to effect synchronization when a small frequency difference exists (which case corresponds to the very slow motion of the pointer of an ordinary synchroscope), we can see that, also in this case, the angle θ has to be limited to correspond to the allowable frequency difference.

It is undesirable here that the pulse have a very narrow width, as the average current flowing in the relay must be of sufficient value to operate the relay. Also pulses of finite widths are more feasible in practice. In this case, the effect of two complete consecutive pulses will always be received by electrode A if δ is not greater than $[(\theta/2)/2\pi]f$. If δ lies between $[(\theta/2)/2\pi]f$ and $[(\theta-W)/2\pi]f$ (where W is the pulse width in radians), electrode A will receive the effect of two or less pulses according to the position of the first pulse on electrode A. For higher frequency differences, electrode A will never receive the effect of two pulses.

It is obvious that in all cases where electrode A receives two, or more, pulses, the two voltages, besides being of very nearly equal frequencies, are almost in phase at the time when the pulses are received, and hence the two necessary conditions for correct synchronization are both present.

The number of consecutive pulses received by electrode B (or missed by electrode A) will be $(f/\delta)\pm 1$ less the number of consecutive pulses received by electrode A.

Estimation of Electrode Angle θ

It has been mentioned that for values of the frequency difference δ between $[(\theta/2)/2\pi]f$ and $[(\theta-W)/2\pi]f$, the average current of electrode A will lie between the values corresponding to one or two pulses. This does not mean that the relay will not operate, but actually the relay will remain unoperated as long as it receives a current less than that of two consecutive pulses. As the phase angle between the incoming and bus-bar voltages is continuously varying, this state of affairs will continue until the incoming voltage phase angle corresponds to the favorable condition giving two consecutive pulses to electrode A. Therefore no positive operation of the relay is to be expected in this region, especially if we bear in mind that the time which elapses until the relay operates is not strictly related to the value of δ (although we can generally say that it will be smaller for smaller values of δ).

The fact that the relay is certain to operate when δ is less than $[(\theta/2)/2\pi]f$ suggests a suitable relation between W and θ which eliminates the inconvenient frequency difference range, and that is by making $[(\theta-W)/2\pi]f=[(\theta/2)/2\pi]f$, or $W=\theta/2$. In this case electrode A will

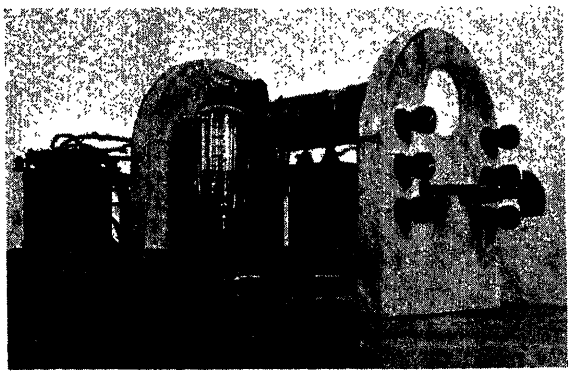

Figure 7 (left). The experimental cathode-ray synchroscope

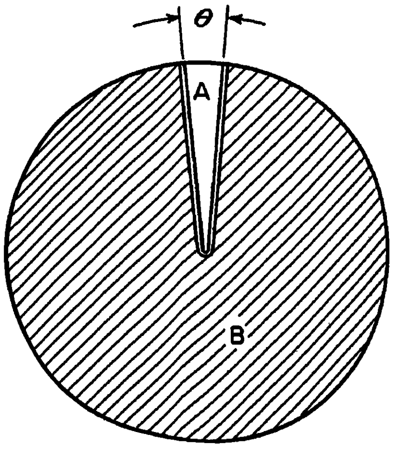

Figure 8 (right). Commutating electrodes of the special cathode-ray tube for the automatic synchronizer

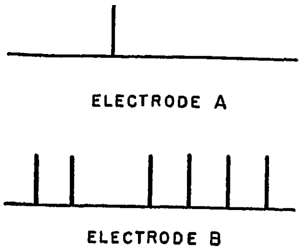

Figure 9. Commutating electrode currents

always receive two (or more) consecutive pulses when δ is less than $[(\theta/2)/2\pi]f$, and receives less than two pulses for larger values of δ.

The value of the angle θ will thus be given by: $\theta=(4\pi\delta)/f$ radians, where δ is the maximum allowable frequency difference for synchronization.

Pulse Width

In the foregoing we were confined to ideal pulses of rectangular shape. However, the operation of the relay is concerned mainly with the shape of the current of electrode A rather than with the shape of the pulse voltage applied to the grid of the tube. The shape of this current, besides being of course affected by the shape of the pulse voltage, is also affected by several other factors, such as the bias voltage, the beam-current/grid-voltage characteristic of the tube, the focusing of the beam, its diameter and electron distribution, the diameter of the circle traced by the beam, the edge effects when the beam traverses one electrode to the other, secondary emission effects, etc.

Perhaps the easiest method taking all such effects into consideration is to trace the actual shape of the electrode current with normal operating values of the different parameters. A rectangular pulse can then be drawn having the same peak value and the same area as the actual pulse, and the width of this rectangular pulse can be taken as the equivalent width of the actual pulse.

Sensitivity

If I_p is the peak electrode current produced by the pulse, and W is the pulse width in radians, then if two consecutive pulses are received by electrode A, the average current flowing in the relay will be given by

$$I_{av}=2\frac{W}{2\pi}I_p$$

The beam current of normal cathode-ray tubes is usually small, but electromagnetic relays of high sensitivity can be easily designed, especially if good-quality core materials are used. Also special cathode-ray guns may be used to give high beam currents.

The Relay

The relay should be of the slow-acting type, operating with a current equal to the average electrode current I_{av} just mentioned, and having an operating time lag slightly less than two periods of the cycle. It is connected to electrode A through a capacitance-resistance circuit of suitable time constant to give the average current of the two received pulses, and zero current during the interval of the missed pulses. An interval will certainly elapse between the reception of the pulses by the electrode and the closing of the circuit breaker, and it may be found necessary to readjust the phase-shifting circuit, described in "Adjustment of Correct Position of Pips," to compensate for this new factor.

Since the average current flowing through the relay winding is affected by many factors and is not expected to be constant, some difficulty may be encountered in the design and adjustment of the delay time of the relay. A better procedure is to use a quick-acting, slow-releasing relay, which will operate as the first pulse current flows through it, but will have a release time lag larger than the period of one cycle. If the relay receives two consecutive pulses, it will remain operated for a period longer than the period of two cycles. This relay, when operated, will close the circuit of a second relay which is energized from a constant voltage supply. This latter relay shall be a slow-acting one, with an operating time lag equal to about the period of two cycles, and thus will only operate if the first relay receives two successive pulses. The second relay will operate the synchronizing circuit breaker.

Focusing the Beam

For proper design and operation of the apparatus, the cathode-ray beam should be well focused by using predetermined voltages applied to the tube focusing and accelerating electrodes.

If it is desired to focus the beam visually, this can be effected by viewing the collecting electrodes, since the incidence of the focused beam is made visible by fluorescence on the electrode surfaces.

Another suggestion is to cut out a sector of electrode B, and cover the glass of the tube behind that sector with fluorescent material, as in ordinary cathode-ray tubes. The collecting electrodes and the screen fluorescent material are made as far as possible in the same plane. The beam can easily be focused as it traverses this sector.

Basic Circuit

The basic circuit for the proposed cathode-ray automatic synchronizer is shown in Fig. 10. It is identical to that of the cathode-ray synchroscope, Fig. 6, used with the rotating spot principle, with the commutating-electrode circuits added.

Resistance R_k added in the cathode circuit of the tube serves to produce some cathode feedback as in ordinary thermionic valves. This will give a more linear grid-voltage/beam-current characteristic and, moreover, will increase the stability of the circuit.

It is also necessary that the collecting electrodes should have a potential higher than that of the accelerating anode, otherwise the electrons impinging on one of the electrodes will cause secondary emission, and electrons will travel back to be collected by the accelerating anode or by the other collecting electrode, especially if we take into consideration the

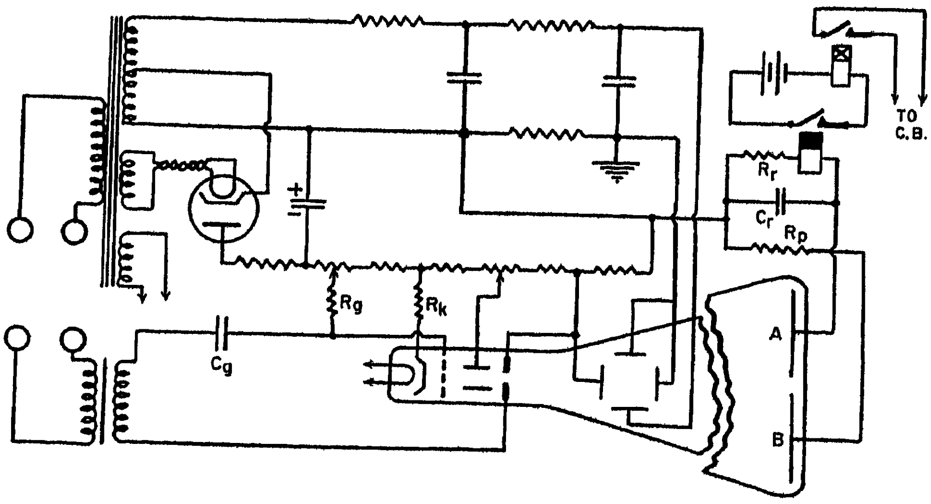

Figure 10. Basic circuit of cathode-ray automatic synchronizer

voltage drop in the circuit connected to the collecting electrodes.

Other methods to minimize secondary emission have also to be taken into consideration, among which we may mention the method adopted by Colebrook,[1] which uses electrodes in the form of buckets to prevent the escape of the secondary emission electrons from the interior electrode space. Again, the collecting-electrode material should be carefully chosen to cause as little secondary emission as possible.

Resistance R_p serves to make the circuits of the two electrodes nearly identical. Capacitor C_r acts as a by-pass to make the average current flow in the relay. The time constant of C_r and the relay circuit should be designed to the proper value. The resistance R_r may be dispensed with if the resistance of the relay is of sufficient value. It also helps to damp out any oscillations that may arise.

Conclusion

The developed synchroscope was tried out for the paralleling of the existing machines. It was found to work quite satisfactorily and to be quite convenient and reliable.

As regards the proposed automatic synchronizer, it has not been investigated experimentally, mainly because the cathode-ray tube is one of special construction and there is a lack of manufacturing equipment. However, since each of the various parts of the apparatus, and especially the cathode-ray tube with commutating electrodes, has been experimented with separately in one form or the other, there is every reason to believe that such an apparatus could be properly designed and constructed, and that good results could be achieved in practice with it.

Discussion

William J. Kassimir (Atlantic Refining Company, Philadelphia, Pa.): The purpose of this discussion is to present other methods and procedures for accomplishing the objectives of Dr. Ahmed's paper, in a simpler manner and with apparatus that is commercially available and in no way special.

CATHODE-RAY SYNCHROSCOPE

The methods given here are those that I have been using for a number of years for setting the governors on small rotary d-c a-c converters and for setting the control rheostats on vibrator type d-c a-c converters. Both types of converters are energized from a d-c source and are used to supply 60 cycles to chart drive motor circuits on shipboard.

The converters were adjusted to 60 cycles by comparing their output with the 60 cycles supplied by the local power company using a cathode-ray oscilloscope for comparison. In this operation we were concerned only with the frequency and not phase-angle difference, but the methods discussed here take care of the phase angles as well.

In our operation we used a commercially available oscilloscope which was equipped with the usual input terminals including a test signal output terminal and sync signal input terminal.

There are numerous methods for using a cathode-ray oscilloscope for comparing frequencies and phase angles. Two simple methods are presented here:

1. The power supply of the oscilloscope is connected to the bus voltage. The test signal terminal, which is connected to the 6.3-volt secondary of the power transformer, is connected to the vertical input and to the sync signal input. The other controls on the oscilloscope are then adjusted to give a single stationary sine wave on the screen. For convenience and for reference purposes, let us assume that the wave is set up in such a way that the positive half-cycle is on the left of the vertical axis and the 180-degree zero-voltage-point goes through the zero-zero point of the co-ordinate graph on the screen.

The test signal is now disconnected from the vertical input terminal but still left connected to the sync signal input terminal. With this latter connection the horizontal sweep is synchronized with the frequency of the power supply.

The incoming generator output is now connected to the vertical input terminals of the oscilloscope and its wave form will appear on the screen. If its frequency is exactly the same as the bus frequency it will appear stationary on the screen by virtue of the fact that the horizontal sweep is synchronized with the bus frequency. If the frequency of the incoming machine is higher than the bus frequency, the sine wave will appear to move from right to left, and if the frequency of the incoming machine is lower than the bus frequency, the sine wave will appear to move from left to right.

The frequency and phase angle of the incoming machine will be correct, for closing the paralleling circuit breaker, when the sine wave on the screen is stationary and occupies the identical position of the sine wave that was initially put on the oscilloscope from the test signal terminal, that is, the positive half-cycle on the left and the 180-degree zero-voltage-point coincident with the zero-zero point on the co-ordinate graph on the screen.

The use of a manually operated switch may be desirable so that the voltage of either the bus or the incoming machine may readily be connected to the vertical input of the oscilloscope and hence provide a ready comparison of the two frequencies and phase angles.

2. Perhaps the most desirable method of comparing the equality of two frequencies and phase angles is to replace the aforementioned manual switch with a commercially available electronic switch. With this device, the sine waves of both the bus and incoming machine may be observed simultaneously on the screen. Any difference in frequency or phase angle is readily apparent. It is desirable but not absolutely necessary to lock in the horizontal sweep frequency with the bus voltage and hence make the bus sine wave stationary on the screen.

Exact equality of the two frequencies is obtained when the relative velocity between the two is zero. Both can be moving in the same direction at the same velocity when the two frequencies are equal. Since the two sine waves appear simultaneously, the phase-angle difference between the two is readily apparent.

By means of a control on the electronic switch, the two sine waves can be brought into exact overlapping alignment or may be displaced vertically from each other. The user may choose any degree of vertical displacement that he desires for comparing the equality of the two frequencies and phase angles.

This latter method, I believe, will appeal to most operators of generating stations because they are familiar with the appearance of an a-c sine wave and it will be easier for them to comprehend exactly what they are trying to accomplish. The use of a circular trace with a pip will not be understood easily by the average station operator unless he has had a course in electronics, without which he would be reduced to a mere automaton.

Another advantage of showing the two wave forms on the screen simultaneously is that the magnitude of the two voltages may be approximately compared. However, for this purpose the switchboard voltmeter will give a more accurate comparison of the two voltages.

AUTOMATIC SYNCHRONIZER

Dr. Ahmed describes a cathode-ray automatic synchronizer in which he uses a special cathode-ray tube with two so-called commutating electrodes. I leave out the word "cathode-ray" because I believe that the same results can be accomplished without a special cathode-ray tube, using only standard electronic parts.

Fig. 1 of the discussion shows a simplified functional diagram of my proposal. The circuit is intended to operate as follows: The plate of the triode receives power from the bus while the grid is connected to the incoming generator. With suitable grid bias the plate current through the relay can be held below the relay operating point until such time as plate and grid are both on their positive half-cycles, with sufficient current will flow through the relay to

PULSE SHAPING CIRCUIT OR DEVICE
TRIODE
INCOMING GENERATOR
BUS

Fig. 1. Functional diagram of circuit used to provide relay operation when two separate a-c sources are in phase with each other

enable it to pull in. Hence, the necessary in-phase relationship is established, because when the two power sources are not in phase the relay will not pull in, owing to insufficient current.

So that the two power sources may be in phase within the allowable small-error angle, pulse-shaping circuits or devices are installed in each supply so that narrow pulses are obtained. If desired, saturable transformers, as described by Dr. Ahmed, may be used, or pulse shaping electronic circuits can be provided. If necessary, phase-shifting circuits can be incorporated.

Regarding the control relay, Dr. Ahmed's system of using fast- and slow-acting relays may be used, or a single relay may be employed, controlled from a pulse-dividing circuit so that several in-phase pulses may be received before the relay closes.

M. Abdel-Halim Ahmed: I agree with Mr. Kassimir that the methods he presented in the first part of his discussion are possible means for affecting synchronization. In fact, they represent two of the many basic methods of using a cathode-ray oscilloscope for the comparison of two sine waves, to which I may add a simpler method. This involves the application of one of the waves to the horizontal deflection plates of the oscilloscope tube, and the other to the vertical deflection plates. The trace will generally be an ellipse of varying shape. When the two waves are exactly of the same frequency and phase, the ellipse reduces to a straight line extending in the first and third quadrants.

The synchroscope presented in the first part of the paper is, however, another possible new means which has its own merits. I believe it is simpler than Mr. Kassimir's two methods, as it uses much simpler and far less expensive apparatus, all the components of which are commercially available. In the meantime, it gives a much simpler trace which is more convenient for observation and more comfortable for the operator, who is certainly familiar with viewing the rotating pointer of an ordinary synchroscope. The adjustment of the sharp rotating pips or spot is definitely more accurate, and the fact that the circular trace is much longer than the horizontal sweep adds to the better accuracy.

I do not agree with Mr. Kassimir that the operator should have a course in electronics before attempting to make use of the rotating pips or spot. On the contrary, this course is more necessary for an operator working with the whole bulk of equipment used in Mr. Kassimir's methods.

There is little to be said about the automatic synchronizer which Mr. Kassimir proposes in the second part of his discussion, as it actually works on the same principles involved in the automatic synchronizer presented in the second part of the paper, and entails all the main items in the latter. The difference lies mainly in the replacement of the commutating-electrode-type cathode-ray tube with an electronic tube, in view of the latter nowadays being commercially available. The paper presents a possible way for development, and in this respect I may mention that cathode-ray tubes similar to the commutating type that I have introduced are now commercially available in many forms for some other special purposes (for example, the ultrahigh frequency deflection tubes, the switch valves, the counter valves, etc). The new type of tube differs mainly in the collecting-electrode structure and therefore there will be no difficulty in developing such a tube. Moreover, this tube has many other applications in which it exhibits unique features. Such a wide scope of applications would justify the manufacture of such a tube.

A point that should be stressed is that the pulse generating device connected to the triode plate must deliver a relatively large instantaneous power during the pulse period, and its characteristics will not be identical with those of the one connected to the grid. It is therefore imperative that provision be made for correcting the discrepancy.

An Instability of Self-Saturating Magnetic Amplifiers Using Rectangular Loop Core Materials

S. B. BATDORF
NONMEMBER AIEE

W. N. JOHNSON
ASSOCIATE MEMBER AIEE

ACCORDING to the simple approximate magnetic amplifier theory, a plot of the average output current against the control current of a self-saturating magnetic amplifier has the shape of the left-hand portion of the hysteresis loop of the core material. Maximum amplification thus calls for the use of a core material having a rectangular hysteresis loop.

The use of rectangular loop core material increases the gain, but gives rise to an unanticipated operating instability sometimes referred to as "triggering." While the load current can be reduced smoothly from its maximum value by suitable adjustment of the control current, once having reached minimum value the load current cannot be increased again smoothly but jumps suddenly to a rather large value, as indicated in Figure 1.

This effect was noted by F. S. Malick in 1950 in an unpublished paper and attributed by him to any of three causes: an improper amount of positive feedback, an inductive load, or the use of rectangular hysteresis loop core material. The mechanism given for the instability when caused by the core material depended upon the difference between a minor and the major hysteresis loop; thus a given value of control current could result in either of two different output currents, depending on whether the material was operating on a minor or major hysteresis loop. The precise nature of the difference between minor and major hysteresis loops was not elaborated in detail, and appears in fact not to have been widely understood for rectangular loop material at the time the writing of this paper was undertaken. Because of this and be-

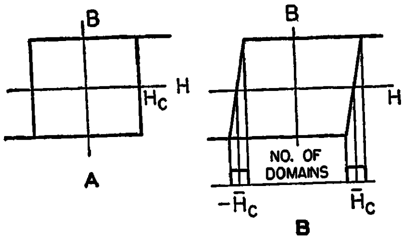
Paper 53-18, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19-23, 1953. Manuscript submitted September 5, 1952; made available for printing November 6, 1952.

S. B. Batdorf and W. N. Johnson are with the Westinghouse Research Laboratories, East Pittsburgh, Pa.



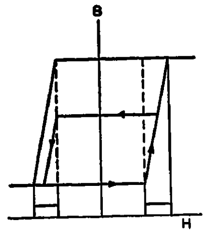


Figure 2 (left). B-H characteristics for three idealized models of a rectangular hysteresis loop material

Figure 3 (right). Magnetic behavior of idealized core material

cause a number of other phenomena such as leakage of rectifiers and eddy currents might be expected to influence triggering, the role of the core material in triggering remained in doubt.

The present investigation was undertaken to clarify the role of the core material. Representative cores were subjected to d-c measurements while being cycled in a manner similar to that occurring in magnetic amplifier operation. Later flux density–field intensity (B-H) traces were made continuously on the Cioffi recording fluxmeter.[1]

It was found that the behavior of rectangular loop core material is such that triggering will occur when it is used in a typical self-saturating magnetic amplifier circuit even if all other circuit elements behave ideally. Although triggering will, of course, be influenced by departures from ideal behavior on the part of other circuit elements, the present paper neglects these secondary effects and concentrates attention on the fundamental aspect of the phenomenon.

Theory

In rough approximation, a rectangular hysteresis loop material behaves as though it consisted of a large number of independent domains, each oriented either parallel or antiparallel to the magnetic field. If in such a material all domains had the same coercive force, the hysteresis loop would have vertical sides as shown in Figure 2(A). (It is here assumed that each domain flips from antiparallel to parallel alignment with the magnetic field at a fixed value of coercive force.) If there were a spread in coercive force about the average value H_c such that equal numbers of domains had their coercive force within equal increments of field strength H, the hysteresis loop would have sloping sides and sharp corners as in Figure 2(B). If the spread in coercive force followed the error frequency distribution, the hysteresis loop would have sloping sides and rounded corners as in Figure 2(C). The lower parts of Figures 2(B) and 2(C) show the number of domains as a function of the coercive force H_c. In the following analysis, the simple model shown in Figure 2(B) will be used, not with the thought that it represents accurately the physical phenomena concerned, but simply because it affords a convenient basis for a phenomenological formulation of the B-H relations of the material.

If a material of the type shown in Figure 2(B) is brought from negative saturation to some value of flux short of positive saturation and then returned to negative saturation, the hysteresis loop will be as shown in Figure 3. While the field is increasing, the material will follow the external hysteresis loop. Upon reversal of the field, the magnetic induction remains constant until the negative field attains a value corresponding to the lowest coercive force. Further increase of the field in the negative direction reverses the magnetization of the domains; this process continues until negative saturation is reached.

Consider next a core of such material in a half-wave self-saturating magnetic amplifier circuit of the type shown in Figure 4. The d-c control current provides a constant bias field (the choke is assumed to eliminate all feed back from the a-c circuit). If the bias current is in the negative saturation region, as at point a of Figure 5, the applied voltage will appear entirely across the load until point b is reached. From b to c most of the voltage appears across the inductance, till at point c the current-resistance drop in the load becomes equal to the applied voltage, which is decreasing at this point. From c to d the voltage again appears entirely across the load, and from d to e it is once more mainly across the inductance. From e until the end of the cycle the voltage is across the rectifier. The current in the load is shown in the lower half of Figure 5. The same sort of behavior, with negative saturation occurring during part of the cycle, will characterize any operating point a to the left of point e of Figure 5.

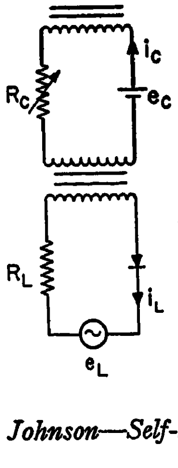

Figure 4 (left). Half-wave magnetic amplifier circuit

Consider next an operating point a', Figure 6, to the right of point e, starting again with a negatively saturated core. The cycle proceeds in the same manner as before except that at the end the material does not return to negative saturation but experiences a net gain in induction $a'f$, see Figure 6(A). During this and each succeeding cycle, the change in induction during the positive half of the cycle is given by the equation

$$(\Delta\phi)^+ = \frac{1}{N}\int_0^{\frac{T}{2}} (e_L - i_L R_L)\,dt$$

unless the occurrence of positive saturation prevents an increase of this magnitude. The decrease in induction during the negative half-cycle would be given by the same expression were it not limited by the fact that the presence of the rectifier prevents the field from dropping below that provided by the bias current. For the material under consideration both $(\Delta\phi)^+$ and $(\Delta\phi)^-$ remain substantially unchanged in successive cycles, so that in each cycle there is a net increase in induction

$$\Delta\phi = (\Delta\phi)^+ - (\Delta\phi)^-$$

Thus, after n cycles the core material will reach positive saturation where

$$n \cong \frac{\phi_s - \phi_c}{\Delta\phi}$$

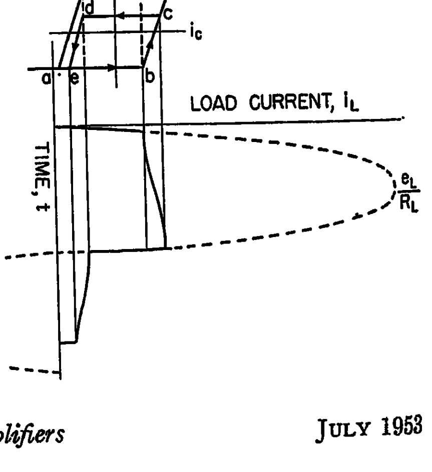

Figure 5. (right). Load current in half-wave amplifier when control current produces negative saturation

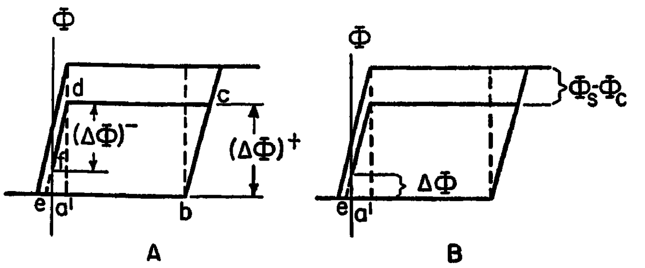

Figure 6. First cycle of ratcheting

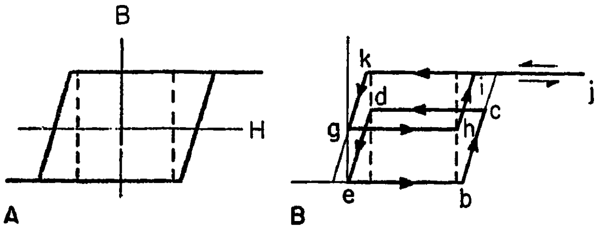

Figure 8. Magnetic characteristic resulting in ratcheting followed by triggering

see Figure 6(B). This situation may be summarized briefly by stating that as the bias current passes to the right of point *e*, Figure 6(A), the operating loop of the core material ratchets up to positive saturation. The final operating loop and the associated load current for the bias indicated in Figure 6 are shown in Figure 7. The sudden increase in load current from the value required to saturate the core to the value e_L/R_L corresponds to the firing of the amplifier. Firing does not occur when the bias is at point *e* even after ratcheting up to saturation because in the final loop saturation only occurs near the end of the cycle when e_L/R_L is equal to the saturation current for the core. Consequently, no discontinuity in the transfer characteristic is associated with the ratcheting, which normally occurs at the bias point *e;* that is to say, the ideal core material under consideration will not trigger in an ideal circuit after the fashion illustrated in Figure 1.

Now experimental evidence, to be discussed more fully later, indicates that a larger field is required to start reversal of magnetization when the core is initially saturated than when it is not. This suggests that the independent domain model employed up to this point should be amended to allow a small interaction resulting in nucleation phenomena. When the material is saturated there are no oppositely oriented domains present to nucleate reversal of magnetization, so that a larger field is required for this purpose than would be required for unsaturated material. Under these circumstances, the upper left-hand corners of all minor loops will be in a vertical line, shown dotted in Figure 8(A), while the upper left-hand corner of the major loop will be displaced to the left of this line. The bias required to start upward ratcheting in a material of this type will be such that when the ratcheting is complete, positive saturation will be reached early enough in the positive half-cycle of the supply voltage so that an appreciable voltage will appear across the load. This will be evident from a study of Figure 8(B). This figure shows the first cycle (*ebcde*) of the ratcheting operation as well as the final operating loop (*ghijkg*). In Figure 9, the hysteresis loop and the transfer characteristic are plotted with a common abscissa, to show the relationship between position of operating loop and output.

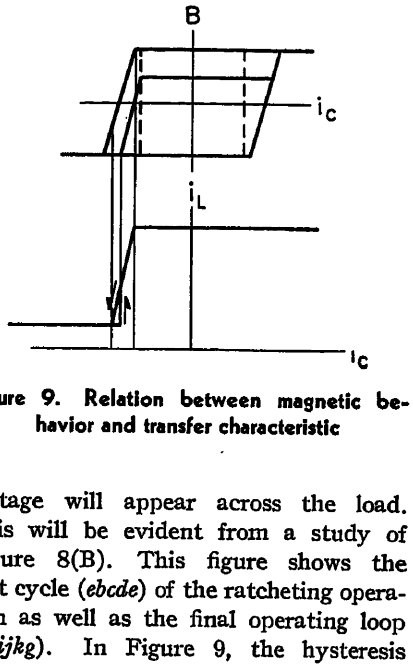

Figure 9. Relation between magnetic behavior and transfer characteristic

Before discussing the experimental part of this investigation, another result of the theory outlined should be mentioned which does not play an essential role in triggering, but can be seen in the data and serves to corroborate some aspects of the theory just outlined. The effect shows up as a peculiarity in the intermediate loops encountered in the upward ratcheting process.

Consider the changes in orientation of the domains during the first 2 cycles of ratcheting. In the first cycle, the material remains in a state of negative saturation in passing from *a* to *b*, Figure 10(A). At point *c*, half the domains are pointing one way, and half the other, those positively oriented being those of lowest coercive force as indicated in the figure. At the end of the cycle, point *f*, the domains are divided into three groups, those of low and high coercive force being negatively oriented and those of intermediate coercive force being positively oriented.

In the second cycle, Figure 10(B), the low coercive force negatively oriented domains are reversed in going from *g* to *h*. The next set of domains are already positively oriented, so no change in induction occurs as the field increases until point *i* is reached on the external hysteresis loop. The external loop is followed until the proper value of $(\Delta\phi)^+$ is attained at *j*, and the field is again reversed. It turns out that the maximum value of induction occurring in a given cycle determines the location of the horizontal portion of the right leg of the hysteresis loop associated with the succeeding cycle. This horizontal portion stretches from the minor to the major loop as shown in the figure.

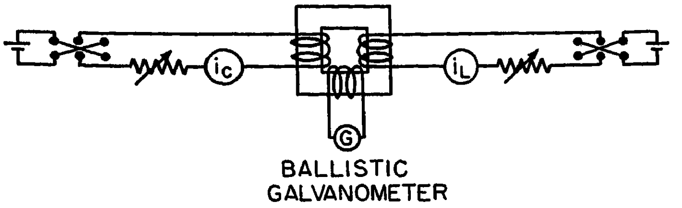

Figure 11 (above). Circuit used to measure magnetic characteristics of core

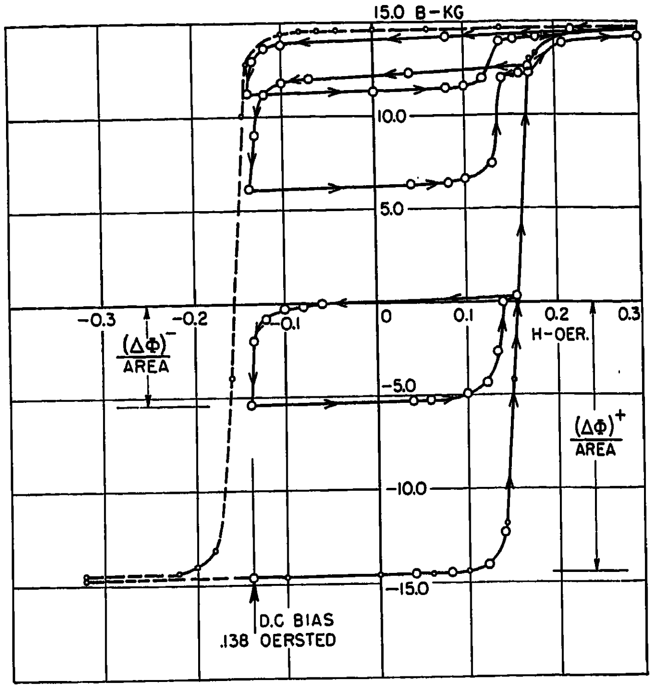

Figure 12 (right). D-c triggering of Hipernik V magnetic amplifier core 3/4 inch by 1 inch by 1/4 inch

Experimental Procedure and Results

The characteristics of several toroidal cores were investigated using the circuit of Figure 11. First, the major hysteresis loop was determined using conventional d-c test procedures involving the ballistic galvanometer.[2] Then after choosing an appropriate bias current i_c, a change of flux $(\Delta\phi)^+$ was obtained by introducing a current i_L into the load circuit in several increments. After thus simulating the rise to maximum current in the self-saturating magnetic amplifier, i_L was reduced to zero in increments in order to complete the cycle. An attempt was made to keep $(\Delta\phi)^+$ constant in successive cycles, but this was done only approximately because it involved guessing the appropriate value of i_L each time.

The ratcheting of Hipernik V is shown in Figure 12. The dashed curve gives the major hysteresis loop. The B-H history during the ratcheting is shown by the solid curves for the case of a bias field of 0.138 oersted. The experimental results exhibit the main features discussed in connection with the theory: the upper left-hand corners of all minor loops lie approximately along one vertical line and the lower right-hand corners of minor loops lie along another; $(\Delta\phi)^-$ is substantially constant in successive cycles except when saturation is reached; and the right-hand sides of minor hysteresis loops have a nearly horizontal portion at the highest value of induction encountered in the previous cycle. In accordance with the theory, there is a slight horizontal deviation between the upper left-hand corner of the major loop and the vertical line joining the upper left-hand corners of the minor loops. This can only be detected upon rather close inspection, but the associated fact that $(\Delta\phi)^-$ after reaching saturation is smaller than $(\Delta\phi)^-$ for minor loops is very evident.

Results for Hipersil and Hipernik cores are shown in Figures 13 and 14 respectively. The Hipersil loop is slightly less rectangular than that of Hipernik V, but has the same general characteristics. Both Hipernik V and Hipersil would be expected to ratchet upward and produce a discontinuity in transfer haracteristic when employed in a self-turating magnetic amplifier, and experi-

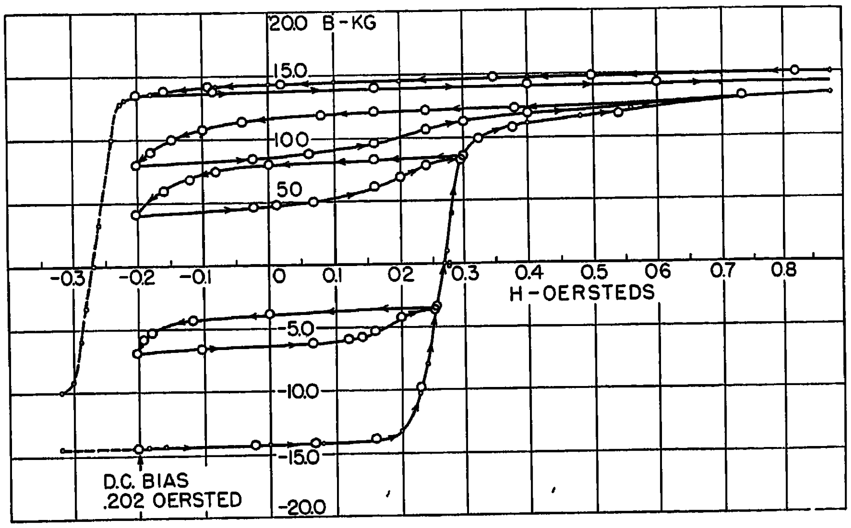

Figure 13 (above). D-c triggering of a Hipersil magnetic amplifier core 3/4 inch by $1\frac{1}{8}$ inches by 1/4 inch

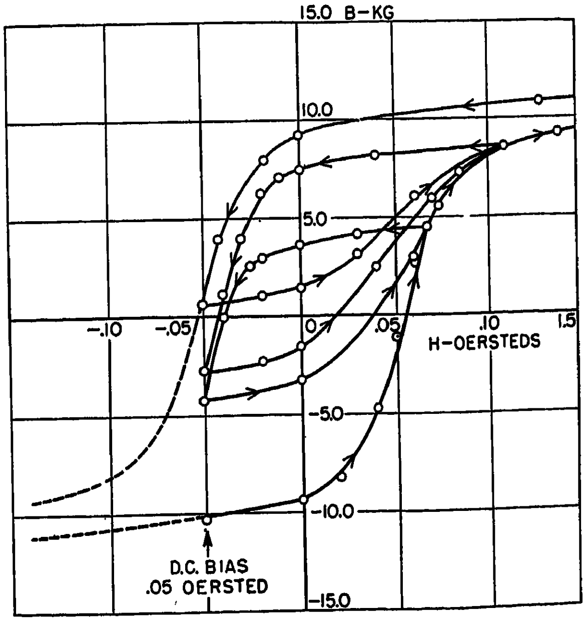

Figure 14 (right). D-c triggering procedure as applied to 0.002 inch Hipernik magnetic amplifier core 3/4 inch by 1 inch by 1/4 inch

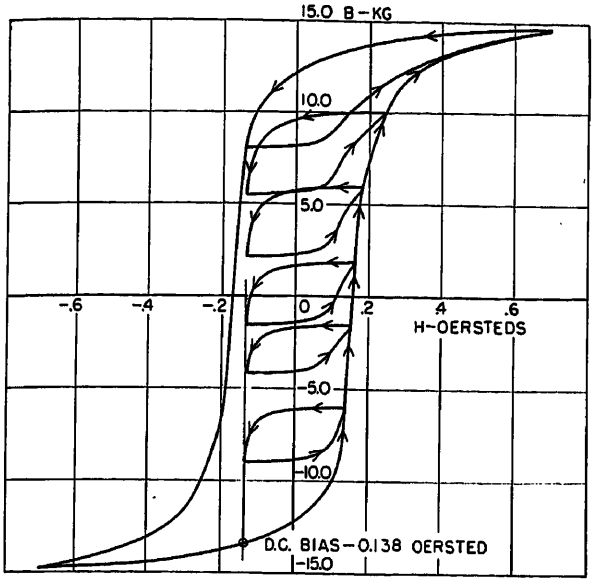

Figure 15 (left). D-c triggering procedure applied to a nonrectangular loop core material

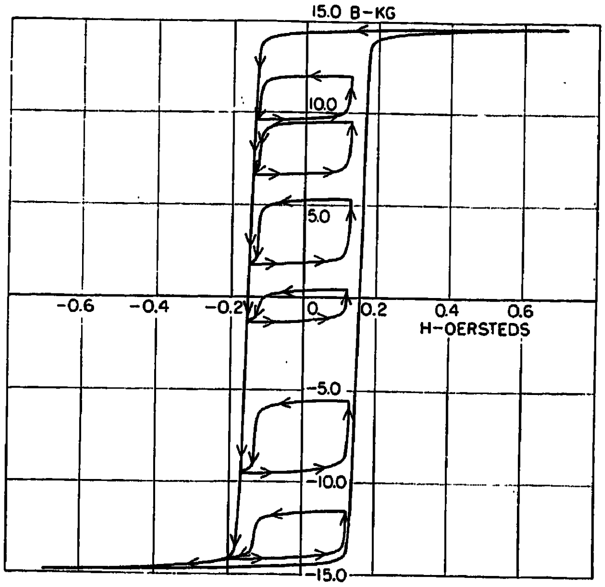

Figure 16 (right). D-c triggering procedure applied to a Hipernik V magnetic amplifier 3/4 inch by 1 inch by 1/4 inch core in downward direction

ment confirms this result. The Hipernik loop is less rectangular than the other two and departs rather widely from the theory outlined. In particular, $(\Delta\phi)^-$ after reaching saturation is substantially the same as $(\Delta\phi)^-$ for interior loops. Accordingly, it would be expected to trigger weakly or not at all in a magnetic amplifier with ideal circuit elements. Experimentally it was found to trigger weakly.

Figure 15 shows similar experimental results for a nonrectangular loop core material. It is seen that $(\Delta\phi)^-$ keeps increasing as the operating loop rises, so that ratcheting to the top would not occur with this material, and there should be no discontinuity in the transfer characteristic. Experimentally, it was found that this core does not trigger.

Figure 16 shows a simulation of the cycling of a magnetic amplifier core during the return to negative saturation. It appears from this diagram that ratcheting downward should not occur. This may be regarded as a consequence of the horizontal portion on the left-hand side of each interior hysteresis loop, the existence of which can be explained in a manner similar to that for the horizontal portions during upward ratcheting. It can be shown that if such horizontal portions did not occur the material would ratchet down to negative saturation at the lowest bias which would prevent positive saturation. Experimentally a weak downward trigger is sometimes noted. The data of Figure 16 make it appear probable that nonideal behavior on the part of other elements in the magnetic amplifier circuit is responsible for such triggering.

The loop shown in Figures 15 and 16 were traced out using the recording fluxmeter developed by P. P. Cioffi.

Summary

On the basis of experimental data a simple phenomenological theory was developed to account for the B-H characteristics of rectangular hysteresis loop core material such as Hipernik V. It was shown theoretically that cores with such magnetic characteristics lead to triggering of self-saturating magnetic amplifiers. This conclusion was verified experimentally in the absence of secondary effects such as feedback, eddy currents, rectifier leakage, and so forth, by subjecting the core to magnetomotive force cycling simulating that encountered in the magnetic amplifier and measuring the resulting changes in magnetic induction. It was also verified by direct check that in a magnetic amplifier cores expected on the basis of theory to trigger actually do trigger and conversely.

Discussion

D. C. Dieterly (Armco Steel Corporation, Middletown, Ohio): We who are interested in the magnetics art, or in magnetic materials, are grateful to the authors for discussing the way cyclic magnetization takes place with the types of minor loops of interest in magnetic amplifier applications. However, it seems to me that the authors' illustrations do not show clear-cut evidence of the type of phenomenon commonly called triggering in a magnetic amplifier, even though I am quite sure from my own experience that characteristics like that shown in Figure 12 of the paper would trigger under many normal operating conditions.

When one attempts to compare the d-c data shown in the authors' illustrations with a-c minor loops in a magnetic amplifier circuit, the comparison becomes difficult because of differences in ΔB amplitudes. Minor loops of such small ΔB amplitudes would hardly be employed in most magnetic amplifier applications. Commonly the voltage impressed across a half-wave element of a self-saturating magnetic amplifier will be such as to produce a ΔB amplitude practically between the positive and negative knees of the normal magnetization curve. If the authors had allowed their ΔH amplitudes to be slightly higher (as they would have been in normal a-c excitation in a typical magnetic amplifier circuit), instead of arbitrarily limiting them to a value sufficient to produce a ΔB amplitude only a fraction of that in a normal magnetic amplifier core, the cores would not have ratcheted through several cycles to arrive at the new stable minor loop condition for that bias value. The final minor loop in Figures 12 through 16 apparently was the stable loop for the bias shown, and under such restrictive ΔH and corresponding ΔB conditions the magnetization could hardly have progressed from the initial state to the final state except through several cycles of ratcheting, as shown.

It also occurs to me that the authors' illustrations might be misinterpreted by their readers, in light of the theory presented, because of failure to take into account the effect of shape parameters on the resultant loop. As an example consider Figure 12, which shows that as cyclic reversals are made on the normal loop and the flux changes from the negative saturation region to the positive saturation region upon the application of positive values of magnetizing force H, the induction B begins its upward swing at a magnetizing force of about 0.100 oersted, reaches a fairly linear region of flux change (where dB/dH is a maximum) at about 0.135 oersted, breaks away from this linear region at about 0.178 oersted, and levels off into the saturated region at about 0.220 oersted. Yet it must be remembered that the abscissas are values of magnetizing force H calculated from current flowing in the magnetizing winding and expressed in terms of oersteds prevailing along the mean path length l, which in most cases, is taken as the algebraic mean of the maximum and minimum path lengths in a ring shaped core. But in the core dimensions used by the authors the corresponding H_i prevailing along the inside periphery l_i (the minimum path length) is 1.17 H and at the same time the H_o prevailing along the outside periphery l_o (the maximum path length) is only 0.875 H. If we calculate the values of H_i and H_o corresponding to the H values previously mentioned as having been taken from Figure 12, we get the following:

	H_i	H	H_o
B starts upswing at	0.117	0.100	0.088
dB/dH curve quite high at	0.158	0.135	0.118
middle of high dB/dH range	0.182	0.156	0.137
end of high dB/dH range	0.208	0.178	0.156
B levels off at	0.257	0.220	0.192

These data indicate that the noticeable upswing in B occurs at $H=0.100$ oersted probably because the corresponding value of $H_i=0.117$ oersted is barely sufficient to cause significant numbers of domains along the inside periphery of the core to reverse their direction of magnetization. When the value of H reaches 0.135 oersted, H_i is 0.158 oersted (apparently a value where large numbers of domains along l_i reverse almost simultaneously) and H_o is 0.118 oersted (where significant numbers of domains along l_o will just begin to reverse magnetization). Then, when the value of H reaches 0.156 oersted, domains along the mean path l are reversing at the maximum rate, while only a few higher energy domains are being reversed by the corresponding value of $H_i=0.182$ oersted at the inside periphery and while significant numbers of low energy domains are being reversed along l_o where the value of H_o is 0.137 oersted. Further increase of H, along mean path length l, to 0.178 oersted has caused reversal of all except a few reluctant domains along that path; but along the inside periphery l_i where the magnetizing force is 0.208 oersted the domain reversals are negligible in number, yet at the outside periphery the magnetizing force H_o of 0.156 oersted is producing domain reversals at the maximum rate. When the magnetizing current increases to a value corresponding to an H of 0.220 oersted along the mean path, the value of $H_i=0.257$ oersted is sufficient to carry the inside periphery into the saturated region where further increase in total flux can be accomplished only by realignment of domains along a path closer to the direction of the applied field than was accomplished by mere domain reversals. At this same value of current the value of H_o is 0.192 oersted, a value which appears high enough that no appreciable contribution to the total flux is now being made by domain reversals at the outside periphery.

Such analysis indicates that practically none of the domains of this material have coercive forces less than 0.120 oersted and practically none higher than 0.190 oersted, and that substantially all of the domains reverse at coercive forces extremely close to 0.155 oersted. Actually the material of this core must have had extremely rectangular characteristics. The seemingly linear slope shown between 0.135 oersted and 0.178 oersted in Figure 12 appears to be due solely to the fact that l_o was 33 per cent longer than l_i, so that between these values of H (along path l) the maximum domain reversals begin at the inside periphery of the core and progress to the outside periphery as the true H along any path reaches about 0.155 oersted. If the outside-diameter–inside-diameter ratio of this core had been nearer 1.00, such a core of this material would have had a higher maximum dB/dH than in Figure 12; and in a core of larger outside-diameter–inside-diameter ratio than used here would have had a loop still more sheared than in Figure 12. Then too, if the outside-diameter–inside-diameter ratio of this core had been considerably closer to 1.00, most of the horizontal part at the upper right-hand corners of the intermediate minor loops would have disappeared.

It is true that there is some connection between extreme rectangularity of d-c hysteresis characteristics and the likelihood of triggering trouble in a magnetic-amplifier, but even the most rectangular material characteristics will not trigger if certain circuit characteristics are present which affect the a-c loop characteristics in such a way as to minimize triggering. On the other hand, I have noted cases of cores which trigger upward and downward and yet do not have highly rectangular d-c loops, and which by the authors' d-c techniques would not be suspected of triggering. Whether a core triggers or not depends primarily on its a-c loop characteristics under operating conditions.

There is much yet to be learned about the factors which contribute to triggering, but it is my opinion these factors may be more effectively studied by a-c test procedures. Carefully made d-c test data, such as Mr. Batdorf and Mr. Johnson have presented in this paper, combined with a-c loop data, both made under normal operating conditions and with due consideration of the effect of shape parameters on the magnetization process, should be helpful in getting a better understanding of triggering. It is to be hoped that these authors, or some other research group, will conduct further investigations of this phenomenon and contribute more of such data to the literature.

S. B. Batdorf and W. N. Johnson: The authors would like to comment on three points raised by Mr. Dieterly. The first of these relates to the magnitude of ΔB used in our experiments. In an initial exploratory study of triggering, the phenomenon appeared to be absent if ΔB was made equal or almost equal to $2B_s$, but was present for smaller values of ΔB no matter how small this might become. The ΔB used in the investigation was therefore chosen for convenience, without reference to whether it was representative of values normally used in amplifier operation. So far as the number of cycles of ratcheting is concerned, however, this is not very directly related to the size of ΔB. In fact, we have many times observed an upward ratchet take more than 5 seconds from start to finish at 60 cycles.

The second point raised by Mr. Dieterly is a suggestion that the steepness of the static hysteresis loop is intimately related to the ratio of external to internal diameter of the core. This we believe to be the case; we made no point of it in the paper, however, because we were not prepared to elucidate this relationship fully.

The third point is Mr. Dieterly's opinion that the factors which contribute to triggering may be more effectively studied by a-c than d-c test procedures. This is really a question of philosophy of research. Our belief is that to arrive at a fundamental under standing of what is going on in triggering as opposed to a quick "fix," it is desirable to separate the factors involved. The d-c test data, as we noted in the paper, permitted a study of the core behavior in a half-wave amplifier divorced from the complicating effects of eddy currents, leakage of rectifiers, inadequate voltage regulation, feedback to the control circuit, and so forth. Such a study will, of course, be an incomplete account of the behavior of the magnetic amplifier until it is supplemented with studies of the effects which have been neglected; however, the principle of separating effects for individual study we believe to be generally sound, and in many cases indispensable for real progress.

The Influence of a Transverse Magnetic Field on an Unconfined Glow Discharge

W. D. McBEE
ASSOCIATE MEMBER AIEE

W. G. DOW
FELLOW AIEE

A 3-KW unconfined glow discharge in air at pressures from 0.3 to 10 millimeters of mercury has been observed in the presence of transverse magnetic flux densities from 0 to 7,000 gausses. Effects observed as the magnetic flux density is increased include:

1. The voltages of the positive column and the anode fall space exhibit very pronounced increases, the former by a factor of at least 100 between zero magnetic field and 6,000 gausses; see Figure 6.
2. The cathode fall of potential exhibits an initial rapid decrease, then a levelling off; in combination with item 1 this results in a minimum value of total discharge potential at an intermediate magnetic flux density; see Figure 6.
3. A transverse wind, directed according to the motor rule, is generated by the positive column plasma; see Figure 4.
4. The equipotentials become skewed, passing diagonally through the discharge; see Figure 5.
5. Cathode fall space phenomena, including the negative glow and the Crookes and Faraday dark spaces, become very much compressed; see Figure 2.
6. The positive column and the anode regions become much more luminous because of their greatly increased gradients; see Figure 2.
7. The sputtering rate increases greatly.
8. Random potential fluctuations, see Figure 7, increase in amplitude, and their characteristic frequency first increases, then decreases.
9. Movement of cathode fall electrons parallel to the magnetic field produces a sharply delimited hollow shell of discharge resembling an axial extension of the cathode post; see Figure 2.

An approximate analysis of the underlying discharge phenomena shows that as the magnetic flux density is increased, the ion drift velocity is only moderately affected, whereas the electron drift velocity is greatly reduced in magnitude and becomes nearly perpendicular to the electric field. Qualitatively, this behavior can be related to many of the experimentally observed phenomena.

The work reported in this paper represents a portion of an initial exploration of the effect of a strong transverse magnetic field on a gaseous discharge at moderately low pressures.[1] The experimental objective was to observe and measure the effect of the magnetic field on as many discharge characteristics as possible. The theoretical aim was an approximate analysis for use as a guide in interpreting and correlating the experimental observations.

A glow discharge was selected for study, partly because its characteristics in the absence of a magnetic field are well known[2, 3] but also because a large difference between positive ion and electron trajectories can be obtained at typical glow discharge pressures by using convenient values of magnetic flux density.

Experimental Observations

The discharge domain is shown in Figure 1. This assembly is immersed in an atmosphere of dry air in a vacuum chamber. Note that the nonconducting boundaries of the discharge are unconfined horizontally. Thus the discharge is free to assume a self-imposed contour in a horizontal plane.

Observed attributes of the discharge were:

1. Visible form and color.
2. Cathode sputtering.
3. Wind (a result of the magnetic field; to be defined later).
4. Volt-ampere characteristics of an auxiliary probe electrode.
5. Time-average discharge potential differences and distributions.
6. Discharge potential variations with time.

These were studied as functions of magnetic flux density, pressure, and discharge current. The magnetic flux density ranged from 50 to 7,000 gausses, the pressure from 0.30 to 10 millimeters of mercury, and the current from 0.05 to 2.5 amperes. As complete data are available elsewhere,[1] only data showing the effect of magnetic field variations at a pressure of approximately 1.2 millimeters and a discharge current of about 0.6 ampere will be presented here.

Figure 2 shows the discharge. The side view is reflected from a mirror to the left of cathode. At negligible magnetic flux density, Figure 2(A), the luminous portion of the discharge consists entirely of the bluish-white negative glow, except for a few small anode spots. Increasing the magnetic flux density results in the following changes, illustrated in Figures 2(B), 2(C), and 2(D):

1. The negative glow is compressed horizontally into a thin circular tube of intense luminosity.
2. The anode spots become more numerous and coalesce to form a ring or rings.
3. The Faraday dark space decreases in extent and a pink positive column appears between cathode and anode. This region is usually striated for moderate fields (200 to 800 gausses); see Figure 2(B). However, as the flux density is increased further, it becomes continuous and brighter, and it assumes a contour in the horizontal plane similar to the shaded area of Figure 5.

Sputtering from the copper cathode is negligible in the absence of a magnetic field but increases rapidly with increasing magnetic flux density. This is evidenced by copper deposits on transite sheets adjacent to the cathode and by the appearance of green color due to excited copper vapor in the region around the cathode.

The presence and direction of the wind[4] caused by the discharge were observed by suspending Fiberglas streamers at various positions around the discharge. With increasing magnetic field these streamers became displaced from their vertical rest position, ultimately becoming horizontal and fluttering as though in a turbulent wind. The wind direction can be reversed by changing the polarity of either the magnetic field or the discharge, but remains the same if both are changed. The wind direction is generally mutually perpendicular to the magnetic field and the current; in more detail, it is always at right angles to the boundary of the discharge. Its sense is given by the motor rule. The approximate velocity of the wind was measured by observing the angular deflection of a small, rectangular mica vane mounted as shown in Figure 3. Wind velocity is plotted as a function of magnetic flux density in Figure 4; absolute values given there may be in error by an appreciable factor either way, but the relative behavior is believed to be correctly indicated.

An attempt was made to obtain information by means of an auxiliary probe

---

Paper 53-154, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted October 22, 1951; made available for printing December 23, 1952.

W. D. McBee is with the Sperry Gyroscope Company, Great Neck, N. Y., and W. G. Dow is with the University of Michigan, Ann Arbor, Mich.

The authors wish to acknowledge the very important contributions made by H. C. Early in relation to the experimental arrangements and criticisms of the manuscript.

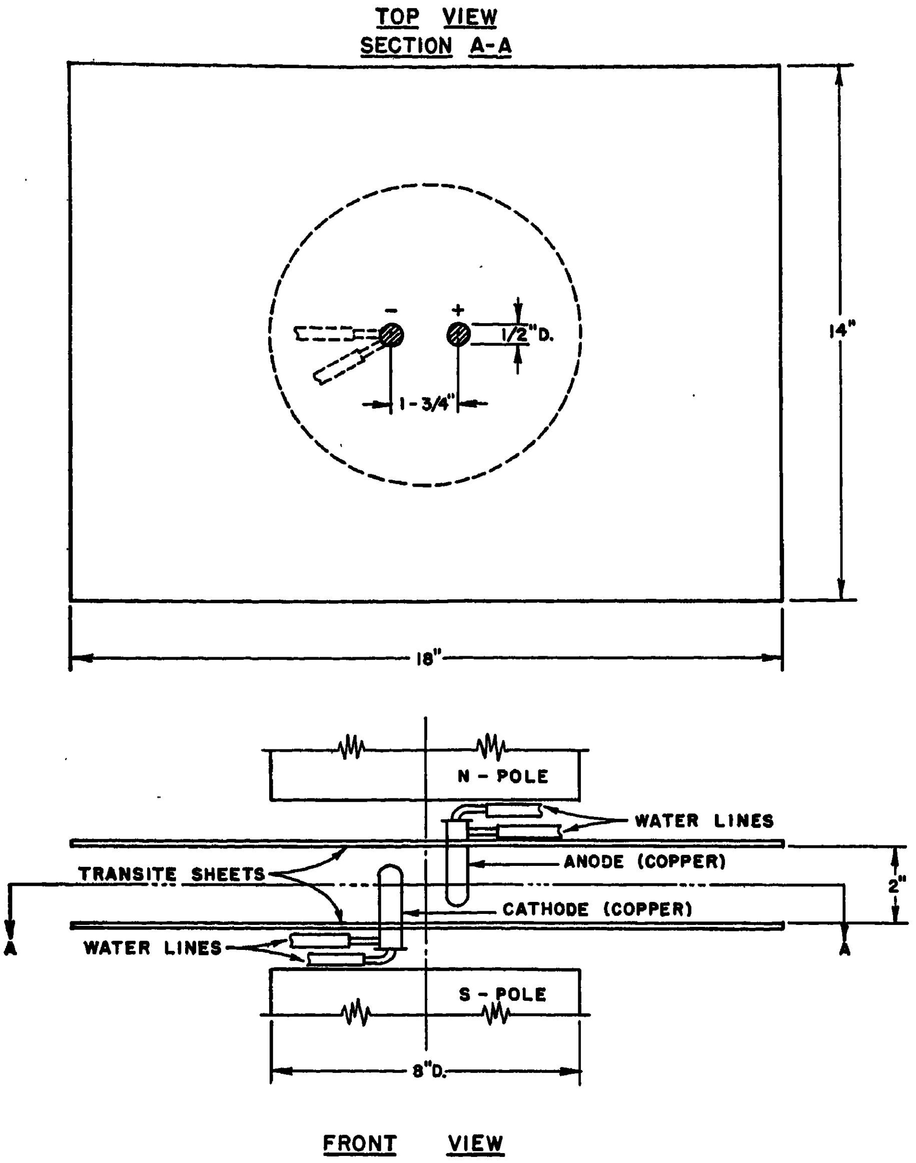

Figure 1. Electrodes, magnetic poles, and insulating discharge boundaries of the experimental apparatus

electrode.[3, 5–7] A disk, 0.020 inch in diameter, surrounded by an equipotential guard ring, was used as a probe. Probe volt-ampere characteristics were taken with the probe surface both parallel and perpendicular to the magnetic field. Because of large variations in discharge potential (discussed later), each point on the probe characteristic represents the average current collected over a range of potential differences between probe and discharge. Therefore, only wide plateaus of current saturation are significant. Plateaus indicative of ion current saturation were observed on all the characteristics. However, saturated electron current plateaus were observed only with the probe surface parallel to the magnetic field and with magnetic flux densities in excess of 1,000 gausses. The ratio of saturated electron current to saturated ion current decreased from 10 at 930 gausses to about 2 at 5,200 gausses. Usual values for this ratio in the absence of a magnetic field exceed 1,000.

The remaining data deal with discharge potentials. Large and rapid fluctuations in plasma potential prevented making plasma probe potential measurements in the usual way.[7] Therefore zero-current probe measurements were made to obtain the data for Figures 5 and 6. The ideal zero-current probe potential would differ from the true plasma potential by about the difference in the electron and ion mean energies (in electron volts), that is, by perhaps as much as 10 volts, which is not significant with the gradients of 200 or more volts per centimeter existing.

However, a probe has a rectifier type of characteristic[6] and a finite capacitance; therefore, depending on the magnitude of the capacitance and the plasma potential fluctuation frequency, a zero-current probe's potential may not follow the plasma potential faithfully during a rapid rise to a fluctuation crest, but will follow the plasma potential on the downswing. Therefore the d-c zero-current probe potential may be lower than the true average plasma potential, perhaps by several times 10 volts. This difference will, however, be consistent in trend throughout the measurements. If its presence is recognized, it need not invalidate interpretations of data based primarily on relative values of d-c zero-current probe voltages.

Thus all of the probe potentials used for Figures 5 and 6 are lower than true plasma potentials, but by consistent amounts, perhaps as much as 50 volts, but probably not more than 100 volts. However, relative values and equipotential shapes are believed to represent the true situation reasonably correctly. Probably the true anode fall of potential is substantially less and the true cathode fall of potential somewhat greater than indicated in Figure 6. This error will be a maximum at the largest B, and will decline to insignificance for small B.

A 0.005-inch-diameter tungsten wire floating probe having a 1/8-inch exposed length was used to obtain the horizontal-plane potential map of Figure 5. Note the skewing of the field, the large potential gradient in the positive column, and the divergent fanning-out of the equipotentials below the lower boundary. Equipotentials near the anode may have true potential values considerably higher than the indicated zero-current probe potentials because of the probe's rectifying characteristic. Thus the steep gradient near the anode may be partially an instrumentation effect.

The total discharge potential difference consists of the cathode fall, the positive column drop, and the anode fall, distinguished experimentally by placing a probe (number 1) 1/8 inch from the cathode and another (number 2) 1/10 inch from the anode. Figure 6 shows illustrative probe and cathode potentials relative to the anode, as functions of magnetic flux density. With increasing B, the positive column voltages increase, whereas the cathode fall decreases, causing a minimum in the total voltage curve.

Potential fluctuations were recorded by photographing the trace of a floating probe's potential on a single-sweep cathode-ray oscilloscope; see Figure 7. The relaxation character of the recorded voltage variations probably results from the probe following plasma potentials faithfully on the downswing, but not on the rise. In general, the fluctuation amplitude increases with both pressure and magnetic flux density. The observed frequency decreases with increased pressure. At low pressures, frequency increases with flux density, but a maximum frequency at an intermediate flux density was observed at the higher pressures. Details of changes in observed frequency may be influenced by changes in the probe volt-ampere characteristic, which affects the faithfulness of response to a potential rise.

Approximate Theory of Particle Mobilities

To indicate trends in interpreting the observed phenomena a roughly approximate mobility theory is useful.

Let

$\mathbf{E}=E_x\mathbf{i}$ = electric field intensity, volts per meter (1A)

$\mathbf{B}=B_y\mathbf{j}$ = magnetic flux density, webers per square meter (1B)

$\xi_0=u_0\mathbf{i}+v_0\mathbf{j}+w_0\mathbf{k}$ = initial velocity of a charged particle trajectory, meters per second (1C)

L = mean free path (1D)

t_L = Mean-free-path time (1E)

$\epsilon_0=\dfrac{mc_0^2}{2q}$ = initial energy of a particle, electron volts (1F)

m = particle mass in kilograms; q = particle charge in coulombs (1G)

The x-z plane is the domain of the complex variable $r=x+jy$ (2A)

The x-z projection of the velocity, also complex $=c=u+jv$ (2B)

For mutually perpendicular electric and magnetic fields, the familiar cycloidal x-z projection of the trajectory, Figures 8, 9 possesses

$$\text{angular velocity:}\quad \omega=B_y\frac{q}{m} \tag{3A}$$

$$\text{generating radius:}\quad R_g=\frac{1}{\omega}\left|w_0-\frac{E_x}{B_y}-ju_0\right| \tag{3B}$$

$$\text{rolling radius:}\quad R_r=\frac{1}{\omega}\,\frac{E_x}{B_y} \tag{3C}$$

With $B > 500$ gausses and E/B as in the experiments, suitable relative magnitudes are

For electrons with $\xi<10$ electron volts, $R_g>5R_r;\ \omega t_L>>1$ (4)

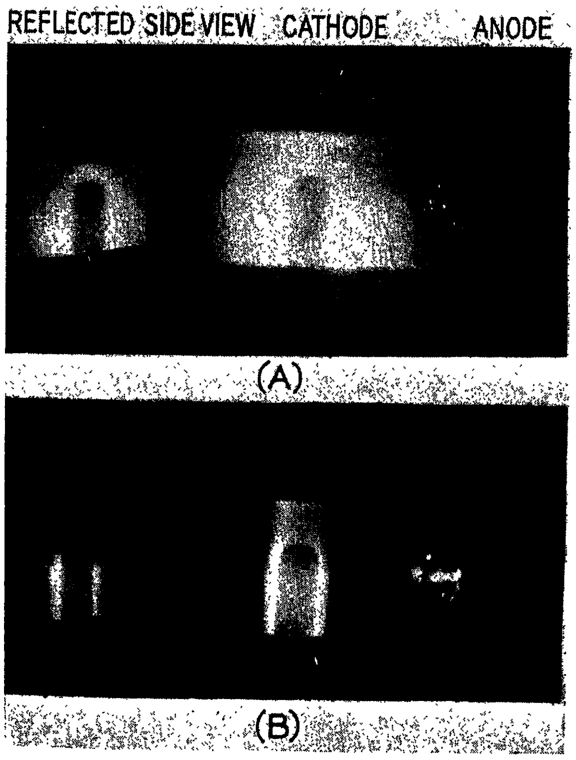
For ions with $\xi<3$ electron volts, $R_g\simeq R_r$ $\left(\text{that is, } |c_0|<<\dfrac{E}{B}\right);\ \omega t_L<<1$ (5)

From equation 4, an $\xi < 10$ electron describes during one free path many cycles of a large-loop cycloid, Figure 8;[5] therefore, the primary motion is a drift at velocity E/B along equipotentials (perpendicular to both E and B). At each collision the generating radius and phase change, but not the E/B drift. On the average, each collision results in a shift of the cycloid's base line in the direction of the electric field force; this is the mechanism of the slight electron drift in the field force direction, when B is large.

Under conditions of equation 5, the typical ion has an initial velocity very modest relative to the E/B velocity. It therefore starts after each collision from a point at or near the cusp of the common cycloid (middle, Figure 9 curve), or at a comparable point on either of the other Figure 9 curves. Thus, on the average, its starting motion is primarily in the direction of the electric field force. Because each free path is a very small fraction of a cycloid's cyclic length, its whole travel during one free path will be chiefly in the direction of the starting motion. Thus ion drift takes place primarily in the direction of the electric field force, with only a modest E/B direction component.

Thus electrons move chiefly along equipotentials, whereas ions have their major drift in the electric field force direction. These contrasting properties dominate the gross nature of the discharge, as described by Figures 5 and 6, and result in the Figure 4 wind.

The general correspondence between the Figure 5 pattern and expected ion and electron behavior, discussed later, suggests that the Figure 7 potential fluctuations do not alter in a major way the general relative magnitudes of the average values of the components of ion and electron drift. They do, however, indicate large statistical departures from the averages, and may markedly affect the absolute values of the averages.



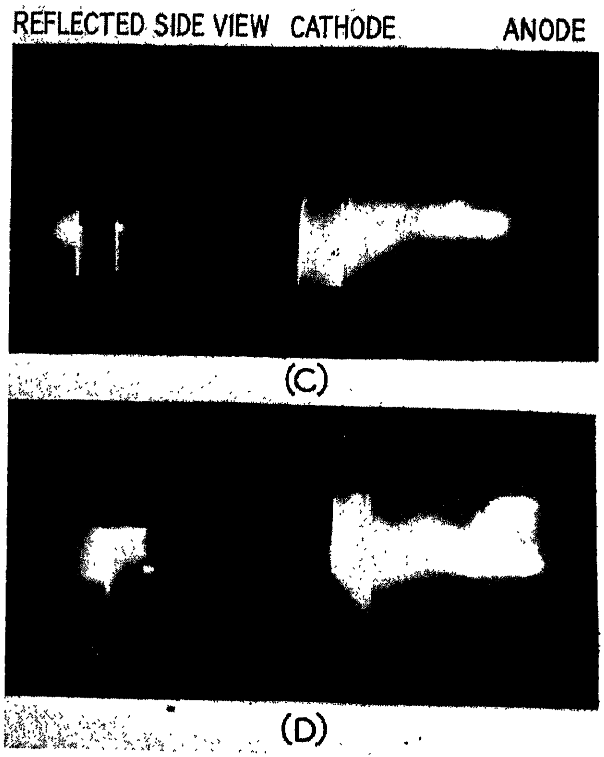


Figure 2. The discharge. The side view is reflected by a mirror. Pressure = 1.2 millimeters of Hg

A. Magnetic flux density = 50 gausses

B. Magnetic flux density = 250 gausses

C. Magnetic flux density = 1,140 gausses

D. Magnetic flux density = 3,900 gausses

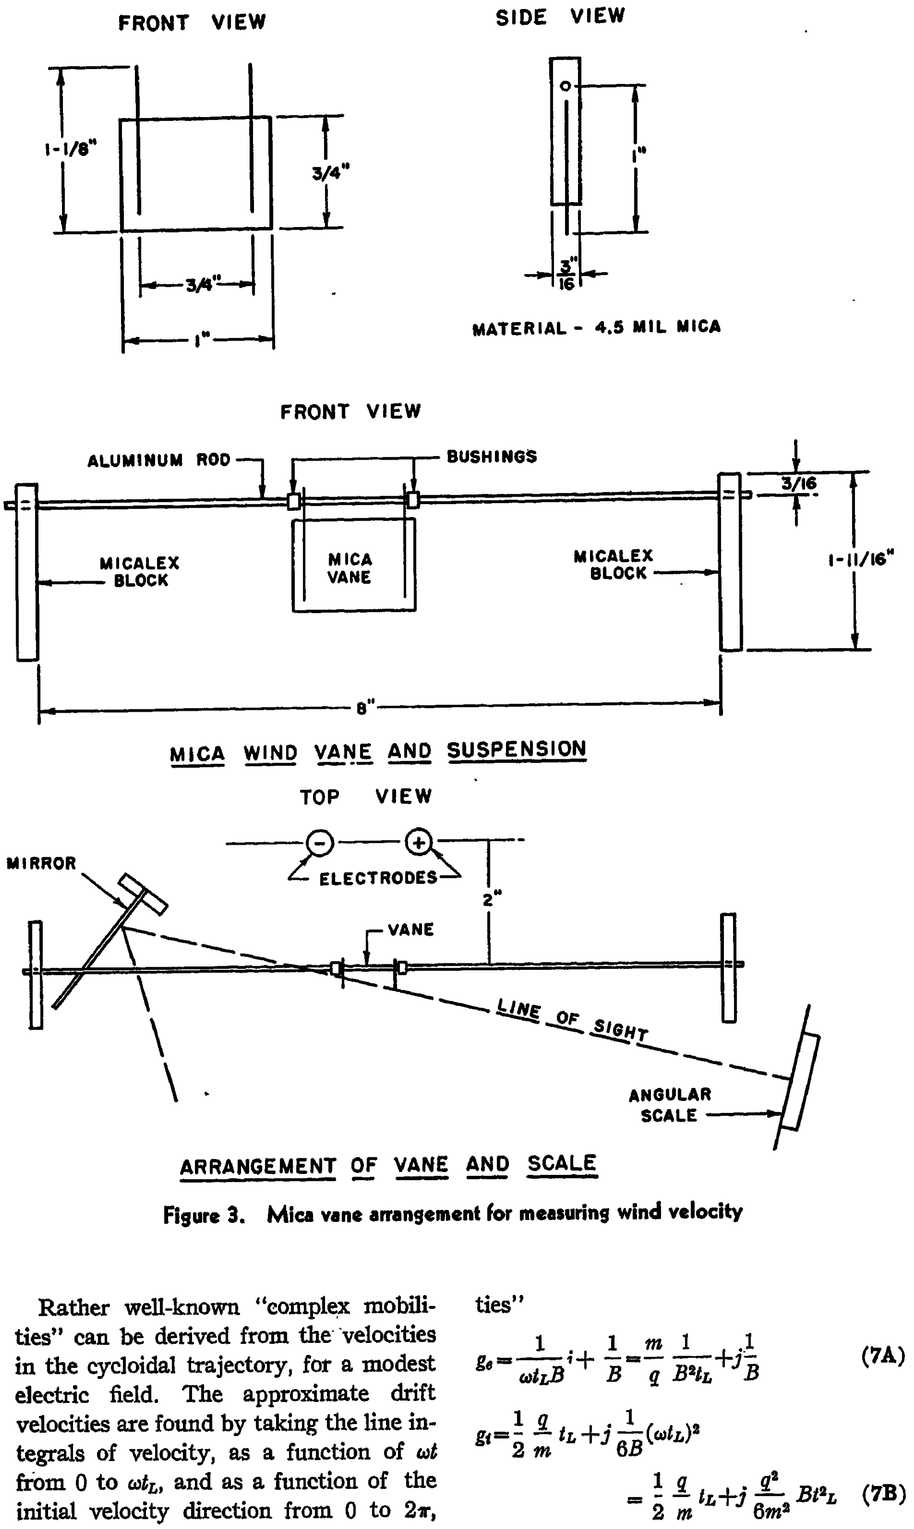

Figure 3. Mica vane arrangement for measuring wind velocity

Rather well-known "complex mobilities" can be derived from the velocities in the cycloidal trajectory, for a modest electric field. The approximate drift velocities are found by taking the line integrals of velocity, as a function of ωt from 0 to ωt_L, and as a function of the initial velocity direction from 0 to 2π, then dividing by $2\pi\omega t_L$. Assuming from equations 4 and 5 that $\omega t_L << 1$ for ions and $\omega t_L >> 1$ for electrons, drift velocities are found to be

$$\text{electrons: drift velocity} = \frac{1}{\omega t_L}\frac{B}{E} + j\frac{E}{B} \tag{6A}$$

$$\text{ions: drift velocity} = \frac{1}{2}\frac{E}{B}\omega t_L + j\frac{1}{6}\frac{E}{B}(\omega t_L)^2 \tag{6B}$$

Dividing by E gives the "complex mobilities"

$$g_e = \frac{1}{\omega t_L B}i + \frac{1}{B} = \frac{m}{q}\frac{1}{B^2 t_L} + j\frac{1}{B} \tag{7A}$$

$$g_i = \frac{1}{2}\frac{q}{m}t_L + j\frac{1}{6B}(\omega t_L)^2$$
$$= \frac{1}{2}\frac{q}{m}t_L + j\frac{q^2}{6m^2}Bt^2_L \tag{7B}$$

Equation 7(A) has no meaning for $B=0$. Equations 7 are represented by the solid-line curves in Figure 10, based on constant mean energies of 1.0 and 0.6 electron volts for electrons and ions respectively. These values are reasonable for a zero magnetic field glow discharge, for pressures and currents here discussed. However, from Figure 6, raising B from 0 to 6,000 gausses causes a positive column average gradient increase by a factor of the order of 100. This obviously increases the mean energy values. Furthermore, the mean free paths necessary for the Figure 10 evaluations are imperfectly known and will be affected by the air temperature rise that must accompany the great increase in energy input to the discharge between 0 and 6,000 gausses. Thus Figure 10 should be thought of merely as exhibiting certain relative-value general trends.

However, in support of the general utility of Figure 10, the equation 4 and equation 5 mean energy limitations to less than 10 and 3 electron volts respectively are probably valid at least to 6,000 gausses. For the electrons, rise to a greater ξ than about 10 causes excitation or ionization that drops ξ again to a low value. There are reasons of the self-consistency type to believe that the ion mean energy (ξ) in the steep magnetic plasma gradient of value E will vary directly as E, just as for ions in a strong nonmagnetic plasma.[5] On this basis, for expected free paths and Figures 5 and 6 gradients, ion mean energies should rise to the order of 1.5 electron volts at 6,000 gausses; this is still within the $\xi<3$ limit in equation 5, used for equation 7.

The equation 7 mobility components are functions of t_L; in general $t_L = L/c$ and c^2 varies in proportion to ξ; therefore t_L^2 varies roughly inversely as ξ. Use of this and the previous paragraph's concepts as to ξ permits comments as to expected deviations from Figure 10 at large values of B as follows:

1. *The imaginary component of g_i.* From Figure 6 the plasma gradient increases, nearly linearly, about one hundred-fold between $B=0$ and $B=6{,}000$ gausses. Therefore, with t_L^2 varying inversely as ξ, and ξ for ions varying as E, t_L^2 should for large B vary about inversely as E. Therefore, from equation 7(B) and Figure 6, the imaginary component of g_i should at 6,000 gausses be less than the Figure 10 values by perhaps a factor of 100.

2. *The real component of g_i.* From equation 7(B) the real component of g_i varies as t_L, therefore roughly inversely with $\sqrt{E}$. Therefore between 0 and 6,000 gausses the real component of g_i should decrease to a value lower by about a factor of 10 than at $B=0$. Thus for all magnetic fields used, the real component of g_i is much greater than the imaginary component of g_i. In this relative magnitude respect, Figure 10 leads to the correct concept, although magnitudes are far from correct for large B.

3. *The imaginary component of g_e.* Because the imaginary component of g_e does not involve the mean energy, it should vary roughly as indicated in Figure 10, except for a more or less abrupt drop to zero at $B=0$; equation 7(A) is not valid at $B=0$.

4. *The real component of g_e.* Because the electron mean energy may reasonably increase from perhaps 1 to 10 electron volts between $B=0$ and $B=6{,}000$ gausses, due to

the major general increase in energy input to the discharge, the real component of g_e must from equation 7(*A*) be greater at 6,000 gausses than Figure 10 indicates. The suggested increase in ξ by roughly ten times would indicate an increase over Figure 10 values by roughly ten times. However, indirect evidence,[7] related to random plasma voltage fluctuations, suggests that at 6,000 gausses the real component of g_e may be greater than the Figure 10 value by a factor between 10 and 50. This still keeps the real component of g_e substantially below the imaginary component; the shape of the equipotentials in Figure 5 is consistent with this point of view and would not be consistent with a real component of g_e larger than the imaginary component at 6,000 gausses.

These comments explain the dashed-line arrows in Figure 10, suggesting estimated values more appropriate at 6,000 gausses than those based on equation 7. They also indicate that for large B the major ion flow will be at right angles to equipotentials and the major flow of electrons along equipotentials.

Cathode and Anode Fall Spaces

The data interpretations given in this paper are consistent with the entire experimental study[1] only partially presented here.

Electron emission results from bombardment of the cathode by positive ions[2, 3, 5] accelerated through the cathode fall of potential. Because the cathode fall space is thin and has a very strong electric field, falling-in ions start their fall at a trajectory point corresponding to a cusp of the Figure 9 cycloid and reach the cathode within one or two free paths. Thus in the cathode fall space, the ion motion is not seriously affected by the magnetic field directly.

In contrast, with a strong magnetic field, the electrons experience a field configuration like that in a high-vacuum diode magnetron. The electrons can escape from rapid circulation around the cathode only by losing kinetic energy. Such loss of kinetic energy occurs only at exciting and ionizing collisions. The strong luminosity of the cathode fall region suggests that many such collisions must occur prior to escape from the tight circulation.

Because emitted electrons circle close in to the cathode, most of the cathode fall space ion generation occurs very near the cathode. This causes a marked contraction of the cathode fall space, together with an increase in luminosity as the magnetic field increases; see Figure 2. Because the ions are generated near the cathode, they suffer fewer collisions and therefore lose less energy in traversing the cathode fall space than in a nonmagnetic glow discharge. Therefore, the cathode fall of potential declines markedly with application of the magnetic field; see Figure 6.

Near the anode, the electric field is radial; only real mobility components carry electric current to the anode. The imaginary component of electron mobility is large, causing electrons to approach the anode in long, slowly-shrinking spirals. During such approach, they produce the ions necessary to the near-the-anode portion of the discharge, and also cause the luminous portion of the discharge to envelop the anode completely, as illustrated in Figure 5.

The Plasma (Positive Column)

Interpretations of positive column phenomena are based on Figures 2, 4, 5, and 6 in the light of the rough relative magnitudes of mobilities represented in Figure 10. No particular claim is made as to correctness of Figure 10 as to absolute values.

THE ZERO MAGNETIC FIELD BASE CONDITION

At zero magnetic field (see Figures 4, 6, and 10) the average longitudinal gradient in the positive column is very gentle, and may be considerably less than the radial gradient. For such a nonmagnetics plasma, the important ion movement in the plasma is radial, in response to a combination of the radial electric gradient and a radial ion concentration gradient. The ions flow outward in all radial directions. The ion and electron concentration within the plasma are about equal, and the plasma is circumferentially enveloped by a positive ion sheath. Recombination occurs only toward the outer edge of and outside the sheath, where random particle energies are small.

The sheath pattern changes when the magnetic field is applied, but a rough equality of plasma electron and ion concentration within the plasma persists, and recombination continues to take place only outside of the plasma proper.

DECLINE OF THE LONGITUDINAL MOBILITIES

Figure 10 indicates that as B is increased upward from zero, the first and most rapid change is the decline of the real part of g_e from an initial value around perhaps 100 on the Figure 10 scale to very much smaller values; the real part of g_e rapidly becomes much less than the imaginary part. This initial very rapid trend is real and important, and accounts for the initial rapid increase of the positive column voltage in Figure 6. The plasma gradient becomes larger in order to compel current to flow in spite of the greatly lowered electron mobility.

The increase in gradient caused by the change in g_e results also in a decline in the real part of g_t.[2, 5, 9] Therefore with increasing B, the components in the electric field force direction of both mobilities decline markedly. This change in the electron behavior is of predominating importance.

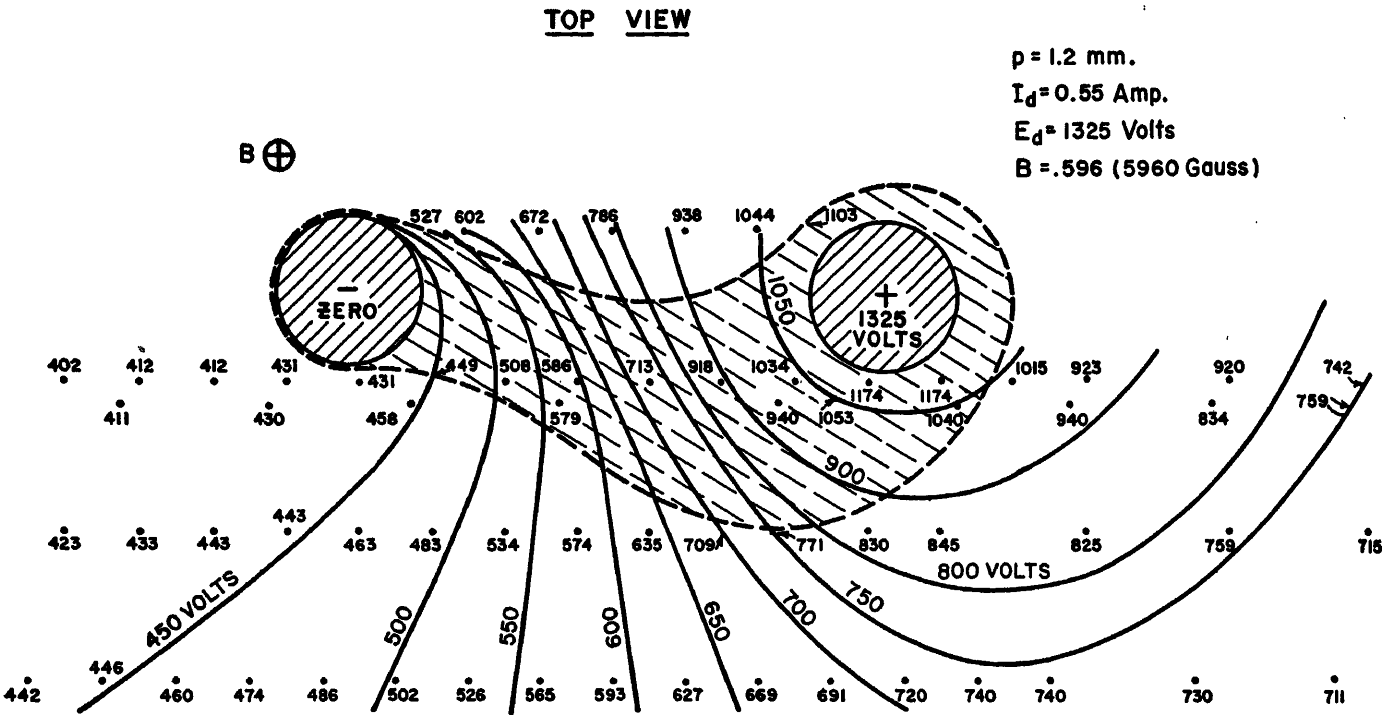

Figure 5. Potential map of a horizontal plane located at the center (vertically) of the visible discharge. The electrodes are shown in cross section and the approximate visible discharge domain in phantom. Pressure = 1.2 millimeters, magnetic flux density = 5,960 gausses, and discharge current = 0.55 ampere. Potentials are indicated in volts

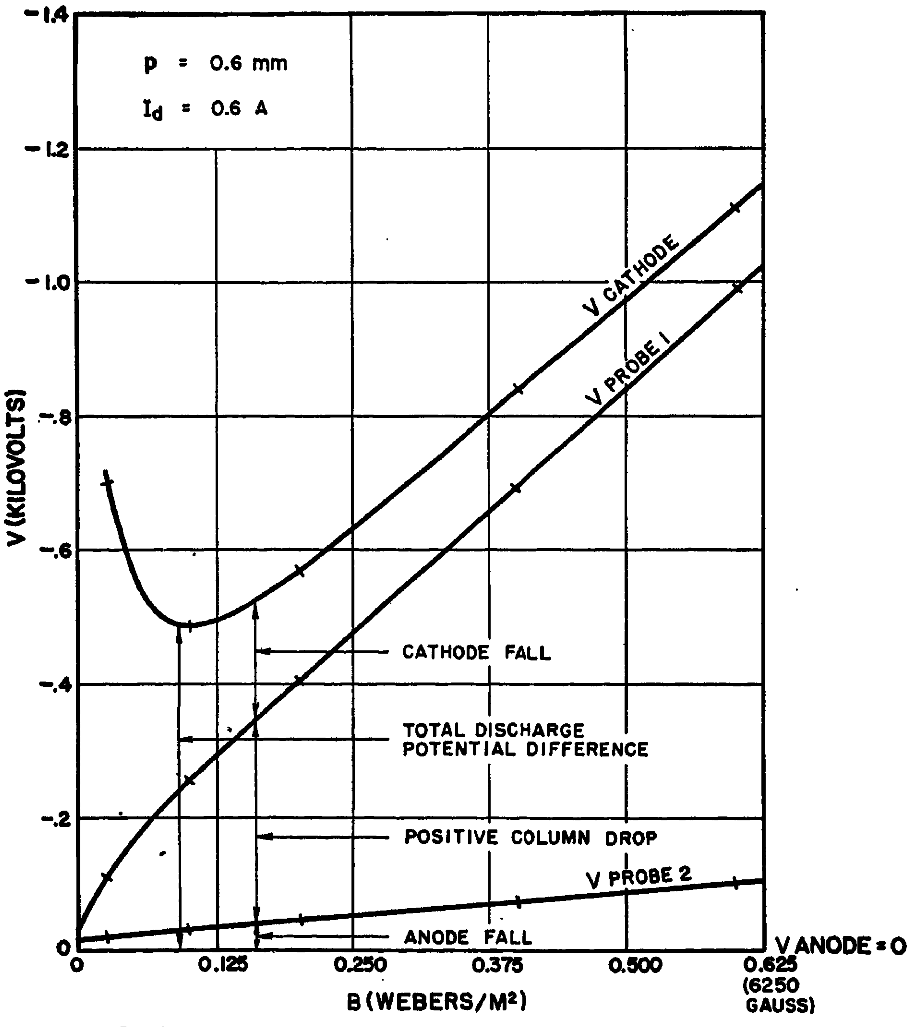

Figure 6. Discharge potential drop components versus magnetic flux density. Pressure = 0.6 millimeter of Hg, I_d = 0.6 ampere

Unbalance of the Potential Field Caused by a Negative Space Charge Sheath

Figure 5 shows for 6,000 gausses and 1.2 millimeters of mercury a markedly asymmetrical electric field configuration, probably characteristic of all values of B which produce appreciable winds. Study of this potential field, in the light of the Poisson's equation description of the flexion of potential distribution curves, will demonstrate a pronounced negative space charge sheath along the lower boundary only of the luminous (shaded in Figure 5) portion of the discharge. This whole potential field may be pictured as the superposition of a strong and symmetrical longitudinal-gradient field and a field due to a negative space charge sheath on one side only. This space charge exists because, above some modest B, a large electron flow occurs along equipotentials, downward and to the right in Figure 5, because of the predominance of the imaginary component of g_e over the real part. The resulting electron accumulation tends to draw the positive ions downward after it. Poisson's law is the mathematical statement of the way the potential field implements this tendency. Of course, there must exist a positive space charge to balance the charge in the negative sheath; the Figure 5 topography suggests that positive space charge predominates within and above the plasma.

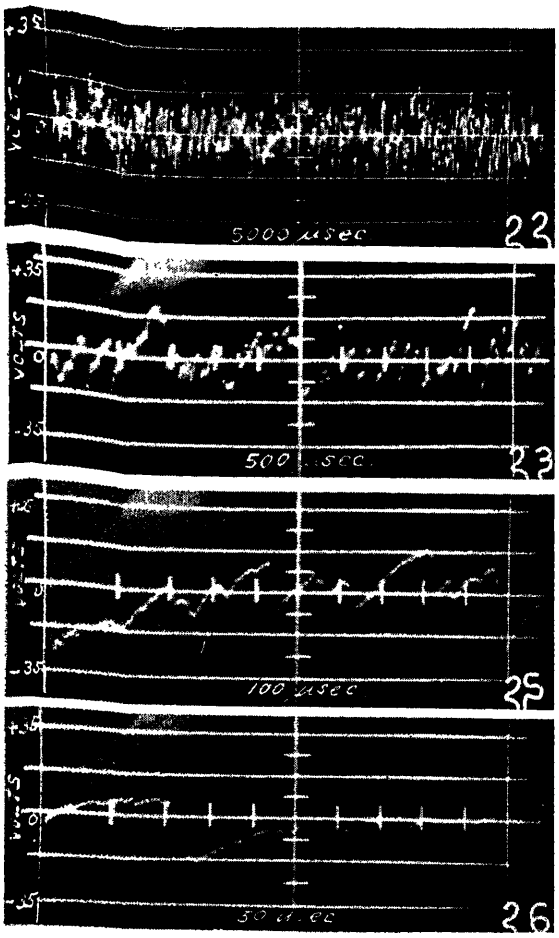

Figure 7 (left). Wave form of potential fluctuations picked up by a floating probe. The horizontal sweep periods of the traces are 5,000, 500, 100, and 50 microseconds, from top to bottom. Pressure = 1.0 millimeter, magnetic flux density = 5,760 gausses, and discharge current = 0.55 ampere

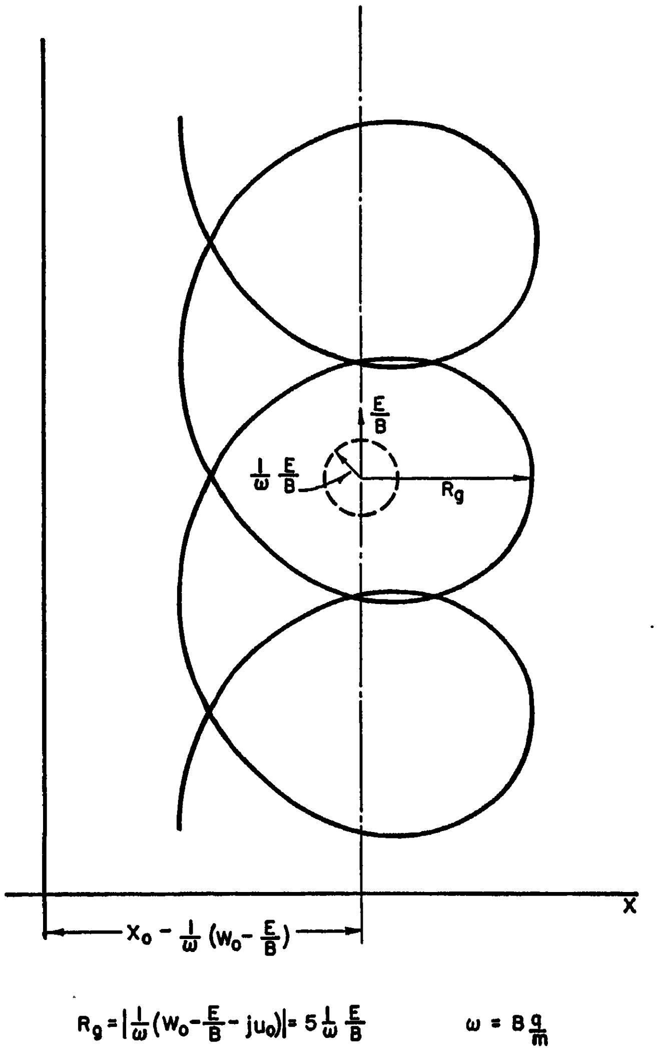


$\frac{E}{B}$
$\frac{1}{\omega}\frac{E}{B}$
R_g
X
$X_0 - \frac{1}{\omega}(W_0 - \frac{E}{B})$
$R_g = \left|\frac{1}{\omega}(W_0 - \frac{E}{B} - ju_0)\right| = 5\frac{1}{\omega}\frac{E}{B}$
$\omega = B\frac{q}{m}$

Figure 8 (right). The x+jz plane projection of the trajectory of an electron with a fairly high initial velocity

Thus the plasma and its environs exhibit the properties of a double line charge, the negative charge existing on the side from which the wind emerges, the positive charge near to and beyond the plasma boundaries on the side into which air enters.

Thus the chain of causative circumstances appears to be as follows:

1. Electron flow occurs chiefly along equipotentials, toward the lower boundary (Figure 5), setting up
2. A negative space charge sheath, causing,
3. The ions to follow the electrons downward because of the transverse component of the electric field due to the negative sheath.

The skewed field shape makes the flow of electrons along equipotentials accomplish part of the total current flow. Thus, because of field asymmetry, the positive column voltage rises less than called for by the decline in real component mobilities alone. This illustrates the general principle that field properties assume whatever co-ordinated pattern is necessary to pass the stated current with a minimum over-all applied voltage.

In the zero-magnetic-field base condition, the equipotential surfaces come close to being cylinders concentric with the axis, because the radial gradient considerably exceeds the longitudinal gradient. Thus quite opposite to one's intuitive concept, the Figure 5 skewed-field equipotentials are probably oriented generally more nearly transverse to the long axis of the discharge than is true in the zero-magnetic-field base condition; the base condition equipotentials are transverse just along the axis, not elsewhere.

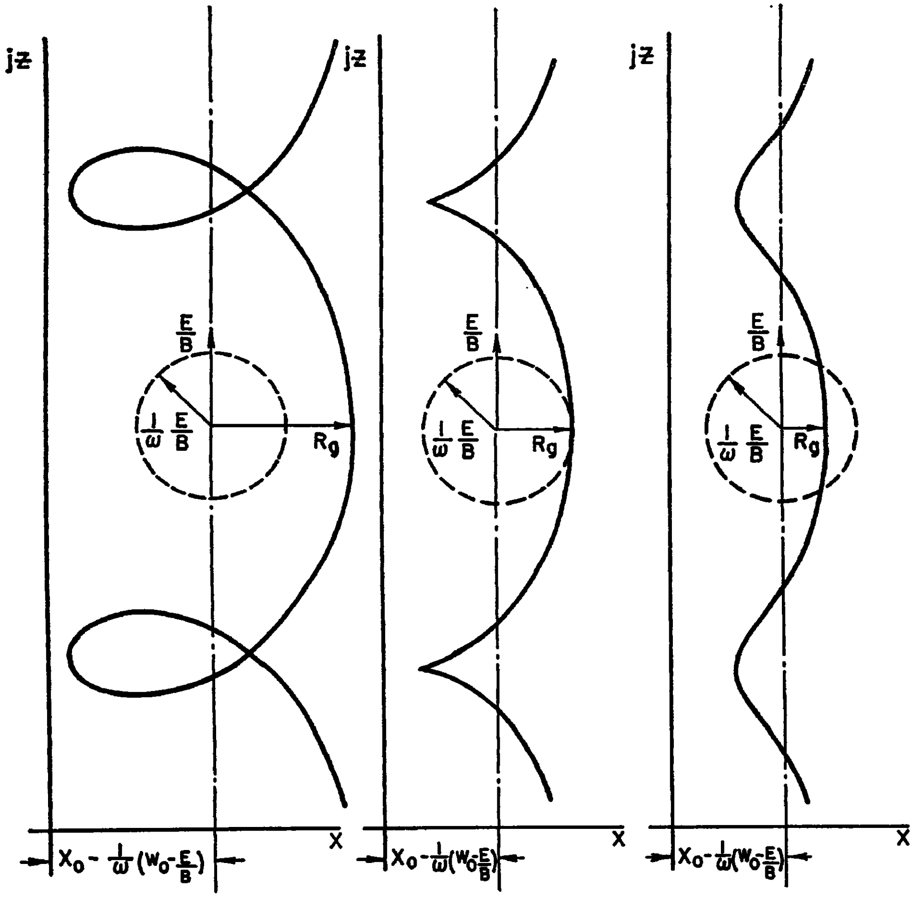
FLOW OF CHARGED PARTICLES IN THE PLASMA

Consider two distinct regions in the Figure 5 plasma. First, for the central region, 450 to perhaps 900 volts, the discussions associated with Figure 10 indicate that the along equipotential (imaginary) component of electron flow provides the most effective charge transport. However, there must be some across-equipotential charge transport to complete the circuit. From the Figure 10 discussion it may well be for the 6,000-gauss condition that the real components of g_θ and of g_θ may have somewhere near the same magnitude. With the two kinds of charge density about equal, the across-equipotential charge transport may have significant contributions from both kinds of particles.

Second, between 900 volts and the anode the along-equipotential electron flow cannot contribute to charge transport generally toward the anode, because the equipotentials encircle the anode. For this region's radial field the Figure 10 contrast between the two g_θ components suggests that the electrons execute many-turn spirals slowly approaching the anode. The excitation caused during this spiralling results in the luminous (cross-hatched) region enveloping the anode, and the ionization produced there prevents space-charge limitation of the electron flow. Presumably as in the central region the across-equipotential charge transport receives significant contributions from both ion and electron flow.

Wind: Momentum Versus Energy Exchange

To discuss wind production, certain basic concepts as to momentum exchange at collisions must be introduced.



CASE I: $R_g > \frac{1}{\omega}\frac{E}{B}$

CASE II: $R_g = \frac{1}{\omega}\frac{E}{B}$

CASE III: $R_g < \frac{1}{\omega}\frac{E}{B}$

$$R_g = \left|\frac{1}{\omega}\left(W_0 - \frac{E}{B} - ju_0\right)\right| \qquad \omega = B\frac{q}{m}$$

Figure 9 (above). Projections in the x+jz plane of the types of trajectories typical of positive ions with fairly low initial velocity

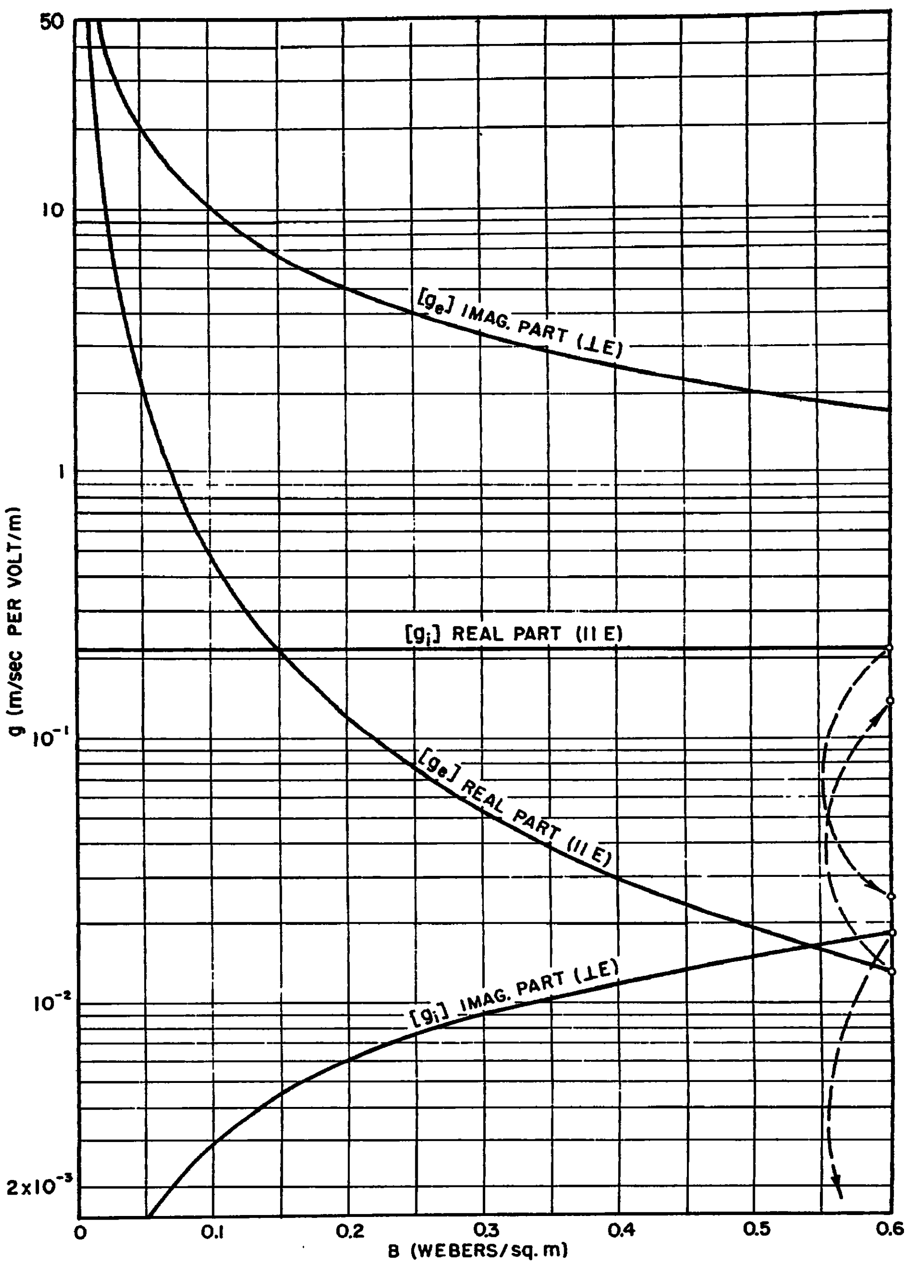


Figure 10 (right). Ion and electron mobility versus magnetic flux density. The real components are parallel to the electric field, the imaginary components are perpendicular to the electric field. $\xi_0 = 1.0$ volt for electrons, $\xi_0 = 0.06$ volt for ions. See text discussion of the dashed-line arrows

If a moving ion makes a head-on nonglancing collision with a stationary gas particle of equal mass, the ion comes to rest and the gas particle moves away with just the momentum and the energy brought in by the ion, as in the comparable billiard-ball impact. There is 100-per-cent transfer of momentum and of energy.

If a moving electron makes a head-on nonglancing collision with a stationary gas particle, the electron bounces back with a velocity almost that of approach but oppositely directed. Thus the transfer of momentum is twice that brought into the collision by the electron, whereas the fraction of energy transferred is very minute. There is 200-per-cent transfer of momentum; the fraction of the energy transferred is of the order of the inverse of the mass ratio, about 1/50,000 for air.

As to momentum exchange in a zero-magnetic field plasma:

1. The electron and ion drift velocities are related about inversely with $\sqrt{m_g/m_e}$, where m_g and m_e are gas-particle and electron masses.
2. The momenta (mv) per charged particle will therefore be related about directly as $\sqrt{m_g/m_e}$.
3. For both particles, the momentum transfer to the gas is of the order of unity, that is, 1 or 2; therefore, the momentum transfer per particle at collisions for ions will be about $\sqrt{m_g/m_e}$ times greater than for electrons.
4. The number of collisions per second varies directly with the velocity; therefore the rate of collision for ions will be about $\sqrt{m_g/m_e}$ times less than for electrons.
5. The total momentum transfer per charged particle per second will vary as the product of the transfer per collision (item 3) by the rate of collision occurrence (item 4); therefore each electron will transfer to gas particles about the same momentum per second as each ion.
6. The concentrations of the two kinds of particles are about equal; in a zero-magnetic field plasma they transfer momentum in opposite directions, therefore there is very little net transfer of momentum to the gas and no observable wind.

In a plasma in a strong magnetic field, as for Figure 5, the momentum transfer in the along-axis direction may still be expected to cancel out to zero, but the transverse momentum transfer for the two kinds of particles acts in the same sense, and will therefore combine additively to produce a transverse wind.

In more detail, in Figure 5 the electron drift vector is directed downward and to the right along the skewed equipotentials, because in Figure 10 at 6,000 gausses the g_e imaginary component greatly exceeds the real one. There is not sufficient evidence to tell by how large a factor the g_i real component exceeds the imaginary one; probably the ion drift vector makes some angle between 45 and 90° with the skewed equipotentials, being directed downward and to the left in Figure 5.

However, it appears that at 6,000 gausses the resultant g_e (nearly wholly imaginary) must greatly exeed the resultant g_i, whatever its direction. Thus the g_e/g_i ratio has at 6,000 gausses the same general order of magnitude as the wholly real g_e/g_i ratio in the zero-magnetic field velocity ratio in item 1. Thus just as in that case the small mass of the electrons may be compensated for, as to momentum transfer, by their greater velocity in combination with their greater collision rate caused by their greater velocity. Thus a reasonable although not firmly demonstrated conclusion is that in a strong magnetic field just as in zero-magnetic field the total momentum transfer due to the electrons may be quite comparable with that due to ions. Transverse (wind-producing) momentum transfer due to the ions is certainly important; the point of this argument is to indicate that the transverse momentum transfer due to the electrons may also be important in spite of the very small electron mass.

A significant experimentally observed fact is that when there is a wind, its direction, for any observed values of current, pressure, and magnetic field strength, is at right angles to the plasma boundary lying adjacent to the place of wind measurement. This suggests that there is some general principle present requiring that the angle of skew and the relative magnitudes of the electron and ion mobility components be so related as to cause the resultant momentum transfer to take place at right angles to the main axis of the plasma.

Discussion

H. C. Early, H. L. Smith (University of Michigan, Ann Arbor, Mich.): This is a very interesting presentation of a subject which may be of considerable engineering significance. An electrical discharge of this type may become useful in connection with low density hypersonic wind tunnels. In such an application, the discharge would function as a "booster" to exert an accelerating force on the air stream, and at the same time add thermal energy to the gas. The heating of the stream would permit higher tunnel velocities to be obtained without difficulties due to condensation.

One very important factor affecting the behavior of the "crossed fields" discharge is the large amount of heat energy which is added to the gas and the resulting thermal expansion. Due to this expansion, the gas leaving the electrode region has a much larger volume and velocity than the gas which enters. Therefore, the gas does not continue as a unidirectional wind or jet, but tends to expand in a hemispherical fashion.

A numerical calculation will illustrate the importance of this thermal effect. An order of magnitude calculation of the gas temperature can be obtained by means of a few simplifying approximations. It appears reasonable to assume that in a 3-kilowatt discharge at least 1 kilowatt of power is expended in heating the air. The other assumptions are as follows:

static pressure = 0.5 millimeter of H_g
cross-sectional area of stream = 15 centimeters squared
velocity of entering air = 100 meters per second
temperature of entering air = 20 degrees centigrade
specific heat of air at constant pressure = 0.28 calorie per gram

If these assumptions can be justified, the air stream reaches a temperature of over 8,000 degrees centigrade and the volume increases by a factor of more than 25.

The curve of wind velocity versus magnetic field strength given in Figure 4 was estimated on the basis of the wind pressure on a mica vane. A meaningful interpretation of wind velocity in terms of pressure on a vane would seem to require more information regarding the temperature and density of the gas than is presently available. Changes in magnetic field strength cause changes, not only in the magnetic force on the conducting plasma but also in the power input and the temperature and density of the air stream. Hence, even the shape of this curve is probably of questionable value.

A quantitative study of this type of discharge requires the development of new methods of instrumentation, in order that such quantities as gas density, ion density, temperature, and velocity can be determined under these unusual conditions. At the present time, a University of Michigan research project sponsored by the Office of Ordnance Research is attempting to develop measurement techniques which will permit a more complete study of this subject than is now possible.

W. G. Dow: In regard to the calculations by H. C. Early and H. L. Smith, leading to the 8,000-degree-centigrade temperature figure, my chief comment would be that their figure of 100 meters per second of velocity of entering air is on the high side, which means that their 8,000-degree-centigrade figure is on the low side.

The question as to the existence or otherwise of such temperatures as they mention in the type of environment described is an important and as yet unanswered basic research question. Because of the low pressure, familiar methods of estimating or measuring temperature have no application in this environment. Adequate mechanisms exist within the discharge for the production of gas temperatures of the order of magnitude of 8,000 degrees centigrade or higher, but we do not yet know how to measure them.

A Mathematical Analysis of a Series Circuit Containing a Nonlinear Capacitor

LOUIS A. PIPES
MEMBER AIEE

Synopsis: This paper presents a mathematical analysis of a general series circuit composed of an inductance and a resistance in series with a nonlinear capacitor. The analysis is based on the assumption that the saturation curve of the dielectric material of the capacitor may be represented by a hyperbolic sine function. A 1-term approximation of the forced steady-state oscillation of the circuit produced by the application of a periodic electromotive force and bias potential is obtained. This one term solution gives the best "least squares" approximation to the amplitude and phase of the steady-state charge and current oscillation of the system and reduces to the usual expression for the steady-state current, if the capacitor is linear. The method of analysis is a general one and is applicable to many problems of forced oscillations of nonlinear dynamical systems, both electric and mechanical. It depends on a procedure by which the "mean square error" involved in the 1-term approximation is minimized. Several special cases are considered, and an estimate of the natural frequency of the free oscillations of the circuit is obtained.

THE CIRCUIT analyzed in this discussion is of fundamental importance in the theory of dielectric amplifiers. Dielectric amplifier circuits are based on the fact that certain dielectrics have nonlinear characteristics. As early as 1912, Debye discovered that when atoms having different electron affinities combined, electric dipoles were formed.[1] By analogy to the nonlinearity of magnetic materials containing iron, the nonlinearity of the dielectric constant caused by the alignment of electric dipoles of atomic ions of certain substances has been termed the ferroelectric effect although there is no iron involved.

Many substances that exhibit the ferroelectric effect have been discovered. Rochelle salt was discovered to be a nonlinear dielectric by Valasek[2] in 1921. The ferroelectric properties of the dihydrogen phosphates and arsenates were studied in 1935 by Busch and Scherrer.[3] Wainer and Salomon[4] discovered the unusual dielectric properties of barium titanate in 1942. The ferroelectric properties of the titanates and some of their applications have been studied by A. von Hippel and his associates at the Massachusetts Institute of Technology.[5]

It is the purpose of this paper to develop a mathematical analysis of a basic series circuit containing as a nonlinear element a capacitor whose dielectric exhibits the ferroelectric effect. The basic circuit is illustrated by Figure 1.

The circuit of Figure 1 is composed of a linear inductor L and a linear resistor R in series with a nonlinear capacitor. The potential impressed upon the circuit consists of a constant potential E_0 in series with a harmonic potential $E_m \sin(\omega t+\theta)$. It is assumed that the potential drop across the nonlinear capacitor is given by $V(q)$, where q is the charge separation of the plates of the capacitor.

Kirchhoff's electromotive force law applied to the circuit of Figure 1 leads to the following differential equation

$$L\ddot{q}+R\dot{q}+V(q)=E_0+E_m \sin(\omega t+\theta) \qquad (1)$$

This differential equation is known in the literature as "Duffing's differential equation."[6,7,8] Equations of this kind occur in the mathematical investigations of physical problems of different types, such as the following ones:

1. The forced oscillations of a pendulum due to the application of an applied periodic force.[9]
2. The forced oscillations of a single mass subjected to an elastic restoring force.[10,11,12]
3. The steady-state oscillations of alternating circuits containing iron core inductances.[9]
4. The problem of hunting of synchronous electric machinery.[7,13]

Although an explicit solution of equation 1 in terms of the elementary functions cannot be obtained, several approximation methods of obtaining the solution for various special functions $V(q)$, have been developed.[6,7,8,9]

In the present discussion, a method of obtaining an approximate steady-state or periodic solution of equation 1 will be developed based on a procedure that minimizes the mean of the square of the error introduced by the approximate solution. The method does not depend

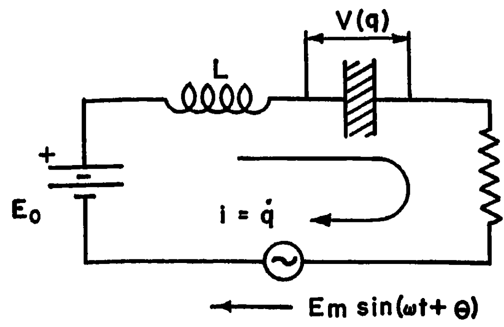

Figure 1 (left). Nonlinear capacitor circuit

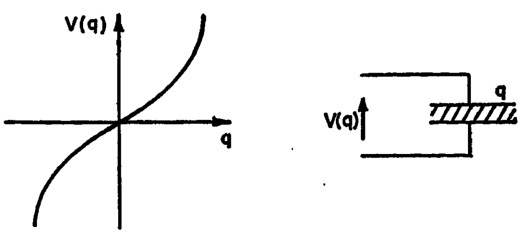

Figure 2 (right). Saturation curve

on the form of the function $V(q)$ but is quite general and

$$L\ddot{q}+G(\dot{q})+V(q)=E_0+E_m \sin(\omega t+\theta) \qquad (2)$$

This equation occurs if the resistance as well as the capacitance of the circuit is nonlinear. In the case of a linear circuit, we have

$$G(\dot{q})=R\dot{q}=Ri \qquad (3)$$

This is the resistive electromotive force drop in the circuit, and

$$V(q)=S_0 q=\frac{q}{C_0} \qquad (4)$$

is the capacitive drop. In this case S_0 is is the elastance and C_0 is the capacitance of the linear capacitor.

Saturation Curve of Nonlinear Capacitor

In order to effect a mathematical solution of equation 2 it is necessary to represent the saturation curve $V(g)$ of the nonlinear capacitor by an analytical expression. The saturation curve of a capacitor that has a typical nonlinear dielectric between its plates has the general form given in Figure 2.

The following analytical expression may be adjusted to fit the saturation curves of nonlinear capacitors having typical nonlinear dielectrics.

$$V(q)=\frac{S_0}{a}\sinh(aq) \qquad (5)$$

In this expression, S_0 is the initial elastance of the capacitor defined by the equation

$$S_0=\left(\frac{dV}{dq}\right)_{q=0} \qquad (6)$$

This is the reciprocal if the initial capacitance defined by

$$C_0=\left(\frac{dq}{dV}\right)_{q=0} \qquad (7)$$

The quantity

$$S_i=\left(\frac{dV}{dq}\right)=S_0\cosh(aq) \qquad (8)$$

is the incremental elastance and

$$C_i=\frac{dq}{dV}=\frac{1}{S_0\cosh(aq)}=\frac{C_0}{\cosh(aq)} \qquad (9)$$

is the incremental capacitance.

It may be noted that the quantity a is a measure of the degree of the nonlinearity of the nonlinear capacitor. That is, if $a=0$, we have the linear case, and then $S_i=S_0$, and $C_i=C_0$.

The variation of the incremental capacitance with the charge separation of the capacitor is indicated graphically by Figure 3.

The No-Load Characteristics of the Nonlinear Capacitor

Before considering the general series circuit of Figure 1, it is instructive to consider the case for which $R=0$ and $L=0$. In this case we have a nonlinear capacitor in series with the electromotive force, $E_0+E_m\sin(\omega t)$ since it is not necessary to consider the phase angle, θ because of the absence of the resistance term. Equation 1 now reduces to

$$\frac{S_0}{a}\sinh(aq)=E_0+E_m\sin(\omega t)=E(t) \qquad (10)$$

Hence

$$\sinh(aq)=\frac{aE(t)}{S_0} \qquad (11)$$

and

$$q=\frac{1}{a}\sinh^{-1}\left[\frac{aE(t)}{S_0}\right] \qquad (12)$$

The current in the circuit is given by

$$i=\frac{dq}{dt}=\frac{\left(\frac{dE}{dt}\right)}{\sqrt{a^2E^2(t)S_0^2}} \qquad (13)$$

but

$$\left(\frac{dE}{dt}\right)=\omega E_m\cos(\omega t) \qquad (14)$$

Hence

$$i=\frac{\omega E_m\cos(\omega t)}{\sqrt{a^2[E_0E_m\sin\omega t]^2+S_0^2}} \qquad (15)$$

This is the current in the circuit. If the bias potential E_0 is large compared with the amplitude of the harmonic potential E_m, we have

$$E_0>>E_m \qquad (16)$$

and equation 14 gives the following approximate value for the current

$$i=\frac{\omega E_m\cos(\omega t)}{\sqrt{a^2E^2+S_0^2}} \qquad (17)$$

It may be seen by considering equation 17 that an increase of the bias potential decreases the amplitude of the current and vice versa. The increase of the effective impedance of the nonlinear capacitor with an increase of the bias potential E_0 is the principle on which dielectric amplifiers operate.

The Minimum Mean Squared Error Method for Solving Nonlinear Differential Equations

A method for the approximate solution of a class of nonlinear differential equations in the steady state will now be described. It will be applied to several special cases of the circuit of Figure 1 in later sections.

$$L\ddot{q}+G(\dot{q})+V(q)=E_0+E_1\sin(\omega t)+E_2\cos(\omega t) \qquad (18)$$

where

$$E_1=E_m\cos(\theta) \qquad (19)$$

$$E_2=E_m\sin(\theta) \qquad (20)$$

Hence

$$E_m=\sqrt{E_1^2+E_2^2} \qquad (21)$$

and

$$\tan(\theta)=\frac{E_2}{E_1} \qquad (22)$$

Now from the general theory of differential equations it is known that the equation 18 has solutions, $q(t)$, that are uniquely determined when $q(0)$ and $\dot{q}(0)$ are prescribed, that is, the inital charge separation on the plates of the capacitor and the initial current of the circuit are given and it is clear that solutions of equation 18 that are not periodic exist. Experimental observations of dynamical systems whose equations of motion are of the form of equation 18 indicate that after some transient dis-

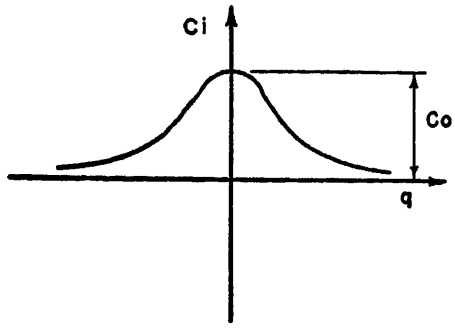

Figure 3. Incremental capacitance

turbances die out the motions of these systems tend to become periodic as the time increases. The experimental and theoretical literature on the subject is devoted almost entirely to the periodic or steady-state solutions.[14,15]

In this analysis, a simple 1-term approximation of the periodic solution of equation 18 will be assumed in the form

$$q_o=A\sin(\omega t)+B=A\sin(T)+B \tag{23}$$

where

$$T=(\omega t) \tag{24}$$

The assumed solution equation 23 may be regarded as the constant and fundamental term of the Fourier series expansion of a general periodic solution whose period is the same as that of the applied harmonic potential.

Let the approximate solution equation 23 be substituted into the left member of equation 18. The resulting equation may be written in the form

$$L\ddot{q}_o+G(\dot{q}_o)+V(q_o)=E_0+E_1\sin(T)+E_2\cos(T)+H(T) \tag{25}$$

Where $H(T)$ is the error introduced because of the approximate nature of the assumed solution q_o.

Let

$$\begin{aligned}F(T)&=L\ddot{q}_o+G(\dot{q}_o)+V(q_o)\\&=-\omega^2LA\sin(T)+G(\omega A\cos T)+V(A\sin T+B)\end{aligned} \tag{26}$$

As a consequence of equations 25 and 26, the error $H(T)$ may be expressed in the form

$$H(T)=F(T)-[E_0+E_1\sin(T)+E_2\cos(T)] \tag{27}$$

The quantity

$$M=\frac{1}{2\pi}\int_0^{2\pi}H^2(T)dT \tag{28}$$

is the mean squared error of the approximate solution taken over a cycle of the oscillation.

It is desired to use equation 27 in some manner to determine the relation between the amplitudes A and B and the constants E_0, E_1 and E_2. To do this, an arbitrary requirement that the mean squared error as defined by equation 28 shall be a minimum will now be imposed. This requirement is suggested by Legendre's principle of "least possible error," and his "method of least squares."[16]

In order to apply the principle of the minimum of the mean squared error to the present situation, the integral, equation 28, will be regarded as a function of E_0, E_1, and E_2. The necessary conditions that M be a minimum are

$$\begin{aligned}\frac{\partial M}{\partial E_0}&=\frac{1}{2\pi}\int_0^{2\pi}\frac{\partial}{\partial E_0}[H^2(T)]dT\\&=-\frac{1}{\pi}\int_0^{2\pi}H(T)dT=0\end{aligned} \tag{29}$$

$$\begin{aligned}\frac{\partial M}{\partial E_1}&=\frac{1}{2\pi}\int_0^{2\pi}\frac{\partial}{\partial E_1}[H^2(T)]dT\\&=-\frac{1}{\pi}\int_0^{2\pi}H(T)\sin(T)dT=0\end{aligned} \tag{30}$$

$$\begin{aligned}\frac{\partial M}{\partial E_2}&=\frac{1}{2\pi}\int_0^{2\pi}\frac{\partial}{\partial E_2}[H^2(T)]dT\\&=-\frac{1}{\pi}\int_0^{2\pi}H(T)\cos(T)dT=0\end{aligned} \tag{31}$$

If the conditions of equations 29, 30 and 31 are used, the following equations are obtained by the integration of equation 27.

$$\int_0^{2\pi}F(T)dT=2\pi E_0 \tag{32}$$

$$\int_0^{2\pi}F(T)\sin(T)dT=\pi E_1 \tag{33}$$

$$\int_0^{2\pi}F(T)\cos(T)dT=\pi E_2 \tag{34}$$

An estimation of the mean squared error may be obtained by a direct integration of equation 28 and the use of equations 32, 33, and 34. After some reductions, the expression may be put into the following form

$$\begin{aligned}M&=\frac{1}{2\pi}\int_0^{2\pi}H^2(T)dT\\&=\frac{1}{2\pi}\int_0^{2}F^2(T)dT-\left[E_0^2+\frac{E_m^2}{2}\right]\end{aligned} \tag{35}$$

This expression is frequently useful in determining the degree of accuracy of the solution by this method.

Equations 32, 33, and 34 give the desired relations between the amplitudes A and B of the assumed solution, equation 23, and the given potential and amplitude E_0 and E_m. Since

$$E_1^2+E_2^2=E_m^2 \tag{36}$$

it can be seen that equations 32 and 36 are two simultaneous equations to determine the unknowns A and B in terms of the known quantities E_0 and E_m. When A and B have been determined, equation 34 fixes E_2 and the phase angle θ between the impressed potential, and the assumed solution is determined by the equation.

$$\sin(\theta)=\frac{E_2}{E_m} \tag{37}$$

This indicates the general procedure of the minimum mean squared error method of solution. The general method will now be applied to the general series circuit under consideration.

Minimum Error Squared Analysis of the General Series Circuit

The differential equation of the general series circuit containing a nonlinear capacitor is

$$L\ddot{q}+R\dot{q}+\frac{S_0}{a}\sinh(aq)=E_0+E_1\sin(T)+E_2\cos(T) \tag{38}$$

For this case, the general function $G(\dot{q})$ and $V(a)$ of equation 25 reduce to

$$G(\dot{q})=R\dot{q} \tag{39}$$

and

$$V(q)=\frac{S_0}{a}\sinh(aq) \tag{40}$$

We also have

$$F(T)=-\omega^2LA\sin(T)+R\omega A\cos(T)+V(q_0) \tag{41}$$

where

$$\begin{aligned}V(q_0)&=\frac{S_0}{a}\sinh(aq_0)=\frac{S_0}{a}\times\sinh[a(A\sin T+B)]\\&=\frac{S_0}{a}\sinh[P\sin T+Q]\\&=\frac{S_0}{a}\sinh(P\sin T)\cosh(Q)+\frac{S_0}{a}\cosh(P\sin T)\sinh(Q)\end{aligned} \tag{42}$$

and

$$P=aA,\ Q=aB \tag{43}$$

The following identities are established in works on Bessel functions.[17]

$$\sinh(P\sin T)=2\sum_{n=0}^{\infty}(-1)^nI(2n+1)\times(P)\sin(2n+1)T \tag{44}$$

and

$$\cosh(P\sin T)=I_0(P)+2\sum_{n=1}^{\infty}(-1)^nI_{2n}(P)\cos(2nT) \tag{45}$$

The functions $I_n(P)$ are the modified Bessel functions of the first kind of order n and argument P. These functions have been extensively tabulated.[18]

As a consequence of equations 44 and and 45, it can be seen that $V(q_0)$ may be written in the following form

$$V(q_0)=\frac{S_0}{a}I_0(P)\sinh(Q)+\frac{2S_0}{a}I_1(P)\cosh(Q)\sin(T)+\phi(T) \quad (46)$$

where the function $\phi(T)$ contains sines and cosines of multiples of T.

Therefore equation 41 reduces to

$$F(T)=\frac{S_0}{a}I_0(P)\sinh(Q)+\left[\frac{2S_0}{a}I_1(P)\cosh(Q)-\omega^2LA\right]\times \sin(T)+R\omega A\cos(T)+\phi(T) \quad (47)$$

The function $\phi(T)$ has the property that

$$\int_0^{2\pi}\phi(T)dT=0$$
$$\int_0^{2\pi}\phi(T)\sin(T)dT=0 \quad (48)$$
$$\int_0^{2\pi}\phi(T)\cos(T)dT=0$$

as a consequence of the orthogonality property of the trigonometric functions. In this case, equations 32, 33 and 34 reduce to

$$\frac{S_0}{a}I_0(P)\sinh(Q)=E_0 \quad (49)$$

$$\frac{2S_0}{a}I_1(P)\cosh(Q)-\omega^2\frac{LP}{a}=E_1 \quad (50)$$

$$\frac{R\omega P}{a}=E_2 \quad (51)$$

These equations determine P and Q and the phase angle θ. From P and Q, A, and B may be determined by the use of equation 43.

CALCULATION OF AMPLITUDES OF STEADY-STATE OSCILLATION

If equations 50 and 51 are squared and added together, the result may be written in the following form

$$[2S_0I_1(P)\cosh(Q)-\omega^2LP]^2+R^2\omega^2P^2=a^2E_m^2 \quad (52)$$

or

$$2S_0I_1(P)\cosh(Q)=\omega^2LP+\sqrt{a^2E_m^2-R^2\omega^2P^2} \quad (53)$$

From equation 49 we have

$$\sinh(Q)=\frac{aE_0}{S_0I_0(P)} \quad (54)$$

By the use of hyperbolic trigonometry we obtain

$$\cosh(Q)=\sqrt{1-\sinh^2(Q)}=\sqrt{1\frac{a^2E_0^2}{S_0^2I_0^2(P)}} \quad (55)$$

If this value of cosh (Q) is substituted into equation 53, the resulting equation is

$$\frac{2I_1(P)}{I_0(P)}\sqrt{S_0^2I_0^2(P)+a^2E_0^2}=\omega^2LP+\sqrt{a^2E_m^2-R^2\omega^2P^2} \quad (56)$$

This is a transcendental equation for P. If numerical values of the parameters of the circuit are available, it may be solved graphically by plotting the left and right members as functions of P and determining the point of intersection of the two curves obtained in this manner.

After the value of P has been thus determined, equation 53 may be used to determine Q and the result written as

$$Q=\sinh^{-1}\frac{[aE_0]}{S_0I_0(P)} \quad (57)$$

As a consequence of equation 20, the required phase angle is given by

$$\sin(\theta)=\frac{E_2}{E_m}=\frac{R\omega P}{aE_m} \quad (58)$$

Therefore when P is known, θ may be determined by equation 58. In this manner the steady-state oscillation of the charge q, of the general circuit is given by

$$q_0=\frac{P}{a}\sin(\omega t)+\frac{Q}{a} \quad (59)$$

and the steady-state current is

$$i_0=\dot{q}_0=\frac{P\omega}{a}\cos(\omega t) \quad (60)$$

as a result of the applied potential

$$E(t)=E_0+E_m\sin(\omega t+\theta) \quad (61)$$

The phase angle θ between the applied harmonic potential and the oscillation of the charge is

$$\theta=\sin^{-1}\frac{[R\omega P]}{aE_m} \quad (62)$$

This outlines the general method of obtaining the approximate steady-state response of the system by the minimum error squared method of analysis. Several special cases of practical importance will now be discussed.

Case of Negligible Resistance and Inductance and $E_0>>E_m$

The case in which the circuit has no resistance or inductance and a large bias potential in comparison with the amplitude of the harmonic potential has been discussed in the section entitled "The No-Load Characteristics of the Nonlinear Capacitor." It is instructive to discuss it as a special case of the method of the section entitled "Minimum Error Squared Analysis of General Series Circuit" with the condition that

$$R=L=0 \quad (63)$$

It will also be assumed that the bias potential E_0 is considerably greater than the maximum value of the applied harmonic potential E_m.

As a consequence of equation 63, equation 56 reduces to

$$\frac{2I_1(P)}{I_0(P)}\sqrt{S_0^2I_0^2(P)+a^2E_0^2}=aE_m \quad (64)$$

The modified Bessel functions $I_0(P)$ and $I_1(P)$ have the following power series expansions.[17]

$$I_0(P)=1+\frac{P^2}{2^2}+\frac{P^4}{2^2\cdot4^2}+\frac{P^6}{2^2\cdot4^2\cdot6^2}+\dots \quad (65)$$

$$I_1(P)=\frac{P}{2}\left(1+\frac{P^2}{2^2\cdot2}+\frac{P^4}{2\cdot2^4\cdot2\cdot3}+\dots\right) \quad (66)$$

In this case equation 50 reduces to

$$2S_0I_1(P)\cosh(Q)=aE_1 \quad (67)$$

Now since E_m is assumed small, therefore aE_1 is also small and because cosh(Q) is never less than 1, it follows that $I_1(P)$ is small and hence may be replaced by the first term of its power series expansion, equation 66. Hence we have in this case

$$I_1(P)\doteq\frac{P}{2} \quad (68)$$

and

$$I_0(P)\doteq1 \quad (69)$$

Therefore equation 64 reduces to

$$P\sqrt{(S_0^2+a^2E_0^2)}=aE_m \quad (70)$$

or

$$P=\frac{aE_m}{\sqrt{S_0^2+a^2E_0^2}} \quad (71)$$

and as a consequence of equation 57 we have

$$Q=\sinh^{-1}\frac{[aE_0]}{S_0} \quad (72)$$

By equation 60 the steady-state current is

$$i_0=\frac{\omega E_m\cos(\omega t)}{\sqrt{S_0^2+a^2E^2}} \quad (73)$$

This result agrees with equation 16.

General Case with Large Bias Potential

The general case for which the condition

$$E_0 >> E_m \tag{74}$$

is satisfied will now be considered because of its practical importance. Since the assumed value of E_m is small, it follows that aE_1 and aE_2 are small quantities and hence as a consequence of equations 50 and 51 the value that P can take is so small that the Bessel functions, $I_0(P)$ and $I_1(P)$ may be replaced by the first terms of their Mclaurin series expansions equations 65 and 66 as given by equations 68 and 69. Hence equation 52 now takes the form

$$[PS_0 \cosh(Q) - \omega^2 LP]^2 + R^2\omega^2P^2 = a^2E_m^2 \tag{75}$$

or

$$P = \frac{aE_m}{\sqrt{R^2\omega^2 + [S_0 \cosh(Q) - \omega^2 L]^2}} \tag{76}$$

and equation 49 now takes the form

$$\sinh(Q) = \frac{aE_0}{S_0} \tag{77}$$

Hence

$$S_0 \cosh(Q) = \sqrt{S_0^2 + a^2E_0^2} \tag{78}$$

If equations 76, 77, and 78 are substituted into equation 59, the following result is obtained.

$$q_0 = \frac{E_m \sin(\omega t)}{\sqrt{R^2\omega^2 + \sqrt{[S_0^2a^2E_0^2] - \omega^2 L)^2}}} + \frac{1}{a} \sinh^{-1} \frac{[aE_0]}{S_0} \tag{79}$$

The phase angle is given by equation 58 in the form

$$\sin(\theta) = \frac{R\omega}{\sqrt{R^2\omega^2 + [\sqrt{(S_0^2 + a^2E_0^2)} - \omega^2 L]^2}} \tag{80}$$

If $a=0$, equation 79 reduces to the usual linear solution for steady-state charge oscillation

$$q_0 = \frac{E_m \sin(\omega t)}{\sqrt{R^2\omega^2 + (S_0^2 - \omega^2 L)^2}} + \frac{E_0}{S_0} \tag{81}$$

The steady-state current oscillation of the circuit may be written in the form

$$i_0 = \dot{q}_0 = \frac{E_m \cos(\omega t)}{\sqrt{R^2 + \left[\omega L - \frac{1}{\omega}\sqrt{(S_0^2 + a^2E_0^2)}\right]^2}} \tag{82}$$

The effect of the bias potential in increasing the effective impedance of the circuit is clearly evident.

Natural Frequency of Free Oscillations

Equation 50 may be used to determine the natural frequency of the free oscillations of the circuit in the absence of applied electromotive forces and resistance. To study this case we have

$$E_0 = E_m = R = 0 \tag{83}$$

Hence $E_1 = E_2 = 0$ and $Q=0$ by equation 49. Equation 50 now reduces to

$$2S_0I_1(P) = \omega^2 LP \tag{84}$$

Hence

$$\omega^2 = \frac{2S_0}{LP} I_1(P) \tag{85}$$

This equation determines the angular frequency ω of the free oscillations of the circuit in the form

$$q = A \sin(\omega t) \tag{86}$$

Since the amplitude A is related to P by $aA = P$, equation 85 may be written in terms of the amplitude, in the following manner.

$$\omega^2 = \frac{2S_0I_1(aA)}{LaA} \tag{87}$$

In the linear case, $a=0$ and equation 87 becomes indeterminate. The indeterminate form may be evaluated by taking $I_1(aA) = aA/2$ by equation 66 and we have

$$\omega^2 = \frac{S_0}{L}, \text{ or } \omega = \sqrt{\frac{S_0}{L}} = \sqrt{\frac{1}{LC_0}} \tag{88}$$

for this case.

In the general nonlinear case however, the natural frequency is a function of the amplitude A and is given by equation 87 when the amplitude is known.

Conclusion

The analysis presented in this paper is an attempt to apply the method of "the least mean square error" to the solution of the basic equation of the general series circuit containing a nonlinear capacitor. Although the analysis is based on the representation of the saturation curve of the nonlinear capacitor $V(q)$ by a hyperbolic function, this is not necessary. The general procedure of the method as described in one section entitled "Minimum Error Squared Analysis of the General Series Circuit" may be applied to functions $V(q)$ represented by other analytical expressions. The least mean square error method may be used to obtain approximate expressions for the harmonic steady-state oscillations of many nonlinear electric circuits of practical importance.

Discussion

Thomas M. Stout (University of Washington, Seattle, Wash.): This paper, possibly the first to analyze a resonant circuit containing a nonlinear capacitor, is an interesting and useful addition to the general literature on nonlinear dynamic systems. One implication of the paper, however, seems to merit some discussion.

Professor Pipes states that his equation 1 is "Duffing's equation" and cites a number of references in which this equation is discussed. The uninitiated reader might easily get the idea that the equation considered in this paper has already been solved by other methods and that solutions to this circuit problem could have been obtained by suitable interpretation of existing solutions. Study of several of the references indicates that this is probably not the case.

For example, Stoker[1] first discusses (page 83) the equation

$$\ddot{x}+c\dot{x}+(\alpha x+\beta x^3)=F\cos\omega t \qquad (1)$$

which he describes as Duffing's equation. Later (page 112) he considers the equation

$$\ddot{x}+\alpha x-\beta x^3=H_1\cos\omega_1 t+H_2\cos\omega_2 t \qquad (2)$$

and tabulates (pages 116–17) solutions of these equations for various special cases.

McLachlan[2] discusses the two equations

$$\ddot{y}+ay+by^3=f\cos\omega t \qquad (3)$$

$$\ddot{y}+2k\dot{y}+ay+by^3=f\cos(\omega t+\phi) \qquad (4)$$

Lyon and Edgerton[3] consider the equation

$$P_j\ddot{\theta}+P_d\dot{\theta}+P_m\sin\theta=P_0+P_L \qquad (5)$$

in which P_0 is the initial load on the synchronous machine and P_L is a suddenly applied constant load.

These investigators, at least, do not consider a forcing function which is a constant plus a sinusoid, as Pipes does. Because solutions of nonlinear differential equations cannot be superimposed, any solutions for these other forcing functions are not very useful in the present problem. The analysis which Pipes presents is evidently not an alternative procedure for obtaining known solutions, but a treatment of a previously unsolved problem.

This impression is strengthened by attempts to use his equation 1 in analyzing a series resonant circuit containing a nonlinear inductor. Both Stoker[1] and Minorsky[4] indicate that the differential equation of this circuit might be written as

$$\ddot{\phi}+\frac{1}{C}(\alpha\phi-\beta\phi^3)=0 \qquad (6)$$

where ϕ is the magnetic flux, if the circuit contains no resistance and no voltage sources; this is presumably the sort of equation referred to by Pipes.[5] The second restriction is not essential, but including the resistive term leads to an equation similar to equation 2 of the paper, as Keller shows,[6] not to equation 1. While the method described in this paper would be applicable for Keller, the solutions are not interchangeable.

Many investigations of circuits containing nonlinear inductors have been made, and much labor could be saved if the results of this work could be used to explain the properties of circuits containing nonlinear capacitors. Study of this attractive possibility has led to consideration of the principle of duality as it applies to nonlinear systems.[7]

As in the case of linear networks, the dual of a nonlinear network is obtained by replacing voltages by currents, currents by voltages, inductance by capacitance, resistance by conductance, capacitance by inductance, and series circuits by parallel circuits. A nonlinear inductor becomes a nonlinear capacitor, and conversely. Two examples of series nonlinear circuits and their duals are given in Figure 1 of this discussion.

For complete correspondence between the original network and its dual, the nature of the nonlinearity should be such that one analytic approximation can be used. Surprisingly or naturally enough, depending on the viewpoint, it happens that this is possible for the ordinary nonlinear dielectric and magnetic materials. The hyperbolic sine employed by Pipes is a permissible, though not entirely satisfactory, approximation to the magnetization curve for some materials and has been used in work on magnetic amplifiers.[8–12]

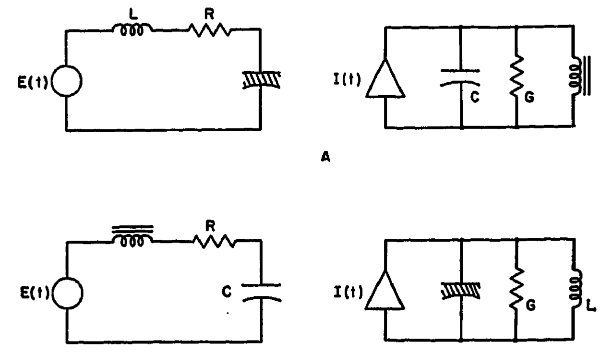

Figure 1. Two series resonant circuits containing a nonlinear element and their duals

Following the pattern of equation 5 of the paper, we can write that the current in an iron-core inductor is

$$i_L=\frac{1}{bL_0}\sinh b\lambda \qquad (7)$$

where b is a parameter used in curve fitting, L_0 is the initial inductance, and $\lambda=N\phi$, the flux linkages. In the linear case, $b=0$ and $L=L_0$.

If this approximation can be used, the circuits shown in Figure 1 of the discussion are complete duals and solutions can be interchanged merely by changing the notation. Consider the circuit treated by Pipes, Figure 1(A) of the discussion. The equations for this circuit are

$$e_c=E(t)-Ri-L\frac{di}{dt} \qquad (8)$$

$$=\frac{1}{aC_0}\sinh aq \qquad (9)$$

$$q=\int i\,dt \qquad (10)$$

For the parallel circuit which is the dual of this series circuit, the corresponding equations are

$$i_L=I(t)-Ge-C\frac{de}{dt} \qquad (11)$$

$$=\frac{1}{bL_0}\sinh b\lambda \qquad (7)$$

$$\lambda=\int e\,dt \qquad (12)$$

The duality of the other pair of circuits can be established in similar fashion.

Professor Pipes has made an important contribution to the collection of solutions available for series resonant circuits containing a nonlinear element. Solutions for the dual parallel circuits can be obtained with very little additional labor.

Y. H. Ku (University of Pennsylvania, Philadelphia, Pa.): I should like to congratulate Professor Pipes for his fine contribution to the mathematical analysis of a nonlinear problem. With the recollecting that Dr. Pipes has previously analyzed the nonlinear problem with a variable inductance, it occurs to me that a series circuit with nonlinear inductance and nonlinear capacitance may be further studied by various methods. A series circuit with the elements R, L, C is truly a simple circuit. However, when one, two, or three elements of this series circuit become nonlinear, the solution will be rather complicated. We need more analytical results[1–5] and yet we like to see some of these results expressed in graphical form.[2–5] Besides the isocline method and the Liénard construction, it may be mentioned that another graphical method has been presented.[6]

Louis A. Pipes: Professor Stout emphasizes the fact that solutions of nonlinear differential equations cannot be superimposed and that because of this, addition of terms to a nonlinear equation frequently changes entirely the method required for its solution. For this reason, it is desirable to consider the system being analyzed in its most general form wherever possible. The procedure for extending the applicability of known solutions to other systems by the use of the principle of duality, as suggested by Professor Stout, appears to be a very useful one. The full consideration and extension of this process seems to be a very promising field for future investigation.

As Professor Ku has pointed out, graphical or topological methods are very valuable and powerful in the analysis of nonlinear differential equations. The graphical methods of the phase-plane have been widely used in the analysis of autonomous systems. The differential equations of these systems are characterized by the fact that the independent variable t does not appear explicitly in the equation. The system considered in the paper is a nonautonomous system and the differential equation that governs its behaviour contains the independent variable t explicitly. The presence of the variable t makes it necessary to modify the isocline and the Liénard techniques considerably before they can be adapted to the solution of this problem.

Professor L. S. Jacobsen has given a powerful graphical procedure for the solution of the differential equations of nonautonomous systems if they are of the second order.[1]

Influence of A-C Reactance on Voltage Regulation of 6-Phase Rectifiers

R. L. WITZKE
FELLOW AIEE

J. V. KRESSER
MEMBER AIEE

J. K. DILLARD
ASSOCIATE MEMBER AIEE

INVESTIGATIONS made during the past few years have shown that methods normally used for the calculation of rectifier voltage regulation have definite limitations not generally appreciated by application engineers. It has been established that conventional methods of calculating regulation are valid only if the angle of overlap is less than 360 degrees divided by the number of phases. With larger overlap angles any a-c reactance common to two or more simple rectifiers introduces a delay angle, even though the rectifiers are operated without intentional delay. This inherent delay reduces the direct voltage and therefore increases the voltage regulation. In special applications involving large overlap angles, these limitations are of primary importance, because considerable error is possible if they are not recognized.

The purpose of this paper is to discuss the influence of common a-c reactance on the operation of 6-phase rectifiers, to present equations that can be used to calculate regulation in applications where conventional equations are not applicable, and to present curves for estimating rectifier voltage regulation.

Nomenclature

α = angle of forced commutation delay
δ = angle of simultaneous commutation at each end of the commutating period
$\omega = 2\pi f$
$E_{a,b,c}$ = source line-to-neutral instantaneous voltages
$E_{a',b',c'}$ = transformer primary line-to-neutral instantaneous voltages
$E_{1,2,3}$ = instantaneous anode voltages
e_d = instantaneous direct voltage under load
E_d = average direct voltage under load
E_{do} = average direct voltage at no-load
E_s = transformer secondary line-to-neutral rms voltage at no load
i = instantaneous value of commutation current
$i_{a,b,c}$ = instantaneous alternating currents in source
I_c = commutated direct current
I_cX_c/E_s = reactance factor based on commutated direct current
I_d = load current
L = commutating inductance
$p = d/dt$
t = time in seconds
u = commutating (overlap) angle
X_c = commutating reactance $= X_s + X_t$
X_s = source reactance only
X_t = reactance in transformer circuit only

Summary

Mathematical expressions have been derived for calculating the voltage regulation of the delta, 6-phase, delta, double-way (full-wave bridge) rectifier for load currents between zero and short-circuit values. Calculated curves are presented for estimating voltage regulation. In addition, regulation curves obtained in the laboratory are included to substantiate the general trend of the calculated curves.

The analysis is based on rectifiers operating without phase control; that is, the direct voltage is not controlled by delaying the firing time of ignitor circuits or by grid control. As is customary, the load circuit is assumed to have sufficient inductance to sustain an essentially flat-topped load current.

Although this paper deals with specific transformer connections, by following a similar analysis it can be shown that the equations derived are not affected by transformer connection. The most common basic rectifier power circuit is the 6-phase double-wye. Since double-wye rectifier transformers are constructed with the secondary windings closely linked together, the reactance between secondary windings is small compared to the leakage reactance between the primary and either secondary winding.[1] If the leakage reactance between secondaries is zero, the double-wye primary circuit reduces to the same circuit as that of the full-wave bridge. Therefore, for practical purposes the curves and equations presented in this paper are valid for double-wye circuits.

In this paper it is shown that there are three modes of operation, as load current is varied from zero to short-circuit value. In the first mode of operation, as load current is increased from no load, the commutating or overlap angle u increases from zero to 60 degrees. During the second mode, the commutating angle is fixed at 60 degrees, but the start of commutation is delayed by an inherent delay angle α, which varies between zero and 30 degrees as the rectifier supplies increasing load current. The angle of inherent delay does not increase during the third mode, while the commutating angle increases to 120 degrees at short circuit. The three modes of operation are summarized in Table I, where I_cX_c/E_s = reactance factor based on commutated direct current.

In the full-wave bridge circuit the commutated direct current I_c is the same as the load current I_d. In the double-wye

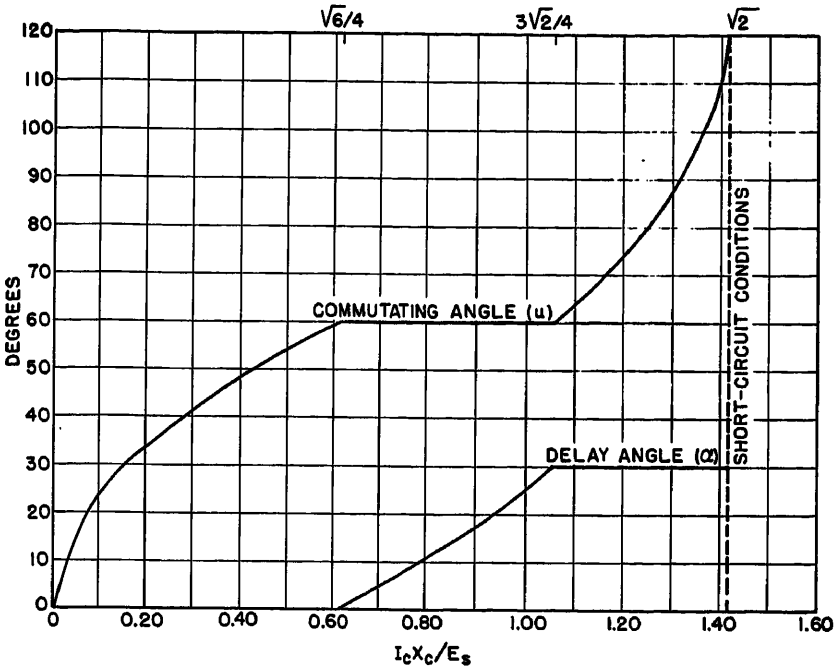

Fig. 1. Commutating angle and forced delay angle in 6-phase bridge rectifier

rectifier the commutated direct current is one-half of the load current.

Calculated values of commutating angle u and angle of inherent delay α are plotted against reactance factors in Fig. 1. The ratio of direct voltage to no-load direct voltage (E_d/E_{do}) is plotted against reactance factors in Fig. 2. Reactance factors may be converted to per-unit reactance drop by multiplying by $2/\sqrt{6}$. This figure is obtained by expressing I_cX_c in per unit on the transformer primary kilovolt-ampere base. Equations used in calculating the curves are derived in the appendix and for convenience are summarized now.

Mode 1,

$$u \leqq 60°,\ \alpha=0, \frac{I_cX_c}{E_s} \leqq \frac{\sqrt{6}}{4}$$

$$\frac{I_cX_c}{E_s}=\frac{\sqrt{6}}{2}(1-\cos u)$$

$$\frac{E_c}{E_{do}}=1-\frac{I_cX_c}{\sqrt{6}E_s}$$

Mode 2,

$$u=60°,\ \alpha \leqq 30°,\ \frac{\sqrt{6}}{4} \leqq \frac{I_cX_c}{E_s} \leqq \frac{3\sqrt{2}}{4}$$

$$\frac{I_cX_c}{E_s}=\frac{\sqrt{6}}{2}\sin(\alpha+30°)$$

Table I. Three Modes of Operation

Mode	u	α	I_cX_c/E_s
1......	0→60	0	$0\to\sqrt{6}/4$
2......	60	0→30....	$\sqrt{6}/4\to(3\sqrt{2})/4$
3......	60→120....	30	$(3\sqrt{2})/4\to\sqrt{2}$

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}}{2}\cos(\alpha+30°)$$

Mode 3,

$$60° \leqq u \leqq 120°,\ \alpha=30°,$$
$$\frac{3\sqrt{2}}{4} \leqq \frac{I_cX_c}{E_s} \leqq \sqrt{2}$$

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}}{2}[1-\sin(u-30°)]$$

$$\frac{I_cX_c}{E_s}=\frac{\sqrt{2}}{2}+\frac{\sqrt{6}}{4}\sin u-\frac{\sqrt{2}}{4}\cos u$$

Qualitative Discussion

A 3-phase double-way rectifier, commonly referred to as a 6-phase bridge or a full-wave bridge rectifier, is shown in Fig. 3. It consists of two simple rectifiers, group I and group II, in series across the d-c bus. The total reactance to the rectifying elements, including transformer and source reactance, which in this circuit are directly additive when on the same base, is designated as the commutating reactance X_c. In the discussion to follow, the line-to-neutral voltages (E_a, E_b, and E_c) back of the commutating reactance are assumed to have *a-b-c* phase rotation. Line-to-neutral voltages on the rectifier side of the commutating reactance are designated as E_1, E_2, and E_3 for simple rectifier group I and $-E_1$, $-E_2$, and $-E_3$ for simple rectifier group II.

When the rectifier operates without phase control, that is, without delay, the tubes, or rectifying elements, T_1, T_2, T_3, T_4, T_5, and T_6, pick up or start to conduct in the sequence defined by the subscripts. These conductions start at times t_1, t_2, t_3, etc., as shown in Fig. 4. Normally, in calculating rectifier performance the line-to-neutral voltages on the two sides of the commutating reactance are assumed to be equal, that is, $E_1=E_a$, $E_2=E_b$, etc., as shown in Fig. 4. In many applications this assumption results in valid conclusions because the assumed relations do exist at the beginning of each conduction period. However, in many other applications this assumption is not valid and can result in considerable error. To illustrate the latter contention, consider the time interval following the start of conduction in tube T_1. During this period tubes T_4, T_5, and T_6 are conducting, and terminals 1 and 3 are short-circuited through T_1 and T_5, resulting in a system short-circuit current i flowing as illustrated in Fig. 3. From circuit theory the following relations are established

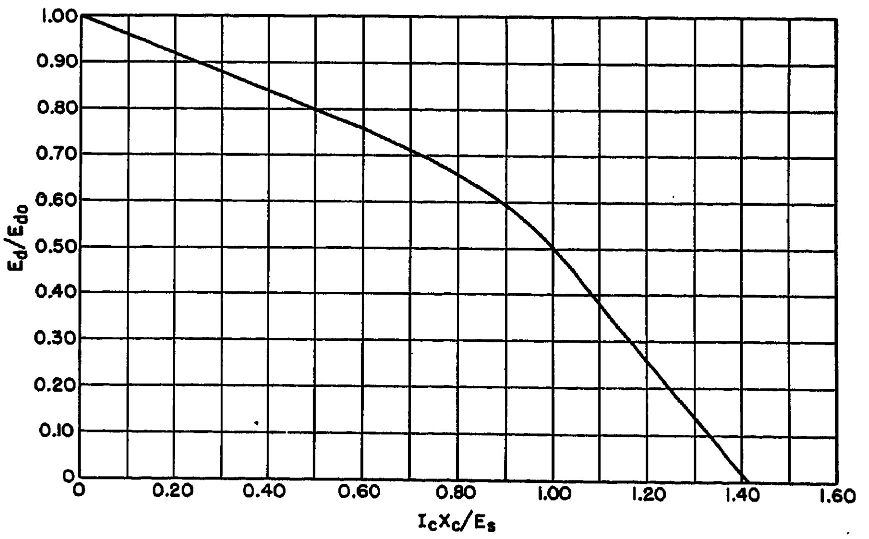

Fig. 2. Voltage regulation curve for 6-phase rectifier

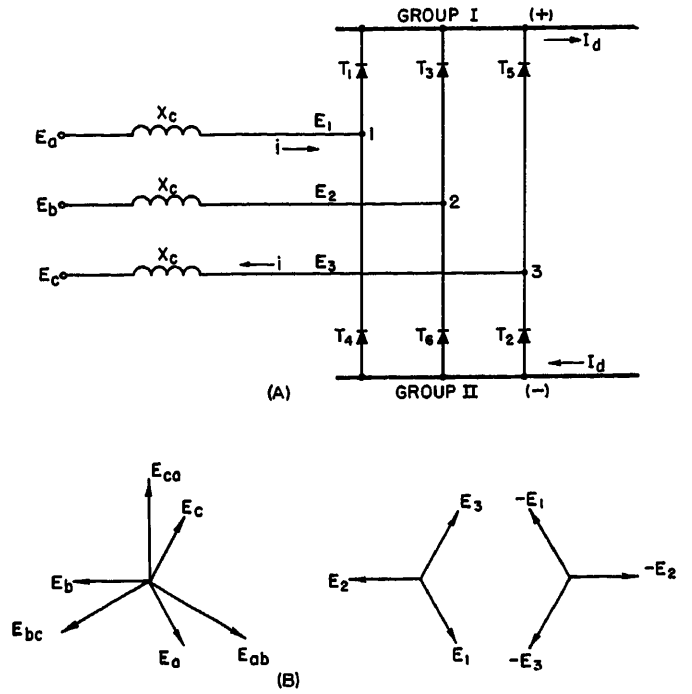

Fig. 3. Six-phase double-way rectifier circuit

A: Circuit diagram for bridge circuit

B: Voltage phasor diagrams

E_1, E_2, E_3 are line-to-neutral voltages associated with simple rectifier group I $-E_1$, $-E_2$, $-E_3$ are line-to-neutral voltages associated with simple rectifier group II

E_a, E_b, E_c are line-to-neutral voltages back of commutating reactance X_c, which includes both transformer and source reactance

$$i=\frac{E_a-E_c}{j2X_c}$$

$$-E_3=-(E_c+jiX_c)=\frac{E_b}{2}$$

$$-E_2=-E_b$$

Sixty degrees after tube T_1 picks up, tube T_2 should start to conduct; however, this conduction cannot start until voltages $-E_3$ and $-E_2$ are equal. Reference to Fig. 5 will show that these voltages are not equal until 30 degrees after time t_2, the instant of a normal, undelayed commutation, if the T_6 to T_1 commutation in group I has not been completed. Tube T_2 therefore cannot start to conduct until the group I commutation is completed, or until 30 degrees after commutation normally starts, whichever occurs first. In either event the rectifier operates with a forced, or inherent, delay whenever the angle of overlap, as calculated without delay, exceeds 60 degrees. All tubes will operate with the same delay because of symmetry.

Mathematical expressions are derived in the Appendix for all modes of operation from no-load to short-circuit conditions. The curves in Fig. 1 were calculated using these derived relations. For reactance factors between zero and $\sqrt{6}/4$ the delay angle is zero, and the angle of overlap varies between zero and 60 degrees. With reactance factors between $\sqrt{6}/4$ and $(3\sqrt{2})/4$ the overlap angle remains at 60 degrees, and the delay angle increases from zero to 30 degrees. Within this zone the rectifier operates with sufficient delay to commutate the load current within 60 degrees. One commutation starts just when the previous one ceases, no simultaneous commutations taking place. When the reactance factor is larger than $(3\sqrt{2})/4$, one commutation starts before the previous one ceases, and so simultaneous commutations occur. The delay

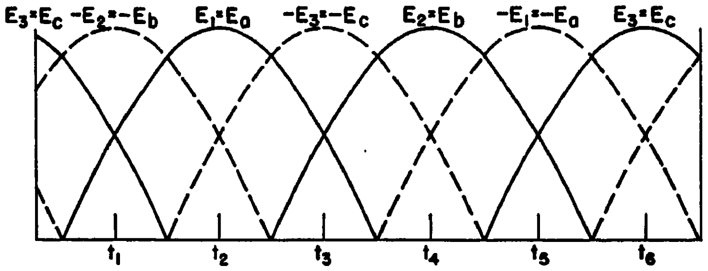

Fig. 4. Voltage relations normally assumed in calculating rectifier performance

angle remains at 30 degrees, and the overlap angle varies between 60 and 120 degrees; depending upon the reactance factor, which is $\sqrt{2}$ at short circuit.

It has been recognized previously that rectifiers pass through various modes of operation between no load and short circuit,[2,3] and the first two modes outlined here agree with previous work. The contention that the overlap angle increases beyond 60 degrees in the third mode differs from prior analyses.

Laboratory Studies

The analog computer, or Anacom, is a useful tool for studying complicated circuits where analytical solutions are difficult to obtain or require extensive calculations.[4] Both full-wave bridge and double-wye rectifiers were studied on the Anacom. Data taken on the Anacom substantiate the validity of the calculated curves and the mathematical expressions presented in this paper.

The full-wave bridge circuit was supplied from a 19-volt 3-phase source of low reactance, providing an essentially infinite bus. Anacom transformers are specially built on high-grade hypersil-steel cores, and require exciting currents which are negligible relative to the current base used in the laboratory study. These were connected to provide rectifier transformers with a line-to-line turns ratio of unity. The transformers have an inductance of 7 millihenrys per phase. Computer reactors of 93 millihenrys were connected in each phase, giving a total reactance of 37.7 ohms per phase.

One problem encountered in setting up the laboratory circuit was in finding rectifier elements having low voltage drop in the forward direction and very high impedance in the reverse direction. Selected selenium cells, about 2 inches in diameter, were found to have the best all-around characteristics. Forward and reverse volt-ampere curves for the cells used are shown in Fig. 6. The forward-direction volt-ampere curve is shown on an expanded scale in Fig. 7.

With a circuit which gave wave forms judged to be good when viewed on an oscilloscope, data shown on the regulation curve of Fig. 8 were taken. Data shown by crosses in Fig. 8 were corrected for voltage drop across the rectifier cells by adding the voltage drop corresponding to the load current, but no account was taken of losses in computer transformers and reactors. The total a-c resistance in the circuit used in the laboratory, including transformers, was 2.80 ohms per phase. Corrections were made for this resistance by dividing the watts loss in the a-c circuit by the current in the d-c circuit. In a 6-phase bridge, the current in the a-c circuit is 81.6 per cent of the load current. This is the conventional procedure of correcting for a-c circuit losses in rectifier circuits having low ratios of resistance to reactance. The circles in Fig. 8 were plotted from data corrected for voltage drop across the a-c circuit resistance. The solid line in Fig. 8 is the calculated voltage-regulation curve from Fig. 2.

Sample oscillograms made on the laboratory circuit are shown in Fig. 9. Oscillograms 9A, 9C, and 9E show the no-load line-to-line voltage on the rectifier side of the transformer, superimposed on the line-to-line voltage under load. Oscillograms 9B, 9D and 9F show anode-to-cathode voltages at no load and under load and a trace of the anode current under load.

Comparison of Laboratory and Theoretical Wave Shapes

To understand the operation of a full-wave bridge circuit more fully during the third mode of operation, it is helpful to deduce the voltage and current waves by physical reasoning. Line-to-line voltage, anode current, and anode-to-cathode voltage have been constructed for the case of 30 degrees inherent delay and 90 degrees overlap and the resulting wave forms compared with laboratory oscillograms.

Line-to-Line Voltage

Consider the circuit and vector diagrams shown in Fig. 3 and the corre-

E and F: $\alpha=30$ degrees, $u=60$ degrees

sponding sine curves of Fig. 10A. For the condition of 30 degrees inherent delay, commutation from tube T_5 to tube T_1 will occur at an angle α, after no-load voltages on the two tubes are equal. This has been shown in Fig. 5. At the time $(t_1+\alpha)$, when this commutation begins, T_4 and T_6 are already conducting, and a temporary 3-phase short circuit results. The plotted line-to-line voltage E_{12} is therefore zero and remains zero until the commutation T_4 to T_6 is completed 30 degrees later, at time t_2. At time t_2, T_4 goes out, and a temporary line-to-line short circuit remains through T_1 and T_5. The voltage relations are

$$E_1=E_3$$

$$E_{13}=E_1-E_3=0$$

$$E_{12}=E_1-E_2=-\frac{3}{2}E_2$$

Since a new tube must pick up every 60 degrees, the line-to-line short circuit lasts only 30 degrees, until time $(t_2+\alpha)$ when T_2 begins to conduct. A 3-phase short circuit is again impressed on the system, and the line-to-line voltage collapses to zero. After 30 degrees the commutation T_5 to T_1, which has lasted for the overlap period of 90 degrees, is completed, and T_5 goes out. As T_1, T_2, and T_6 are still conducting, the voltage relations are

$$E_2=E_3$$

$$E_{23}=E_2-E_3=0$$

$$E_{12}=E_1-E_2=\frac{3}{2}E_1$$

As before, this line-to-line short circuit lasts 30 degrees until T_3 picks up at time $(t_3+\alpha)$ to impose another 3-phase short circuit. The line-to-line voltage remains at zero for 30 degrees until T_6 goes out, at the end of the 90-degree commutating period of T_6 to T_2. At time t_4 three tubes are conducting: T_1, T_3, and T_2. Obviously there is a short circuit on the voltage E_{12}, and the voltage remains at zero to the end of the half-cycle $(t_4+\alpha)$. An extension of this analysis will produce the negative half-cycle of the line-to-line voltage.

ANODE CURRENT

This sequence of operation will be considered to plot, in Fig. 10, the anode current through tube T_1. When T_1 picks up at time $(t_1+\alpha)$, T_4, T_5, and T_6 are conducting. The circuit is shown in Fig. 11A. The steady-state current in T_1 is equal to the 3-phase fault current $-I_c$, which is 90 degrees behind the phase voltage E_3 producing it and has a crest value of $(\sqrt{2}E_s)/X_c$. At time $(t_1+\alpha)$, therefore, the current $-I_c$ is at a negative maximum, as shown in Fig. 10B. Since the current i_1 cannot change instantly because of circuit inductance, the current wave $-I_c$ must be displaced to zero to properly describe i_1 in the interval $(t_1+\alpha)$ to t_2. At time t_2, tube T_4 cuts off and T_1, T_5, and T_6 are left conducting, as shown in Fig. 11B. The steady-state current in T_1 is now fault current I_a for a phase-*a* to phase-*c* fault. For such a fault, I_a lags its phase voltage E_1 by 120 degrees, or is in phase with E_2. It has a crest value of $(\sqrt{2}\sqrt{3}E_s)/2X_c$. Since circuit inductance forces i_1 just before t_2 to be equal to i_1 just after t_2, current I_a must be displaced upward to coincide with i_1 at time t_2 to properly describe the current in the interval t_2 to $(t_2+\alpha)$.

At $(t_2+\alpha)$, when T_2 picks up, T_1, T_5, and T_6 are already conducting, as shown in Fig. 11C. The current i_1 becomes 3-phase fault current I_a, which leads $-I_c$ by 60 degrees. As before, this current must be displaced, and that portion of the wave between $(t_2+\alpha)$ and t_3 is the current i_1. At time t_3, tube T_5 cuts off, leaving T_1, T_2, and T_6 conducting. The current is then equal to I_a for the next 30 degrees.

When tube T_3 picks up at $(t_3+\alpha)$, a 3-phase short circuit is again imposed through the paths illustrated in Fig. 11D. The current i_1 is 3-phase fault current I_a, and may be displaced and plotted for the interval $(t_3+\alpha)$ to t_4. Tube T_6 cuts off at t_4, leaving a phase-*a* to phase-*b* fault, Fig. 11E. Current i_1 is equal to current I_a for a phase-*a* to phase-*b* fault and leads 3-phase fault current I_a by 30 degrees, as plotted in Fig. 10B. With the proper displacement to make i_1 equal just before and just after t_4, I_a represents i_1 in the interval t_4 to $(t_4+\alpha)$. At time $(t_4+\alpha)$, tube T_4 begins conduction with T_1, T_2, and T_3 already conducting. The 3-phase fault is shown in Fig. 11F, and current i_1 is equal to $-I_b$, for a 3-phase fault. This current, leading 3-phase fault current I_a by 60 degrees, is plotted in Fig. 10B, and describes i_1 in the interval $(t_4+\alpha)$ to t_6, to complete the conduction period of 210 degrees.

ANODE-TO-CATHODE VOLTAGE

The anode-to-cathode voltage readily follows from the plot of line-to-line voltage. Fig. 10C shows the theoretical trace of anode-to-cathode voltage for tube T_1. Reference to the circuit of Fig. 3 shows that whenever T_3 is conducting, the anode-to-cathode voltage of T_1 will be the same as line-to-line voltage E_{13} plotted in Fig. 10A, neglecting, of course, tube drop. Tube T_3 conducts from time $(t_3+\alpha)$ to t_1, a total of 210 degrees. At t_1, tube T_3 goes out, leaving T_5, T_4, and

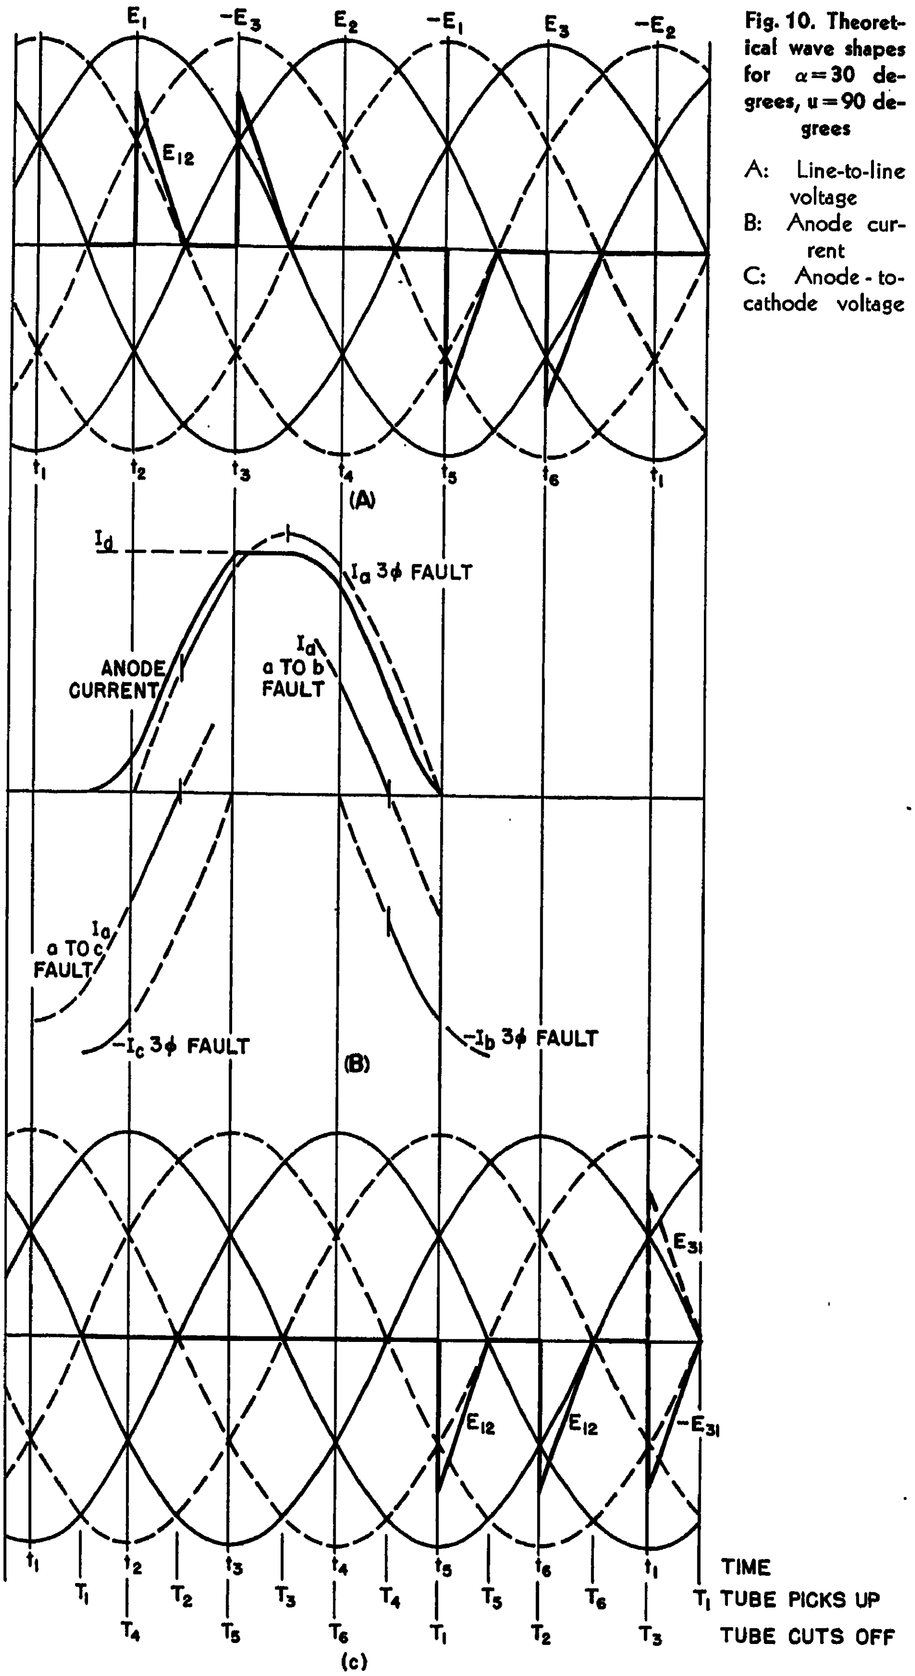

Fig. 10. Theoretical wave shapes for $\alpha = 30$ degrees, $u = 90$ degrees

A: Line-to-line voltage

B: Anode current

C: Anode-to-cathode voltage

T_6 conducting. The voltage across T_1 is then $E_1 - E_3 = E_{13} = -E_{31}$. From the consideration of a balanced 3-phase vector diagram, E_{31} is 120 degrees ahead of E_{12}. Since the voltage $-E_{31}$ appears across T_1 for 30 degrees, until T_1 picks up at $(t_1+\alpha)$, only 30 degrees of E_{31}, plotted as a dashed line, is shown. The negative of this voltage produces the third pip of the anode-to-cathode voltage in the interval t_1 to $(t_1+\alpha)$. After T_1 picks up at time $(t_1+\alpha)$, the anode-to-cathode voltage remains at zero to the end of the cycle at $(t_6+\alpha)$ or, more specifically, all the way to t_5, when T_1 stops conduction.

Laboratory Oscillograms

Oscillograms taken on the Anacom forceably illustrate the accuracy of the foregoing constructions. Fig. 12A shows the oscilloscope calibration, line-to-line voltage at no load, and a line-to-line voltage for 30 degrees inherent delay, with approximately 90 degrees overlap. The oscilloscope was adjusted to make one time division equal to approximately 36 degrees, and this calibration was maintained for all pictures. Fig. 12B illustrates a line-to-line voltage, such as E_{12} plotted in Fig. 10A, and a corresponding anode-to-cathode voltage such as that plotted in Fig. 10C. Fig. 12C shows a no-load anode-to-cathode voltage for reference, an anode-to-cathode voltage for a tube under load, and the current through the same tube.

Appendix. Delta 6-Phase Delta Double-Way Rectifier (Full-Wave Bridge)

This circuit is shown in Fig. 13. Resistance is assumed to be negligible, and transformer leakage reactance is shown external to an ideal transformer. The ratio of transformation between primary and secondary line-to-line voltages is chosen as unity. Line-to-neutral voltages behind source reactance are

$$E_a = \sqrt{2}E_s \cos\left(\omega t - \frac{\pi}{3}\right)$$

$$E_b = \sqrt{2}E_s \cos(\omega t - \pi)$$

$$E_c = \sqrt{2}E_s \cos\left(\omega t + \frac{\pi}{3}\right) \qquad (1)$$

where E_s is the rms value of transformer secondary no-load line-to-neutral voltage.

Line-to-neutral voltages applied to the anodes of one 3-phase rectifier group, and the cathodes of the other 3-phase rectifier group are E_1, E_2, and E_3. Normal commutation from tube T_5 to tube T_1 of rectifier group I occurs when their anode-to-cathode voltages are equal, that is, when $E_3 = E_1$. Equations 1 have been selected with the time-axis reference such that commutation from T_5 to T_1 of rectifier group I normally starts when $t = 0$.

Commutation in rectifier group II will occur when one cathode-to-anode voltage starts to become more negative than the others. This is the same as when the negative of the line-to-neutral voltage applied to one cathode becomes equal to the one on the conducting phase of group II. The negative of the line-to-neutral voltages applied to the cathodes of rectifier group II are $-E_1$, $-E_2$, and $-E_3$.

From the phasor diagram of Fig. 13, it can be seen that the two groups are displaced by 60 degrees. The circuit is equivalent to two 3-phase rectifiers in

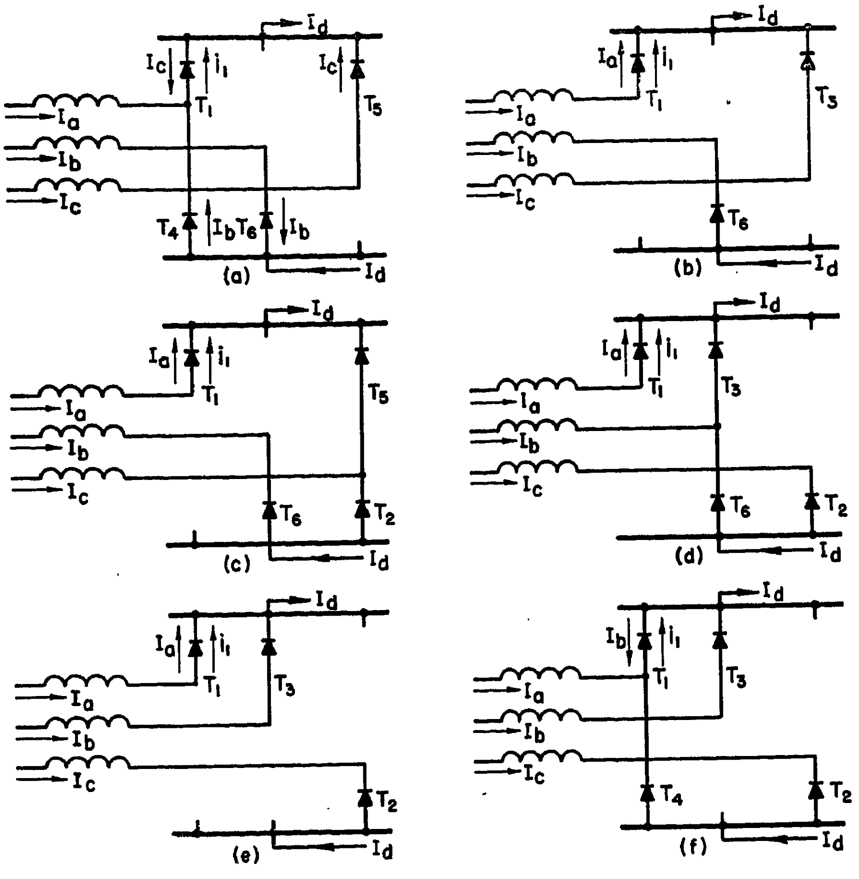

Fig. 11 (left). Circuit diagrams for the construction of the anode current in tube T₁

B: Line-to-line and anode-to-cathode voltages

C: Anode-to-cathode voltage and anode current

series with their alternating voltages displaced by 60 degrees. From the symmetry of the system, the average direct voltage can be obtained by figuring the average of the instantaneous voltage over a 60-degree period.

First Mode of Operation

Simultaneous conduction on two phases results in a temporary line-to-line short circuit on the secondary of the transformer. From Fig. 13

$$E_{ca}=Lpi_c-Lpi_a+E_{c'a'} \qquad (2)$$

During a T_5 to T_1 commutation, $E_3=E_1$ and

$$E_{c'a'}=E_{31}=E_3-E_1=0 \qquad (3)$$

Since T_6 is the only other tube conducting during this period, $i_c=-i_a$; therefore

$$E_{ca}=-2Lpi_a \qquad (4)$$

During the first mode of operation, the instantaneous direct voltage has two distinct intervals, the commutation period and the noncommutation period. Measuring time from t_1 of Fig. 4, the instant of normal commutation from T_5 to T_1 on rectifier group I, the first interval will be from $\omega t=0$ at the start of commutation to $\omega t=u$ at the end of commutation, and the second interval will be from $\omega t=u$ to $\omega t=60$ degrees, when a commutation starts on rectifier group II. From Fig. 13, remembering that T_1, T_5, and T_6 are conducting, the instantaneous direct voltage is given by

$$e_d=-E_2+E_1=-E_{b'}+E_{a'}=E_{a'b'}$$

$$e_d=E_{ab}-Lpi_a+Lpi_b \qquad (5)$$

But during the first interval, with T_6 being the only tube conducting in group II, $i_b=-I_d$ a constant; therefore from equation 4

$$e_{d1}=E_{ab}-Lpi_a=E_{ab}+\frac{E_{ca}}{2}$$

$$e_{d1}=\frac{3}{2}\sqrt{2}E_s\cos\omega t \qquad (6)$$

During the second interval only T_6 and T_1 are conducting; $i_a=-i_b=I_d$, a constant. From equation 5

$$e_{d2}=E_{ab}=\sqrt{3}\sqrt{2}E_s\cos\left(\omega t-\frac{\pi}{6}\right) \qquad (7)$$

The average direct voltage is

$$E_d=\frac{3}{\pi}\left[\int_0^u\frac{3}{2}\sqrt{\ }\;E_s\cos\omega t\,d(\omega t)+\int_u^{\pi/3}\sqrt{6}E_s\cos\left(\omega t-\frac{\pi}{6}\right)d(\omega t)\right] \qquad (8)$$

Evaluating the two definite integrals between the indicated limits, collecting terms and reducing, there is obtained

$$E_d=\frac{3}{\pi}\sqrt{6}E_s\left(\frac{1+\cos u}{2}\right) \qquad (9)$$

This is twice the value of a 3-phase single-way rectifier, whose average direct voltage is

$$E_d=\frac{3}{\pi}\sqrt{\frac{3}{2}}\,E_s\left(\frac{1+\cos u}{2}\right)$$

which verifies the statement that a single bridge circuit is equivalent to two 3-phase rectifiers in series. In addition, the 60-degree shift between the two groups of the bridge make it an equivalent 6-phase circuit.

The commutating angle u is obtained by integrating equation 4 and evaluating the integral at the boundaries $\omega t=0$, at which $i_a=0$, and $\omega t=u$, at which $i_a=I_d$

$$I_d=\int_0^{u/\omega}\frac{-E_{ca}}{2L}\,dt=\int_0^u\frac{\sqrt{3}\sqrt{2}}{2X_c}E_s\times\cos\left(\omega t-\frac{\pi}{2}\right)d(\omega t)$$

After integrating and rearranging

$$\cos u=1-\frac{2I_dX_c}{\sqrt{6}E_s} \qquad (10)$$

Substituting equation 10 in 9

$$E_d=\frac{3}{\pi}\sqrt{6}E_s\left[1-\frac{I_dX_c}{\sqrt{6}E_s}\right] \qquad (11)$$

The no-load direct voltage is obtained from equation 11 with $I_d=0$

$$E_{do}=\frac{3\sqrt{6}}{\pi}E_s \qquad (12)$$

Dividing equation 11 by 12, the direct voltage in per unit of the no-load voltage is

$$\frac{E_d}{E_{do}}=1-\frac{I_dX_c}{\sqrt{6}E_s} \qquad (13)$$

This is the conventional equation for the direct voltage ratio. The quantity I_dX_c/E_s is called the reactance factor.

Second Mode of Operation

Following the T_5 to T_1 commutation in rectifier group I is a T_6 to T_2 commutation in rectifier group II. Commutation between

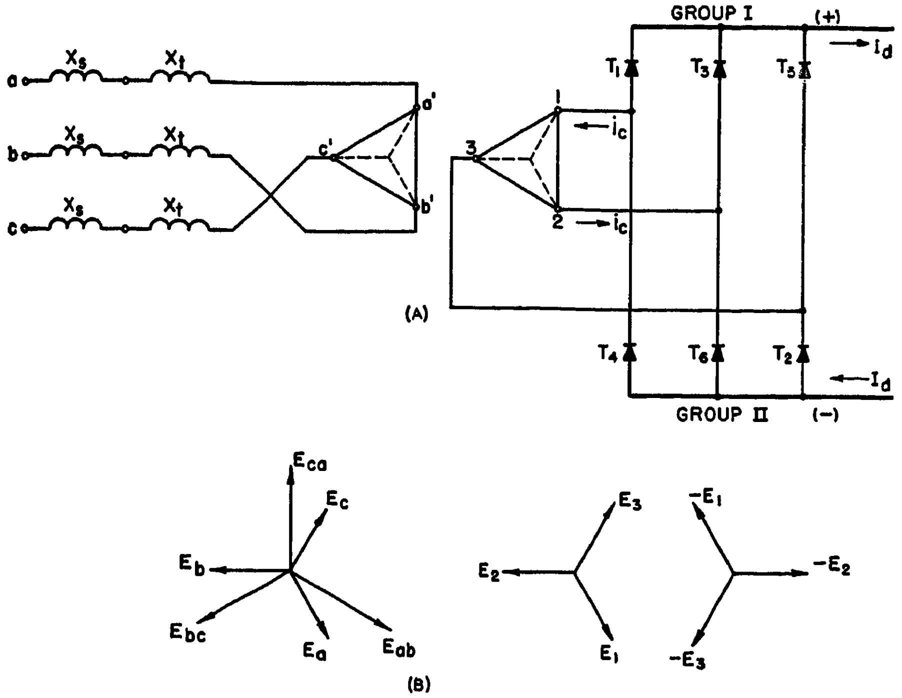

Fig. 13. Delta 6-phase delta double-way rectifier

A: Circuit diagram for bridge circuit B: Voltage phasor diagrams

these two starts when $-E_2=-E_3$ or when

$$-E_{b'c'}=-E_{23}=E_3-E_2=0 \tag{14}$$

Normally this voltage becomes zero 60 degrees after the start of commutation from T_5 to T_1 on group I. From Fig. 13

$$E_{bc}=Lpi_b-Lpi_c+E_{b'c'} \tag{15}$$

During commutation from T_5 to T_1, with T_6 being the only tube conducting in group II, from equation 4

$$E_{ca}=2Lpi_c \tag{16}$$

Since $i_b=-I_d$, a constant, from equations 15 and 16, there results

$$-E_{b'c'}=-E_{bc}-\frac{E_{ca}}{2}$$

$$-E_{b'c'}=\frac{3\sqrt{2}}{2}E_s\cos\omega t \tag{17}$$

If the commutation from T_5 to T_1 on group I tends to exceed 60 degrees, commutation from T_6 to T_2 on group II cannot start at its normal time since, according to equation (17) for $\omega t=60$ degrees, $-E_{b'c'}>0$. Thus, for reactance factors exceeding those for which $u=60$ degrees, commutation cannot start at normal time. Since commutation from T_6 to T_2 on group II cannot start at normal time, by the same reasoning, commutation from T_5 to T_1 on group I did not start at its normal time if there was still a commutation on group II. Thus, a forced delay in commutation is introduced for values of reactance factors greater than that which make $u=60$ degrees. From equation 10, this value is $\sqrt{6}/4$. When the reactance factor is greater than $\sqrt{6}/4$, the commutating angle u remains constant at 60 degrees, with forced delay in commutation being introduced. This can be verified by drawing sine waves with delayed commutation and an overlap angle u of least 60 degrees, remembering that symmetry must be retained.

The average direct voltage for this type of operation is obtained from equation 8, with the limits of integration being α and $\alpha+60$ degrees for the first integral; the second not being involved, since commutation occurs during the entire 60-degree period considered in obtaining the average direct voltage. The angle α is the angle of forced delay.

$$E_d=\frac{3}{\pi}\int_{\alpha}^{\alpha+\pi/3}\frac{3}{2}\sqrt{2}E_s\cos(\omega t)d(\omega t)$$

Evaluating this integral between the given limits and reducing terms

$$E_d=\frac{9\sqrt{2}}{2\pi}E_s\cos(\alpha+30°) \tag{18}$$

Dividing equation 18 by 12

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}}{2}\cos(\alpha+30°) \tag{19}$$

From equation 4

$$I_d=\int_{\alpha}^{\alpha+\pi/3}\frac{\sqrt{3}\sqrt{2}}{2X_c}E_s\cos\left(\omega t-\frac{\pi}{2}\right)d(\omega t)$$

After integrating and rearranging

$$\cos(\alpha+30°)=\sqrt{1-\left[\frac{2I_dX_c}{\sqrt{6}E_s}\right]^2} \tag{20}$$

Rearranging equation 20

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{6}}{2}\sin(\alpha+30°) \tag{21}$$

Equation 21 gives reactance factors for angles of inherent delay between 0 and 30.

Third Mode of Operation

When $\alpha=30$ degrees the two voltages about to commutate become equal, even if there is still a commutation in the other rectifier group. For example, with a T_5 to T_1 commutation occurring in group I, the voltages in group II involved in the next commutation, $-E_2$ and $-E_3$, are equal at $\alpha=30$ degrees, as shown in Fig. 5. The commutation from T_6 to T_2 would therefore start with a delay of 30 degrees, even with reactance factors larger than $(3\sqrt{2})/4$. With increases in the reactance factor above $(3\sqrt{2})/4$, the delay angle is constant at 30 degrees, the overlap angle increases beyond 60 degrees, and both rectifier groups then commutate simultaneously for a part of the cycle.

Referring to Fig. 11A, when T_1 picks up at $(t_1+\alpha)$, tubes T_4, T_5, and T_6 are already conducting. Since T_2 is not conducting, $i_1=-i_c$, where i_1 is the instantaneous current in T_1. As there is a temporary 3-phase short circuit on the rectifier

$$i_a+i_b+i_c=0$$

and

$$E_{a'b'}=E_{b'c'}=E_{c'a'}=0$$

Therefore

$$E_{ca}=Lpi_c-Lpi_a$$

$$E_{ab}=Lpi_a-Lpi_b \tag{22}$$

which give

$$2E_{ca}+E_{ab}=3Lpi_c=-3Lpi_1 \tag{23}$$

or

$$pi_1=\frac{\sqrt{2}E_s}{L}\cos(\omega t-120°) \tag{24}$$

Measuring time from t_1, equation 24 is valid for the interval $\omega t=\alpha=30$ degrees to $\omega t=(\alpha+\delta)=(u-30$ degrees), as shown in Fig. 14.

When $\omega t=(\alpha+\delta)$, T_4 cuts off. Then $i_1=i_a=-i_c$, as shown in Fig. 11B, since there is a temporary line-to-line short circuit on the rectifier. From Fig. 13, $E_{c'a'}=0$; therefore

$$E_{ca}=Lpi_c-Lpi_a=-2Lpi_a=-2Lpi_1 \tag{25}$$

or

$$pi_1=\frac{-E_{ca}}{2L}=\frac{\sqrt{3}}{2}\left(\frac{\sqrt{2}E_s}{L}\right)\times\cos(\omega t-90°) \tag{26}$$

Equation 26 is valid for the interval $\omega t=(\alpha+\delta)=(u-30$ degrees) to $\omega t=(t_2+\alpha)=90$ degrees.

When $\omega t=(t_2+\alpha)$, T_2 picks up. As shown in Fig. 11C, there is again a temporary 3-phase short circuit on the rectifier and $i_1=i_a$. Also

$$i_a+i_b+i_c=0$$

and

$$E_{a'b'}=E_{b'c'}=E_{c'a'}=0$$

Therefore

$$E_{ca}=Lpi_c-Lpi_a$$

$$E_{bc}=Lpi_a-Lpi_c \tag{27}$$

which give

$$2E_{ca}+E_{bc}=-3Lpi_a=-3Lpi_1 \tag{28}$$

or

$$pi_1=\frac{2E_{ca}+E_{bc}}{-3L}=\frac{\sqrt{2}E_s}{L}\cos(\omega t-60°) \tag{29}$$

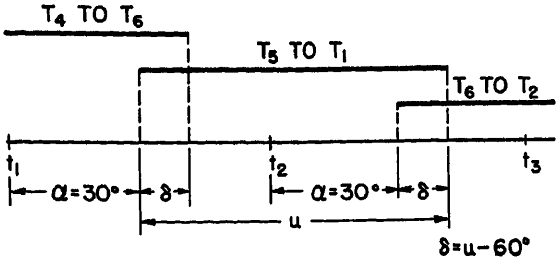

Figure 14. Graph showing the interval of commutations in the period from times t_1 to t_3

Equation 29 is valid for the interval $\omega t=(t_2+\alpha)=90$ degrees to $\omega t=(t_2+\alpha+\delta)=(u+30$ degrees).

When $\omega t=\alpha$, $i_1=0$ and when $\omega t=(t_2+\alpha+\delta)$, $i_1=I_d$. Using these boundaries to evaluate equations 24, 26, and 29

$$I_d=\left[\int_{\alpha}^{\alpha+\delta}\frac{\sqrt{2}\,E_s}{X_c}\cos(\omega t-120°)\times d(\omega t)+\int_{\alpha+\delta}^{t_2+\alpha}\frac{\sqrt{3}}{2}\left(\frac{\sqrt{2}\,E_s}{X_c}\right)\times \cos(\omega t-90°)d(\omega t)+\int_{t_2+\alpha}^{t_2+\alpha+\delta}\frac{\sqrt{2}\,E_s}{X_c}\cos(\omega t-60°)\,d(\omega t)\right] \quad (30)$$

From Fig. 14, $\alpha=30$ degrees, $\delta=u-60$ degrees, $t_2=60$ degrees; therefore $\alpha+\delta=u-30$ degrees, $t_2+\alpha=90$ degrees, and $t_2+\alpha+\delta=u+30$ degrees. Thus the solution of equation 30 can be rearranged to give

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{2}}{2}+\frac{\sqrt{6}}{4}\sin u-\frac{\sqrt{2}}{4}\cos u \quad (31)$$

Equation 31 permits calculation of the reactance factor for any angle of overlap between 60 and 120 degrees, the latter occurring at short circuit.

During the intervals covered by equations 24 and 29, there are temporary 3-phase short circuits on the rectifier, and the direct voltage is zero. During the interval $\omega t=(\alpha+\delta)=(u-30$ degrees) to $\omega t=t_2+\alpha=90$ degrees, covered by equation 26, tubes T_1, T_5, and T_6 are conducting. It was shown in equation 6 that the direct voltage in this interval is

$$e_d=\frac{3\sqrt{2}}{2}E_s\cos\omega t \quad (32)$$

The average direct voltage is

$$E_d=\frac{3}{\pi}\left[\int_{u-30°}^{t_2+\alpha=90°}\frac{3\sqrt{2}}{2}\times E_s\cos\omega t d(\omega t)\right] \quad (33)$$

From equation 12

$$E_{do}=\frac{3\sqrt{6}}{\pi}E_s \quad (34)$$

Dividing equation 33 by 34 and integrating

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}}{2}[1-\sin(u-30°)] \quad (35)$$

Equation 35 gives the voltage ratio for overlap angles between 60 and 120 degrees.

Discussion

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa): May I offer my thanks to the authors of this excellent paper for the theoretical and laboratory corroboration they have provided for much of the material in my paper on extended regulation curves.[1] It should be pointed out that both papers were prepared independently and with no knowledge of the other.

The results presented in both papers apply only to truly free rectifier tubes, in which conduction can be initiated in any part of the cycle whenever the anode becomes more positive than the cathode. This precludes the use of impulse-fired igniters without holding electrodes or grids with an impulse shorter than 60 degrees.

The statement made in the summary of the paper that the equations derived are not affected by transformer connections is too broad. Without further proof the equations should be considered applicable only to the 6-phase double-way and double-wye rectifiers. I take it that the authors had only these two connections in mind.

It is also stated that reactance factors may be converted to per-unit reactance drop by multiplying by $2/\sqrt{6}$. This is true only for the first mode of operation and does not hold for modes 2 and 3. While this is hardly the time to bring the ASA Standard C 34.1[2] under discussion, this error confirms my earlier contention that the term "reactance factor" and its definition in ASA Standard C 34.1 was an unwise choice. To me the term connotes constancy, in the same way that the reactance of a transformer is constant. The term "load factor" used in my paper is not a happy choice, either. Its use does not imply constancy over a range of load, and does result in simpler expressions, but a better name is needed.

It is suggested that to facilitate practical computations equations 19 and 35 should be converted or expanded to include expressions in F_x (if we wish to stay with the reactance factor). Also equation 31 should be simplified to involve only a single trigonometric term in u. These equations could be written as follows

$$\frac{E_d}{E_{do}}=\frac{1}{2}\sqrt{3}\sqrt{1-\left[\sqrt{\frac{2}{3}}F_x\right]^2} \quad (19)$$

$$F_x=\frac{1}{2}\sqrt{2}[1+\sin(u-30)] \quad (31)$$

$$\frac{E_d}{E_{d_o}}=\sqrt{3}\left[1-\frac{1}{2}\sqrt{2}F_x\right] \quad (35)$$

The oscillograms reproduced in Fig. 9 of the paper are of special interest in that they illustrate very clearly the existence of the delay angle α, without the positive-voltage loop that normally exists during this interval in phase-controlled rectifiers.

R. L. Witzke, J. V. Kresser, J. K. Dillard: Several interesting observations have been made by Mr. Dortort, who has prepared a fine paper on this same subject.[1] His suggestions relative to equations 19, 31, and 35 are desirable for the reasons he has given. These equations also appear in the text of our paper, where equations describing the three modes of operation are summarized. The form suggested for equation 35 shows that the voltage ratio is a linear function of the reactance factor F_x (equal to I_dX_c/E_s in our notation) during the third mode of operation.

In our statement referring to transformer connections, we were thinking principally of connections used with 6-phase double-way and double-wye circuits. If other 6-phase connections are encountered, the specific circuit should be investigated separately.

The statement that reactance factors may be converted to per-unit reactance drop by multiplying by $2/\sqrt{6}$ has caused some misunderstanding. Our intention was to show the relationship between the reactance factors used by us, and the load factors used in an earlier paper by Mr. Dortort[2] and repeated in his current paper.[1] Multiplying the abscissas of our Fig. 2 by $2/\sqrt{6}$, we get the curve *abc*, given in Fig. 11 of the latter paper, all the way out to short circuit.

Neither of the papers presented here includes consideration of leakage reactance between secondary windings of double-wye connections. However, a detailed analysis of this interesting case is given in our discussion of Mr. Dortort's paper.[1] For most practical applications, this reactance is negligible.

It is appropriate at this time to mention some earlier work on regulation of rectifiers which came to our attention after our paper had been submitted for publication. A. J. Maslin published an excellent article[3] several years ago, in which he recognized the three modes of operation, and the same regulation characteristics given in our paper for the double-way circuit. The modes of operation for the double-wye circuit were also recognized by Prince and Vogdes.[4] We regret that we were not cognizant of these works during the preparation of our paper, for it would have been of inestimable value in setting up our laboratory study.

New Method for the Optimum Design of Permanent Magnets Subjected to Demagnetizing Effects

HANS K. ZIEGLER
NONMEMBER AIEE

Synopsis: Extensive design investigations with the presently most important permanent-magnet materials have disclosed that optimum operating conditions for all practical interesting demagnetizing conditions are confined to minor hysteresis loops originating from a portion of the main demagnetization curve between the point of maximum-energy product and a point below, which differs for various materials. It has also been revealed that the results of design methods, based on the assumption of one constant slope for all minor loops, may be rather sensitive to the choice of the constant value. Combining both results in the use of an average slope value computed for the confined optimum range, new design relations for permanent magnets subjected to demagnetizing effects by varying either external reluctance or externally applied magnetomotive force have been developed. They can be utilized to derive analytically or graphically general design charts for each permanent-magnet material, permitting the direct reading of the optimum per-unit values of the magnet dimensions, depending upon the degree of demagnetization, and the selection of the material which offers the smallest size or the most suitable shape for a considered application. Interrelations for the two types of demagnetization have been developed.

THE development of improved permanent-magnet alloys, especially of the alnico type, has advanced the application of permanent magnets in many fields to an enormous extent. The demand for alnico-type magnets has reached proportions which cannot be satisfied by the limited allotment of necessary scarce materials, particularly cobalt and nickel, compatible with the overall national need for these materials. For the past several years, therefore, increased attention has been directed to the goal of utmost economical utilization of permanent-magnet alloys containing scarce materials, and to the development of new alloys which do not require critical components. The replacement of cut-and-try designs of magnets by systematic design methods to obtain optimum dimensions has been found indispensable for the conservation of materials, as well as for the evaluation of newly developed alloys. The problem of the optimum design of permanent magnets has been studied by several investigators.[1–5] This paper presents a method for the solution of the problem different from any used previously, which has been utilized since 1947 with very satisfactory practical results by the Signal Corps Engineering Laboratories. It lends itself particularly to a rather accurate analytical treatment, and therefore offers a tool for general design investigations which will be appreciated by many designers.

Elementary Assumptions

Concurrent with previous studies on the subject [1–5] the following assumptions will be used in this paper:

1. The magnet has uniform cross section and is uniform in properties and magnetic state.

2. The magnet has initially been magnetized to saturation, in the preferred axis if the material is anisotropic.

3. The minor hysteresis loop originating from the main demagnetization curve are of so small an area that they can be replaced for practical purposes by a straight line connecting their tips.

4. All leakage flux is assumed to come from the ends or the pole shoes of the magnets. Leakage is therefore regarded as a terminal factor and the optimum design is achieved for the required total magnetic flux Φ_t including leakage. Where excessive leakage originating from the lateral magnet faces invalidates such simplification, this part of the leakage is assumed to be replaced by an equivalent fictitious terminal leakage.

5. The main demagnetization curve of permanent-magnet materials can be closely approximated by hyperbolas, as derived by Watson[6] from Lamont's equation.[7] (Investigations indicate that this is true with very high accuracy for all alnico alloys.)

The form of the equation is chosen in accordance with Underhill[4]

$$\mathbf{B}=\frac{\mathbf{H}_c-\mathbf{H}}{\mathbf{H}_c-a\mathbf{H}}\,\mathbf{B}_r \tag{1}$$

whereby the materials constant a is defined as

$$a=2\sqrt{\frac{\mathbf{B}_r\mathbf{H}_c}{\mathbf{B}_0\mathbf{H}_0}}-\frac{\mathbf{B}_r\mathbf{H}_c}{\mathbf{B}_0\mathbf{H}_0} \tag{2}$$

where $\mathbf{B}_0$ and $\mathbf{H}_0$ = the magnetic induction and the magnetizing force corresponding to the point of maximum energy product
$\mathbf{B}_r$ = the residual induction
$\mathbf{H}_c$ = the coercive force
$\mathbf{B}$ and $\mathbf{H}$ = the magnetic induction and the magnetizing force for points on the main demagnetization curve

6. The centimeter-gram-second system of units is used throughout this paper (see nomenclature).

Nomenclature

a = materials constant, defined by equation 2
a_{op} = optimum magnet cross section per unit flux, centimeters^2 per maxwell
A = cross section of magnet, general, centimeters^2
A_m = cross section of magnet, optimum, centimeters^2
A_0 = cross section of magnet, ideal, centimeters^2
b = materials constant, defined by equation 47
$\mathbf{B}$ = magnetic induction, general, gausses
$\mathbf{B}_0$ = magnetic induction, at point of maximum energy product, gausses

Paper 53-152, recommended by the AIEE Basic Sciences and Rotating Machinery Committees and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted October 17, 1952; made available for printing December 5, 1952.

HANS K. ZIEGLER is with the Signal Corps Engineering Laboratories, Fort Monmouth, N. J.

This paper represents part of the results of a research and development program covering the optimum design of permanent magnets, permanent-magnet generators, and related equipment conducted from 1947 to 1951 by the Signal Corps Engineering Laboratories.

The author wishes to express his appreciation to G. C. Uchrin for his assistance in calculating and preparing the diagrams of this paper.

$\mathbf{B}_{op}$ = magnetic induction, optimum, gausses
$\mathbf{B}_{or}$ = magnetic induction, at origin of optimum minor loop, gausses
$\mathbf{B}_r$ = magnetic induction, residual, gausses
c = demagnetization factor F_a/F_t
$\mathfrak{F}_a$ = magnetomotive force, externally applied, gilberts
$\mathfrak{F}_c$ = magnetomotive force, coercive of magnet M_s, gilberts
$\mathfrak{F}_{co}$ = magnetomotive force, coercive of magnet M_{so}, gilberts
$\mathfrak{F}_t$ = magnetomotive force, specified for normal operation, gilberts
$\mathfrak{F}_2$ = magnetomotive force, corresponding to point 2, Figures 5 and 7, gilberts
$\mathfrak{F}_3$ = magnetomotive force, corresponding to point 3, Figures 5 and 7, gilberts
$\mathbf{H}$ = magnetizing force, general, oersteds
$\mathbf{H}_c$ = magnetizing force, coercive, oersteds
$\mathbf{H}_o$ = magnetizing force, at point of maximum energy product, oersteds
$\mathbf{H}_{op}$ = magnetizing force, optimum, oersteds
k = demagnetization factor $\mathcal{R}_o/\mathcal{R}_t$
l = length of magnet, general, centimeters
l_m = length of magnet, optimum, centimeters
l_o = length of magnet, ideal, centimeters
l_{op} = length of magnet, optimum per unit, centimeters per gilbert
m_s = designation of minor loop corresponding to shape factor s, Figures 5 and 7
M_s = designation of main demagnetization curve corresponding to shape factor s and Φ_r, Figures 5 and 7
M_{so} = designation of main demagnetization curve corresponding to shape factor s and $\Phi_{ro} = \Phi_t$, Figures 5 and 7
$\mathcal{R}_o$ = open-circuit reluctance, gilberts per maxwell
$\mathcal{R}_t$ = operating-circuit reluctance, gilberts per maxwell
$\mathcal{R}_{ta}$ = designation for parallel displaced characteristic $\mathcal{R}_t$, Figures 5 and 7
$\mathcal{R}_a$ = designation of shifting auxiliary line, Figures 5 and 7
s = shape factor of magnet, general, per centimeter
s_m = shape factor of magnet, optimum, per centimeter
s_o = shape factor of magnet, ideal, per centimeter
v = magnet volume per unit external magnetic energy, general, centimeters^3 per maxwell-gilbert
v_{op} = magnet volume per unit external magnetic energy, optimum, centimeters^3 per maxwell-gilbert
V = magnet volume, general, centimeters^3
V_m = magnet volume, optimum, centimeters^3
V_o = magnet volume, ideal, centimeters^3
z = terms defined by equations 23 and 24
z_m = terms defined by equations 23 and 24
η = volume correction factor, general
η_m = volume correction factor, optimum
λ = magnification factor (ratio of magnetic inductions), general
λ_m = magnification factor (ratio of magnetic inductions), optimum
μ_a = average slope of minor loops for defined zone and shape factor 1, gausses per oersted
μ_{as} = resultant average slope of minor loops for defined zone and shape factor s, maxwells per gilbert
μ_d = differential permeability at the point $\mathbf{B}_r$, gausses per oersted
μ_Δ = slope of straight line replacement for minor loop, gausses per oersted
Φ_r = residual flux of magnet M_s, maxwells
Φ_{ro} = residual flux of magnet M_{so}, maxwells
$\tan^{-1} \mu_{as}$ = angle of inclination of minor loop corresponding to slope μ_{as}
I, II, III, IV, V, VI, XII = alnico grades

Considerations Regarding Slope of Minor Loops

Depending upon the type of magnetic alloy, the slope of the minor loops may vary considerably with the point of their origin at the main demagnetization curve. The actual variations can be considered in graphical or analytical point-by-point methods of solutions.[1,5] Complete ana-

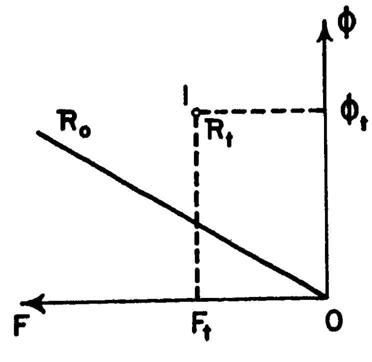

Figure 3 (left). Problem specification for demagnetization by varying external reluctance

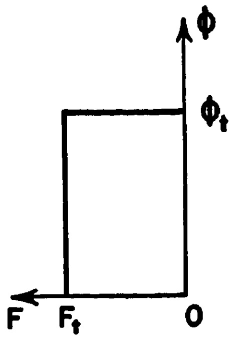
Figure 4 (right). Main demagnetization curve of hypothetical ideal magnet



lytical methods require the knowledge of analytical relations for the slope variations, or the assumption of one constant slope, which must be chosen to approach as closely as possible the results obtained under consideration of the actual variations.

The conditions for the various alnico grades are qualitatively illustrated in Figure 1, which is based on manufacturers' quotations of slope values. The slope of the straight-line replacement for the minor loops originating at the main demagnetization curve and ending at the B-axis is designated with μ_Δ. The slope of the main demagnetization curve at the point of residual induction B_r is denoted with μ_d. The diagram exhibits the changes of the ratio μ_Δ/μ_d versus the ratio B_{or}/B_r pertinent to the magnetic induction B_{or} at the point of origin of the minor loops. With the exception of the grades of alnico IV and XII, the variations are quite large and do not suggest the assumption of a constant slope. The previously proposed adoption[4] of a constant slope μ_Δ equal to the differential permeability μ_d at the point B_r, that is $\mu_\Delta/\mu_d=1$, does not appear justified for each type of alloy, unless it is proved that the influence of the variations upon optimum design dimensions is within the accuracy limitations which must be allowed for any permanent-magnet design method because of the many other simplifying assumptions and variations in the materials charactersitics.

The influence of the choice of the value of a constant slope μ_Δ upon the optimum size of the magnet for alnico V material is illustrated in Figure 2. The diagram exhibits the optimum volume v_{op} of magnetic material per unit of externally available magnetic energy $\Phi_t \mathfrak{F}_t$ for various degrees $k=\mathcal{R}_o/\mathcal{R}_t$ of demagnetization by reluctance increases from $\mathcal{R}_t$ to $\mathcal{R}_o$, depending upon the choice of the value μ_Δ/μ_d, which according to Figure 1 can be taken for alnico V between 1 and 3.2. A practically linear decrease of the magnet volume with the increase of μ_Δ/μ_d is indicated, increasing in magnitude with increasing ratio of k. Maximum volume variations of 16 per cent to 34 per cent, for practical k values from 2 to 10, are affected between the border values 1 and 3.2 of μ_Δ/μ_d. These volume variations are too excessive to be negligible even for design methods claiming only limited accuracy. Design methods based on the assumption of one constant slope when applied to magnetic materials with considerable variations of the slope, therefore require particular considerations in the selection of a proper slope value to obtain optimum design accuracy.

As a first approach towards this goal, the arithmetical average of the slope of all minor loops originating from the main demagnetization curve could be introduced. Investigations started from this assumption have, however, uncovered general physical relations which permit a closer approach.

For all the permanent-magnet materials investigated as of the present, comprising all alnico grades and a number of newer materials, it was found that all optimum designs for any chosen degree of demagnetization are materialized for operating conditions which are associated with minor loops originating from a limited zone of the main demagnetization curve. The upper border of this limited zone was found for all materials to be equal to the point of maximum-energy product, corresponding to a magnetic induction B_o, while the lower border varies with the type of material and the range of considered degrees of demagnetization, and may be located between $B_{or}<B_o$ and $B_{or}=0$. The discovery of the insignificance of minor loops originating from points above the maximum-energy product for optimum designs is of great importance. Previous investigations[8] have revealed that it appears a general rule for all permanent-magnet alloys that the slope of the minor loops is subjected to its major changes for magnetic inductions above B_o. This rule can also be seen proved by the steep descent of the functions between the points marked B_o, which correspond to $B_{or}/B_r=B_o/B_r$ and $B_{or}/B_r=1$ in Figure 1. Permitting the designer to disregard these portions then leaves him with the remaining flatter portion of the functions between $B_{or}/B_r=B_o/B_r$ and $B_{or}/B_r=0$, and also in a much better position to derive an average value which does not deviate much from the maximum and minimum values. This condition is further improved by the observation, that is obviously a regularity, that magnetic materials showing large variations of the slopes, such as alnico V alloy, have their lower border closer to B_o than magnetic materials with smaller slope variations, which in general have their lower border closer to, or at, $B_{or}=0$. The range of slope values to be considered for materials of large variations is thus limited to a still smaller zone.

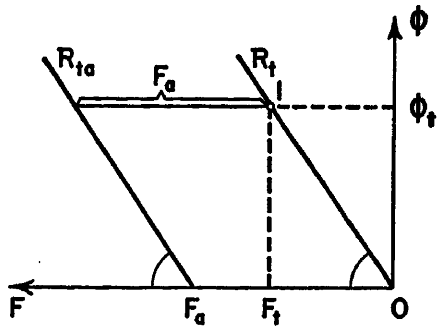


Figure 6. Problem specification for demagnetization by external applied magnetomotive force

An illustration of the results explained in the preceding is given in the design charts, Figures 12 and 17, which contain, for alnico V, VI, and XII, the relations for the magnetic induction B_{or} at the origin of those minor hysteresis loops which lead to optimum designs, depending upon

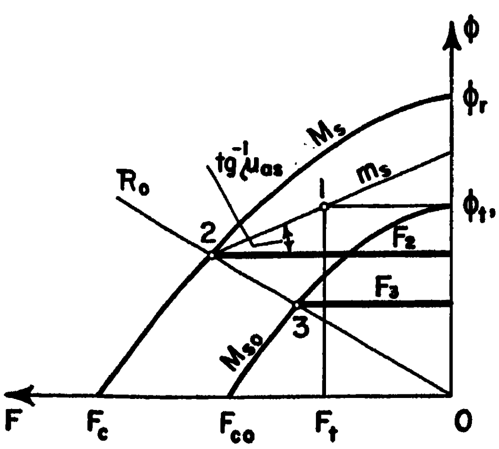

Figure 5 (left). Diagram showing basic geometrical relations for magnetization by varying external reluctance

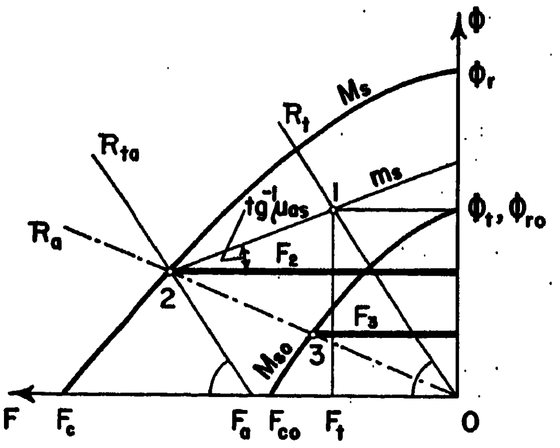
Figure 7 (right). Diagram showing basic geometrical relations for demagnetization by external applied magnetomotive force



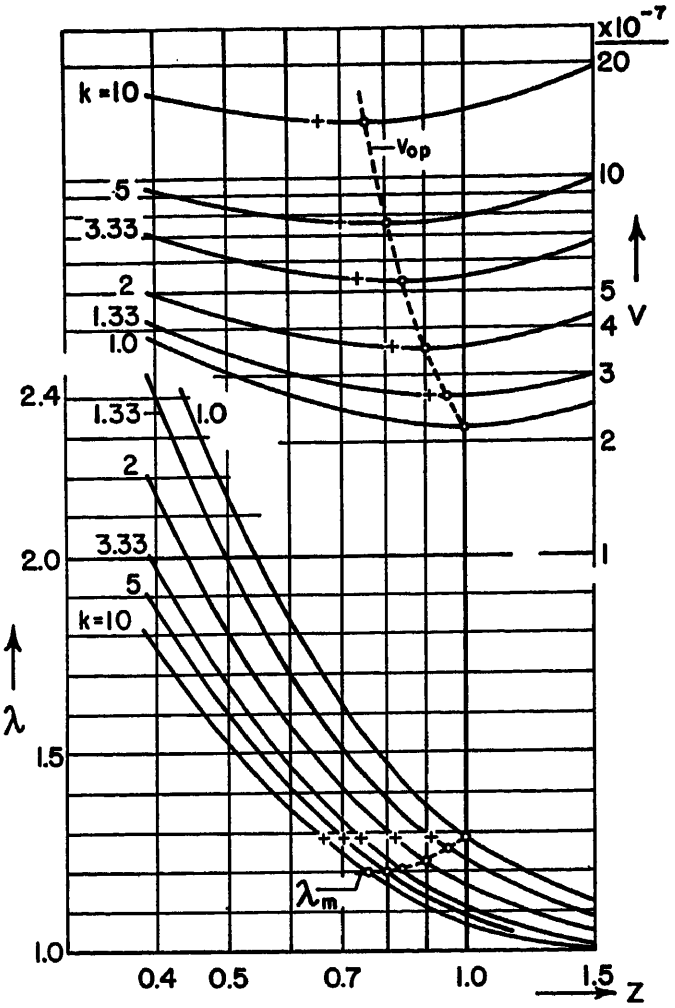


Figure 8. Design chart, containing v and λ functions versus z for alnico V, case A

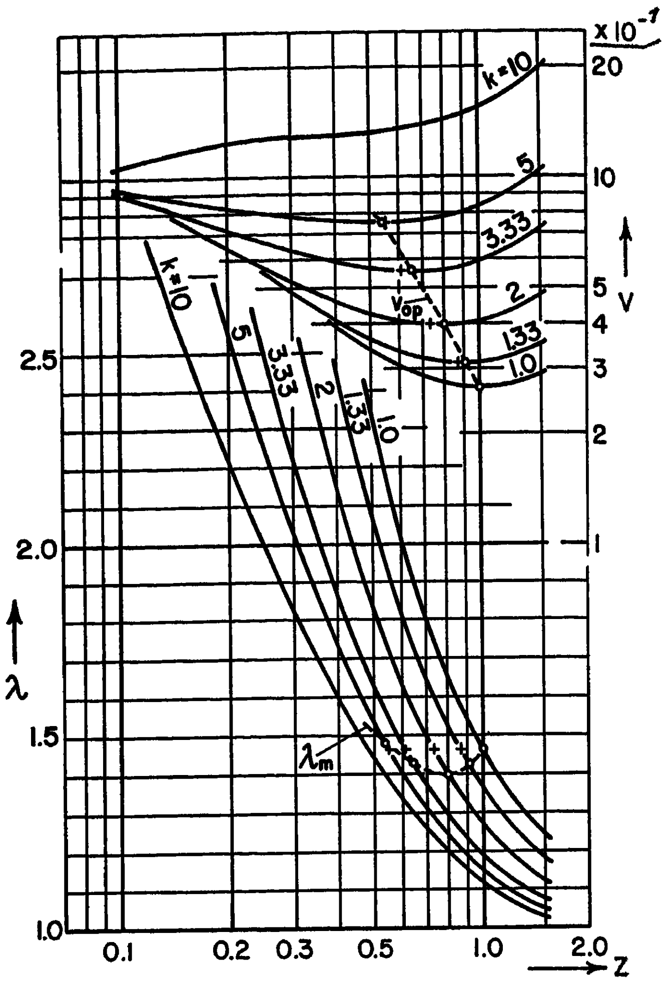

Figure 9. Design chart, containing v and λ functions versus z for alnico VI, case A

the degree of demagnetization k and c respectively. In no case does B_{or} exceed B_o. For alnico V, a definite zone is indicated, approaching a maximum range extending between $B_{or}=B_o$ and $B_{or}\approx 0.85B_o$. For alnico VI and XII, larger zones are indicated, increasing with the degree of demagnetization. For practical purposes only degrees of demagnetization k and c below 10 are generally of interest, which for alnico VI and XII results in relatively small zones. For alnico V, VI, and XII, the zones for $1\leq k\leq 10$ and $0\leq c\leq 10$ are marked in Figure 1 by the shaded portions of the curves. The average slope for these portions, which may be designated by μ_a, can then be used as a constant slope in design relations valid for the indicated range of demagnetization, and which, for materials of large slope variations, will result in more accurate results than those obtained with previous assumptions. It is understood that an average value μ_a, derived from a zone, may be used in the process of the design calculations without objectionable error transitory for the range of the entire main demagnetization curve, if the evaluation of results is finally restricted to the zones to which it actually applies. For an initial investigation of a newly developed permanent-magnet alloy, the zone can be established by first using an average value μ_a computed for the range between $B_{or}=B_o$ and $B_{or}=0$, and then to further limit the range in accordance with the results of these design calculations. The calculations should then be repeated with the improved average value computed from the zone. Hardly more than one repetition will ever be necessary to define the zone with sufficient accuracy to permit the development of design charts.

The relations for the values B_{or} which determine the zones of optimum design are listed in Appendix II, equations 50 and 51.

Principle of Design Method

Case A: Demagnetization by Varying External Reluctance

The problem should be defined as illustrated in Figure 3. A normal operating point, 1, calling for a total magnetic flux Φ_t and a total magnetomotive force $\mathfrak{F}_t$, to which a total magnetic reluctance $\mathfrak{R}_t$ corresponds, and a demagnetizing condition caused by an open-circuit magnetic reluctance $\mathfrak{R}_o$, represent the problem specifications. No restrictions are imposed upon the operating reluctance $\mathfrak{R}_t$ regarding its constancy for values of magnetic flux other than specified, which means the normal external magnetic circuit may be linear or nonlinear. R_t may be considered also an apparent reluctance, given by the quotient $\mathfrak{F}_t/\Phi_t$, where $\mathfrak{F}_t$ may contain constant components of applied magnetomotive force. The open-circuit reluctance $\mathfrak{R}_o$ is assumed to be linear, which, in many practical cases, is actually or approximately correct, because the major open-circuit flux paths are usually located in nonferromagnetic media.

The cross-sectional area of a magnet is denoted by A(centimeters²), the length by l(centimeters) and the volume by $V=Al$ (centimeters³). A shape factor of the magnet is defined as

$$s=l/A \qquad (3)$$

For the optimum magnet, the corresponding values are designated by A_m, l_m, s_m, and V_m.

The degree of demagnetization is characterized by

$$k = \mathcal{R}_0/\mathcal{R}_t \qquad (4)$$

The standard unit volume of a magnetic material, $V=1$ centimeter^3, $A=1$ centimeter^2, and $l=1$ centimeter, has a shape factor $s=1$. The average slope of the minor loops, as defined before, for this standard unit is denoted by μ_a. As for the assumed uniformity of conditions, the magnetic characteristics of a magnet of any other size can be derived from those of the standard unit by variations in proportions to the dimensions, so it can be concluded that the resultant slope μ_{as} depends exclusively upon the shape factor s of the magnet

$$\mu_{as} = \mu_a/s \qquad (5)$$

Previous design methods[1-3,5] were based on the derivation of magnetic energy output curves for various constant degrees of demagnetization, whereby the maximum output was the indication for the optimum operating conditions. The method presented here is based on the introduction of a hypothetical ideal magnet the dimensions of which are subsequently corrected for by factors accounting for the deviations in characteristics between the ideal and the actual magnetic material. The minimum of the volume correction factor signifies the optimum design. For the hypothetical ideal magnet, it is assumed that the magnetic material under consideration has the same values $\mathbf{B}_r$ and $\mathbf{H}_c$ as the actual material, but that the main demagnetization curve is a perfect rectangle as shown in Figure 4, and that no minor hysteresis loops exist. For such an ideal magnet, which would not require a consideration of the demagnetization caused by the open-circuit reluctance $\mathcal{R}_0$, the dimensions would be simply given as

$$A_0 = \Phi_t/\mathbf{B}_r \qquad (6)$$

$$l_0 = \mathcal{F}_t/\mathbf{H}_c \qquad (7)$$

$$V_0 = \Phi_t\mathcal{F}_t/(\mathbf{B}_r\mathbf{H}_c) \qquad (8)$$

The shape factor s_0 of the ideal magnet is then

$$s_0 = l_0/A_0 \qquad (9)$$

To derive the correction factors to modify the ideal dimensions to actual dimensions, the following logical procedure is employed, as explained by means of Figure 5. It is understood that the normal operating point 1 must be located at minor hysteresis loops m_s. An infinite number of different slopes μ_{as} between 0 and ∞, concurrent with an infinite number of different sizes of magnets, which all satisfy the specifications, may be chosen, but according to equation 5, each different slope corresponds for a given material to a definite shape factor s of a magnet. For any chosen value of μ_{as}, a main demagnetization curve M_{s0} of the given material for the corresponding shape factor s can be placed into the diagram, for instance, with a scale for which the residual flux Φ_{r0} is equal to Φ_t. A magnet with a main demagnetization curve M_{s0} does not satisfy the requirements, as M_{s0} does not pass through intersection 2 between the minor loop m_s and the open-circuit line $\mathcal{R}_0$, but the curve M_{s0} must only be magnified by a factor λ which is given by the ratio of

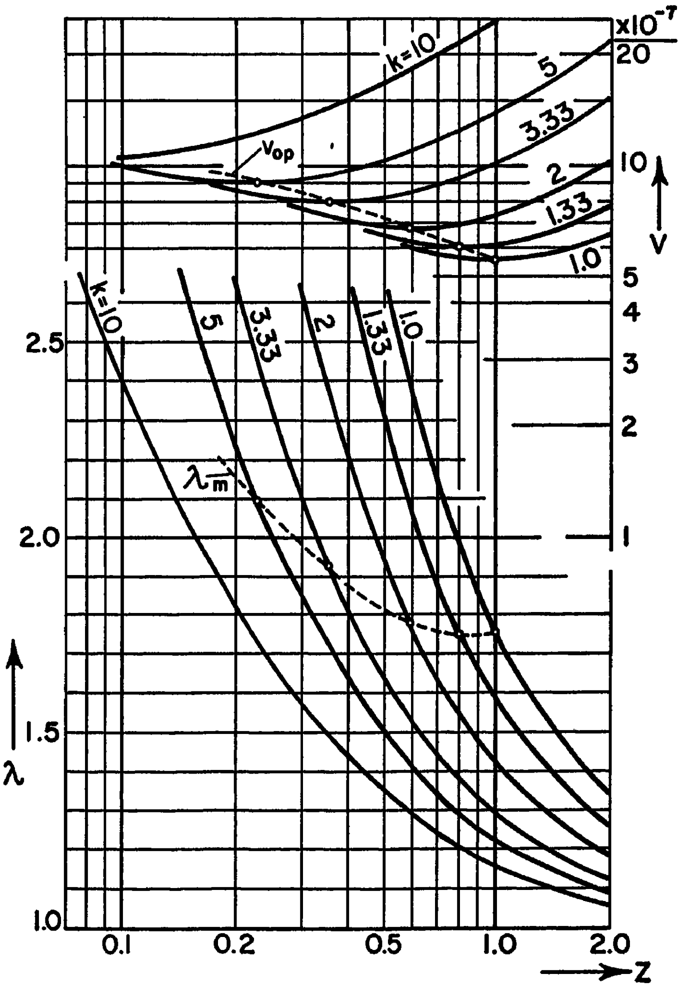

Figure 10. Design chart, containing v and λ functions versus z for alnico XII, case A

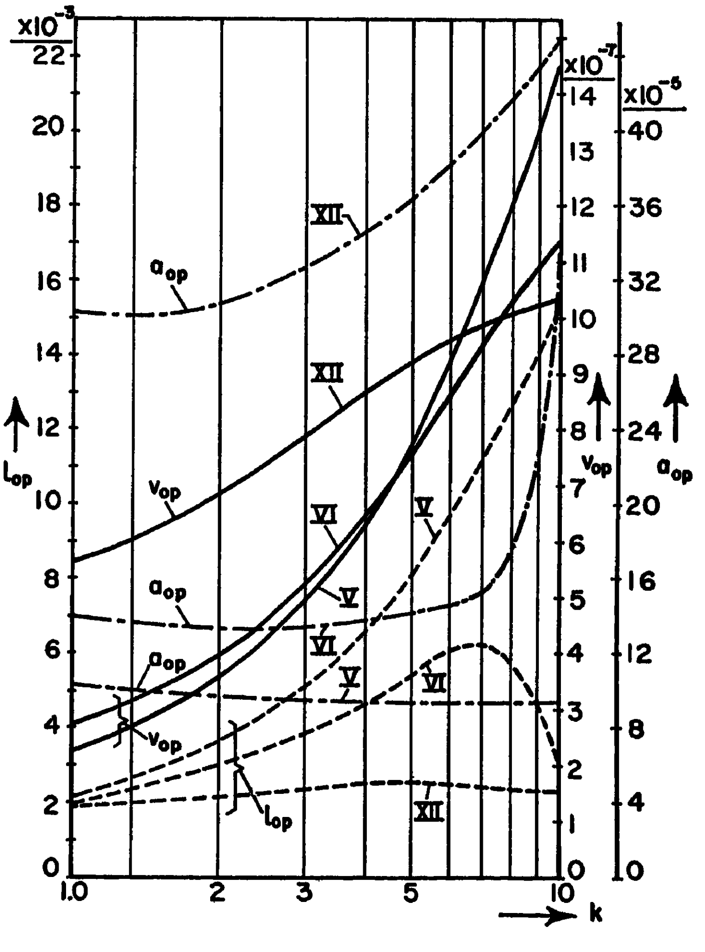

Figure 11. Design chart, containing optimum per-unit magnet dimensions, depending upon degree k of demagnetization, case A, for alnico V, VI, and XII

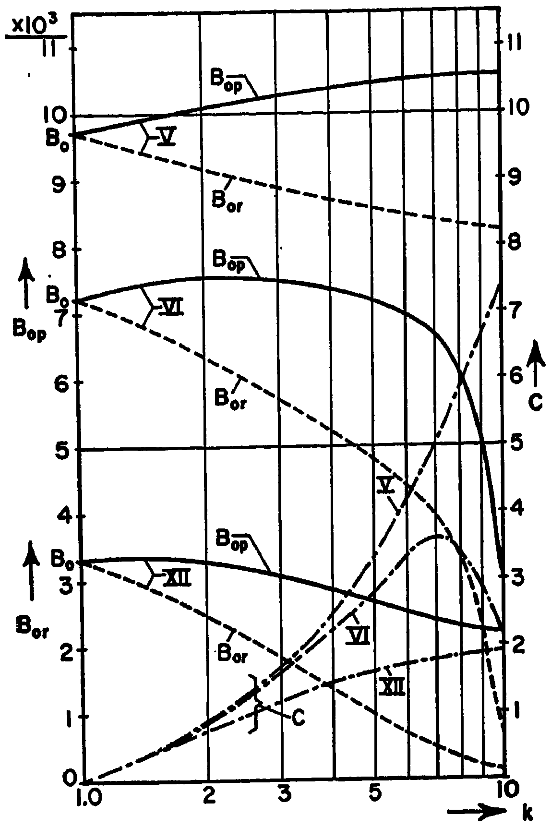

Figure 12 (left). Design chart, containing optimum values B_{op} and B_{or} depending upon degree of demagnetization k, case A, and equivalent values c, for alnico V, VI, and XII

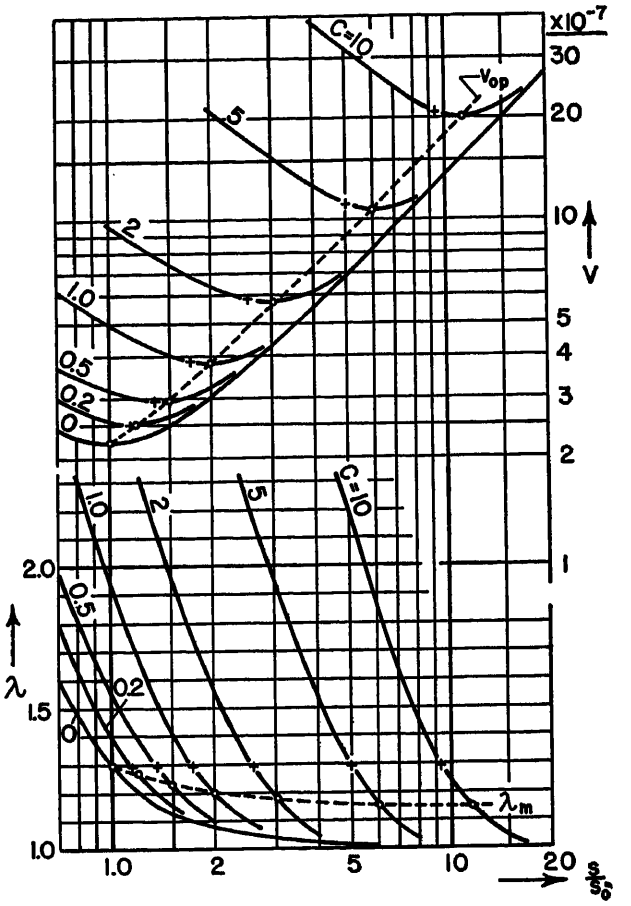
Figure 13 (right). Design chart, containing v and λ functions versus s/s_0 for alnico V, case B



the lengths of the radius vectors 0-2/0-3 to obtain a characteristic M_s which has the same shape factor s as M_{so} and satisfies the requirement. The magnification factor λ can also be expressed by the abscissa values of points 2 and 3, hence

$$\lambda = 0\text{-}2/0\text{-}3 = \mathfrak{F}_2/\mathfrak{F}_3 \tag{10}$$

The residual flux Φ_r of the main demagnetization curve M_s is then

$$\Phi_r = \lambda\Phi_i \tag{11}$$

and the corresponding cross-section area A of the magnet is

$$A = \Phi_r/\mathbf{B}_r = \lambda\Phi_i/\mathbf{B}_r = \lambda A_o \tag{12}$$

The coercive magnetomotive force $\mathfrak{F}_c$ of the curve M_s can be calculated as follows: The coercive magnetomotive force $\mathfrak{F}_i$ and $\mathfrak{F}_{co}$ of the ideal magnet and of the magnet M_{so} are proportional to the lengths of their corresponding magnets, or, as both magnets have the same residual flux and therefore the same cross-sectional area, they are proportional to the shape factors s_o and s of the magnets. Therefore

$$\mathfrak{F}_{co} = (s/s_o)\mathfrak{F}_i \tag{13}$$

The coercive magnetomotive force is then

$$\mathfrak{F}_c = \lambda\mathfrak{F}_{co} = \lambda(s/s_o)\mathfrak{F}_i \tag{14}$$

The corresponding length l of the magnet is therefore

$$l = \mathfrak{F}_c/\mathbf{H}_c = \lambda(s/s_o)(\mathfrak{F}_i/\mathbf{H}_c) = \lambda(s/s_o)l_o \tag{15}$$

and the volume V of the magnet is

$$V = Al = \lambda^2(s/s_o)A_ol_o = \lambda^2(s/s_o)V_o \tag{16}$$

Equation 16 expresses the volume of the magnet by the volume V_o of the ideal magnet, which represents a constant value for each problem specification and each chosen material, and a correction factor

$$\eta = \lambda^2(s/s_o) \tag{17}$$

which accounts for the deviations between the ideal and actual magnetic characteristics. The optimum design is obtained for the minimum value of the correction factor

$$\eta_m = [\lambda^2(s/s_o)]_{\min} = \lambda_m{}^2(s_m/s_o) \tag{18}$$

which is associated with the values s_m/s_o and λ_m. The values of s_m/s_o, λ_m, and η_m inserted in equations 12, 15, and 16, provide the optimum magnet design

$$A_m = \lambda_m A_o \tag{19}$$

$$l_m = \lambda_m(s_m/s_o)l_o \tag{20}$$

$$V_m = \lambda_m{}^2(s_m/s_o)V_o = \eta_m V_o \tag{21}$$

The magnification factor λ can be determined analytically (or graphically) from geometrical relations as a function of s/s_o for constant values of $k = \mathfrak{R}_o/\mathfrak{R}_i$ as parameters, for each permanent-magnet material; see Appendix I, equation 48. As readily seen from equation 12, λ_m is physically the ratio between residual induction $\mathbf{B}_r$ and optimum operating induction $\mathbf{B}_{op}$.

$$\lambda_m = \mathbf{B}_r/\mathbf{B}_{op} \tag{22}$$

From the functions λ, the functions $\lambda^2(s/s_o)$ can be calculated. A plotting of both functions versus s/s_o gives at the minumum of the function $\lambda^2(s/s_o)$ the sought-for pair of values s_m/s_o and λ_m. For the convenience of calculations and best readability of the diagrams, it was found advantageous to use instead of s/s_o as independent variable, the term

$$z = (s/s_o)/k \tag{23}$$

which leads for the optimum design to

$$z_m = (s_m/s_o)/k \tag{24}$$

For the use of this variable, the relations for the optimum dimensions for l_m and V_m must be modified to

$$l_m = \lambda_m z_m k l_o \tag{25}$$

$$V_m = \lambda_m{}^2 z_m k V_o \tag{26}$$

For the final evaluation of the results the hypothetical ideal magnet, which was a convenient means for the derivation of the new relations, may be abandoned again and optimum per-unit values for the magnet dimensions can be defined as

$$a_{op} = \lambda_m/\mathbf{B}_r = 1/\mathbf{B}_{op} \text{ (centimeters}^2\text{ per maxwell)} \tag{27}$$

$$l_{op} = \lambda_m z_m k/\mathbf{H}_c = 1/\mathbf{H}_{op} \text{ (centimeters per gilbert)} \tag{28}$$

$v_{op}=\lambda_m{}^2 z_m k/(\mathbf{B}_r\mathbf{H}_c)=1/(\mathbf{B}_{op}\mathbf{H}_{op})$ (centimeters³ per maxwell-gilbert) (29)

With these definitions, the optimum magnet dimensions are then

$$A_m=\Phi_t a_{op} \qquad (30)$$

$$l_m=\mathfrak{F}_t l_{op} \qquad (31)$$

$$V_m=\Phi_t\,\mathfrak{F}_t v_{op} \qquad (32)$$

In this form of representation the results of the design method are most convenient for the designer.

CASE B: DEMAGNETIZATION BY EXTERNALLY APPLIED MAGNETOMOTIVE FORCE

This problem should be defined as illustrated in Figure 6. A normal operating point 1 (Φ_t, $\mathfrak{F}_t$; $\mathcal{R}_t$) should be specified as in case A. Demagnetization is affected by an externally applied magnetomotive force $\mathfrak{F}_a$, and the degree of demagnetization is defined by the ratio

$$c=\mathfrak{F}_a/\mathfrak{F}_t \qquad (33)$$

Deviating from case A, it is assumed that the normal operation circuit reluctance $\mathcal{R}_t$ is constant and that the circuit under normal operation, point 1, does not contain an externally applied magnetomotive force. Accordingly the characteristic of $\mathcal{R}_t$ is represented by a straight line through origin O and point 1, which under demagnetizing condition is displaced to the left by a distance corresponding to $\mathfrak{F}_a$, and parallel to its original position as signified by the line $\mathcal{R}_{ta}$.

The derivation of the design relations follows exactly the same line of thought as explained in case A. For the derivation of the magnification factor λ, it is necessary to add a shifting auxiliary line $\mathcal{R}_a$, connecting point 2 with the origin O, as demonstrated in Figure 7. The function λ can again be obtained analytically, or graphically, as a function of s/s_0, for constant values of parameters c for each permanent-magnet material; see Appendix I, equation 49.

The introduction of a variable corresponding to z, equation 23, was found unnecessary. Equations 19, 20, and 21 for the optimum dimensions of case A can therefore be utilized without modification. The optimum per-unit dimensions, except for a_{op}, equation 27, change however to

$$l_{op}=\lambda_m(s_m/s_0)/\mathbf{H}_c \qquad (34)$$

$$v_{op}=\lambda_m{}^2(s_m/s_0)/(\mathbf{B}_r\mathbf{H}_c) \qquad (35)$$

The final equations 20, 31, and 32 remain the same for cases A and B.

Demonstrative Examples of Design Charts

The results obtained with the design method presented are illustrated in design charts for alnico V ($\mathbf{B}_r=12{,}500$ gausses, $\mathbf{H}_c=600$ oersteds, $\mathbf{B}_o=9{,}680$ gausses, $\mathbf{H}_o=465$ oersteds, $a=0.916$, $\mu_a=-5.0$ gausses per oersted), alnico VI ($\mathbf{B}_r=10{,}500$ gausses, $\mathbf{H}_c=750$ oersteds, $\mathbf{B}_o=7{,}200$ gausses, $\mathbf{H}_o=515$ oersteds, $a=0.791$, $\mu_a=-5.0$ gausses per oersted) and alnico XII ($\mathbf{B}_r=5{,}800$ gausses, $\mathbf{H}_c=950$ oersteds, $\mathbf{B}_o=3{,}300$ gausses, $\mathbf{H}_o=538$ oersteds, $a=0.427$, $\mu_a=-3.7$ gausses per oersted).

For demagnetization by varying external reluctance, Figures 8, 9, and 10 represent the values v and λ as functions of the variable z for demagnetization factors k between 1 and 10. The value v is the volume of magnet per-unit external mag-

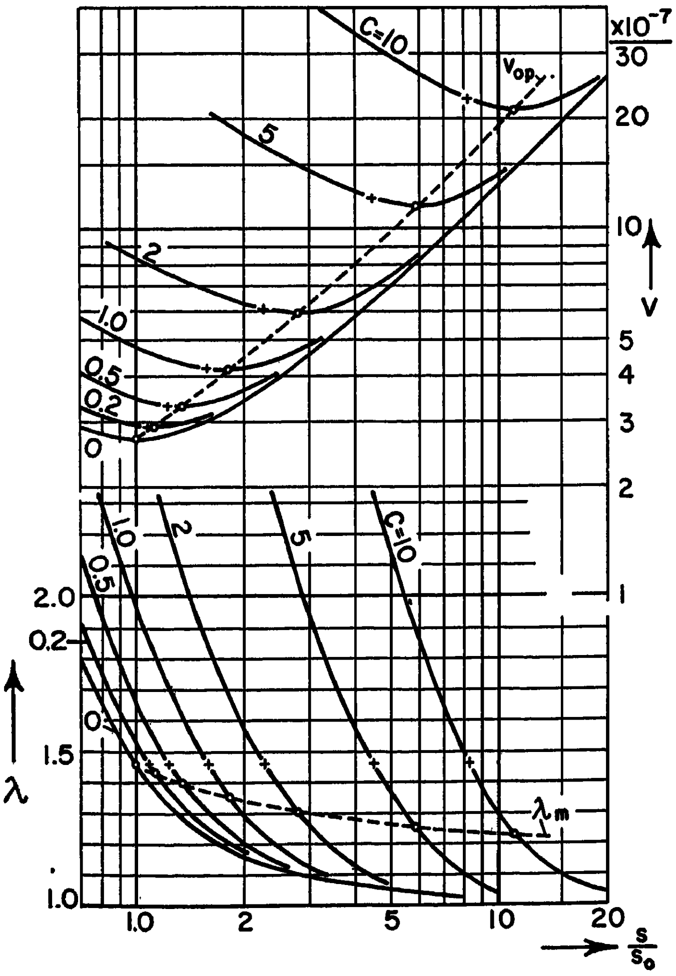


Figure 14. Design chart, containing v and λ functions versus s/s₀ for alnico VI, case B

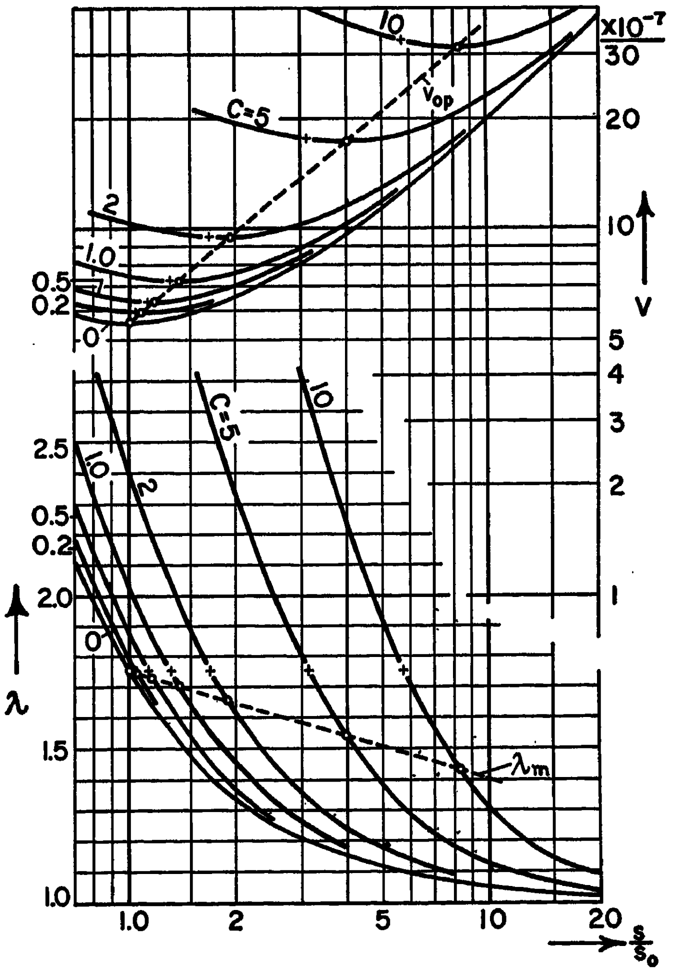

Figure 15. Design chart, containing v and λ functions versus s/s₀ for alnico XII, case B

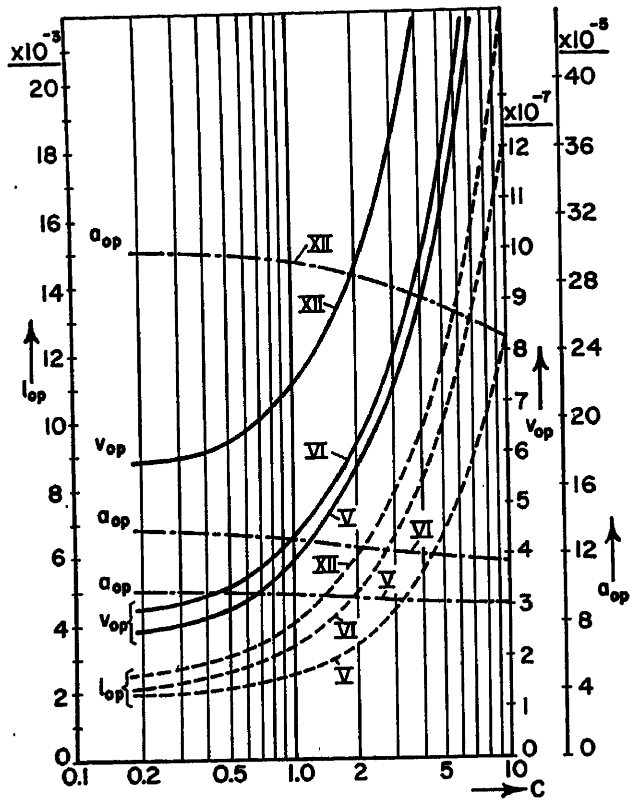

Figure 16 (left). Design chart, containing optimum per unit magnet dimensions depending upon degree of demagnetization c, case B, for alnico V, VI, and XII

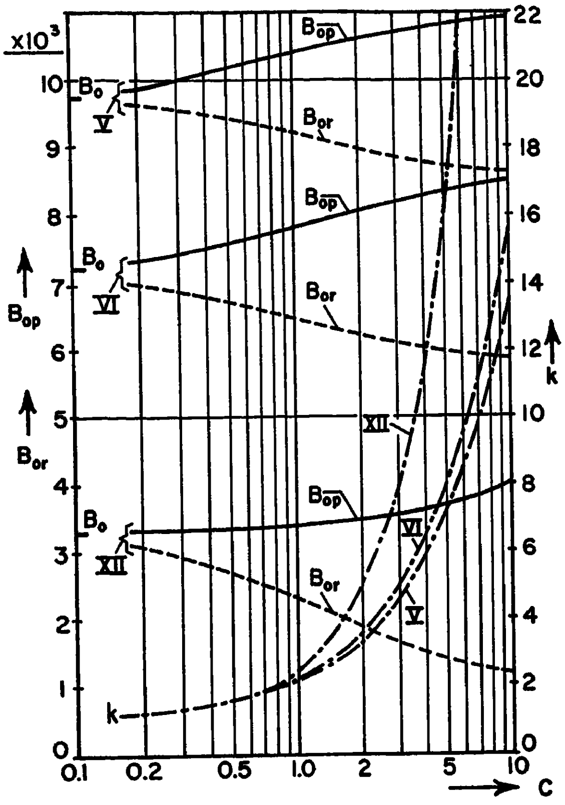

Figure 17 (right). Design chart, containing optimum values B_{op} and B_{or} depending upon degree of demagnetization c, case B, and equivalent values k, for alnico V, VI, and XII

netic energy, and is, in accordance with equation 29

$$v=\lambda^2 zk/(B_rH_c) \qquad (36)$$

The value v has its minimum at the same values of λ_m and s_m/s_0 as the initial correction factor $\eta=\lambda^2(s/s_0)$, and is preferred, as it permits a direct comparison of results from charts for different magnetic materials. The minimum per-unit volume v_{op} and the corresponding value λ_m is marked on the curves, the value z_m is their co-ordinated abscissa value. λ_m and z_m may be used in connection with equations 19, 25, and 26. The pattern of the v-curves changes considerably with the type of material, whereby the constant a is a decisive factor. The minima, although being broad, are well defined.

In the final design charts of Figures 11 and 12, the results of the charts, Figures 8, 9, and 10, for optimum designs are computed. Figure 11 contains the optimum per-unit values of volume v_{op}, cross section a_{op}, and length l_{op}, as defined in equations 27, 28, and 29, plotted versus k. These design charts permit the designer, with the use of equations 30, 31, and 32, to determine at once the magnet dimensions for a given degree of demagnetization k and a chosen magnet material, or to decide which magnet material would offer smallest volume or most desirable shape. The v_{op} curves of the charts reveal, for instance, that for values of k above 4.6 the magnet volume for alnico VI becomes smaller than for alnico V, and that for values k above 7.5 the magnet volume for alnico XII becomes smaller than for both alnico V and VI. At the same time, however, the a_{op} and l_{op} curves indicate that the shape for the magnet varies considerably for the three magnetic materials, calling for flatter magnets for alnico VI, and especially alnico XII, than for alnico V.

Figure 12 illustrates the optimum operating magnetic induction $B_{op}=B_r/\lambda_m$ and the corresponding value B_{or} at the origin of the co-ordinated minor loop, as discussed previously. The optimum magnetic induction B_{op} for $k=1$, corresponds in all charts to the case of no demagnetization effect, and is equal to the value B_0 of the point of maximum-energy product of the main demagnetization curve.

For the case of the demagnetization by externally applied magnetomotive forces, Figures 13, 14, and 15 exhibit the values v and λ as functions of s/s_0 for demagnetization factors c between 1 and 10. In this representation, the per-unit volume v is defined, in accordance with equation 35

$$v=\lambda^2(s/s_0)/B_rH_c \qquad (37)$$

The minimum positions v_{op} of the curves v, and the corresponding values λ_m of the λ functions are marked; the co-ordinated values s_m/s_0, to be utilized in equations 19, 20, and 21, are given by the abscissas. Well-defined minimums are indicated in all cases.

In the final charts, Figures 16 and 17, the per-unit dimensions to be used in connection with equations 30, 34, and 35, and the values B_{op} and B_{or} are again computed, permitting the designer similar interpretations, as discussed in connection with Figures 11 and 12. It is an interesting result that the v_{op} curves of the three materials for case B do not intersect. This indicates that for the considered range of c, alnico VI remains always larger than alnico V, and alnico XII always larger than both alnico V and VI.

Although for both cases of demagnetization, the final charts, Figures 11 and 17, contain all basic design information for the optimum design, the design charts, Figures 8, 9, and 10, and 13, 14, and 15, containing the functions v and λ may be important for practical design work, as they demonstrate the effects of deviations from strict optimum designs upon design economy, and sometimes permit the selection of a magnet which has a more suitable shape than the optimum magnet, without noticeably increasing the volume.

Simplified Approximations for Alnico V and VI

The optimum operating magnetic induction B_{op} for alnico V, in the entire range between $k=1$ and $k=10$ ($c=0$ and $c=10$, respectively), and for alnico VI in the range between $k=1$ and $k=5$ ($c=0$

and $c=5$, respectively), deviates relatively little from the value $\mathbf{B}_o$ of the point of maximum-energy product, as Figures 12 and 17 indicate. This suggests the investigation of the feasibility of an approximation with a constant value of $\mathbf{B}_{op}\approx\mathbf{B}_o$.

The deviations from the minimum volume for $\mathbf{B}_{op}\approx\mathbf{B}_o$, equivalent to $\lambda_m=\mathbf{B}_r/\mathbf{B}_o=\text{constant}$, may be judged from Figures 8, 9, 13, and 14 by the points marked with crosses. It is evident that the deviations do not exceed approximately 5 per cent, for alnico V, and approximately 8 per cent for alnico VI, which justifies the making of the assumption $\mathbf{B}_{op}\approx\mathbf{B}_o$, for preliminary design calculations.

For alnico V and VI for both types of demagnetization, the optimum cross section of the magnet is then given by the equation

$$A_m=\Phi_t/\mathbf{B}_o \tag{38}$$

For alnico V

$1\leq k\leq 10$
$0\leq c\leq 10$
$\mathbf{B}_o=9{,}680$

For alnico VI

$1\leq k\leq 5$
$0\leq c\leq 5$
$\mathbf{B}_o=7{,}200$

The results for the lengths and volume are different for alnico V and VI, as well as for each of the two cases of demagnetization. They may be derived by replacing the functions which are obtained for the cross-marked points for the z_m and s_m/s_o values respectively for the variable k and c respectively by straight-line approximations. The results for alnico V are as follows:

Demagnetization by varying external reluctance

$$l_m\approx(0.62k+0.38)\,\mathfrak{F}_t/\mathbf{H}_o \tag{39}$$

$$V_m\approx(0.62k+0.38)\Phi_t\,\mathfrak{F}_t/(\mathbf{B}_o\mathbf{H}_o) \tag{40}$$

where $1\leq k\leq 10$.

Demagnetization by externally applied magnetomotive force

$$l_m\approx(0.82c+1)\,\mathfrak{F}_t/\mathbf{H}_o \tag{41}$$

$$V_m\approx(0.82c+1)\Phi_t\mathfrak{F}_t/(\mathbf{B}_o\mathbf{H}_o) \tag{42}$$

where

$0\leq c\leq 10$

$\mathbf{H}_o=465$ oersteds
$\mathbf{B}_o=9{,}680$ gausses, in both cases

For alnico VI the results are:

Demagnetization by varying external reluctance

$$l_m\approx(0.46k+0.54)\,\mathfrak{F}_t/\mathbf{H}_o \tag{43}$$

$$V_m\approx(0.46k+0.54)\Phi_t\,\mathfrak{F}_t/(\mathbf{B}_o\mathbf{H}_o) \tag{44}$$

where $1\leq k\leq 5$.

Demagnetization by varying externally applied magnetomotive force

$$l_m\approx(0.71c+1)\,\mathfrak{F}_t/\mathbf{H}_o \tag{45}$$

$$V_m\approx(0.71c+1)\Phi_t\mathfrak{F}_t/(\mathbf{B}_o\mathbf{H}_o) \tag{46}$$

where

$0\leq c\leq 5$
$\mathbf{H}_o=515$ oersteds
$\mathbf{B}_o=7{,}200$ gausses, in both cases

From the approximate equations it can be derived for case A that for $k=4.6$ alnico V and VI result in magnets of same size, which is in agreement with the more accurate results of Figure 11. No c values can be found which render the size of alnico V and VI equal for case B, which agrees with the results of Figure 12.

Interrelations Between Two Cases of Demagnetization

It is evident that a demagnetization affected by reluctance variations permits also the application of a certain maximum external demagnetizing-magnetomotive force to the circuit, when operating at its normal reluctance $\mathcal{R}_t$, without causing further demagnetization. Similarly, a magnet, demagnetized by external magnetomotive force, allows a certain maximum open-circuit reluctance.

These interrelations between the demagnetization degrees k and c are often of practical interest. For instance, in permanent-magnet generator design it is important to know which short-circuit armature reaction will be permissible if the rotor is designed for a certain value of k, corresponding to the rotor out of its stator condition.

Equations 52 and 53 in Appendix III can be easily derived from the geometrical conditions existing in Figure 7. $\mathcal{R}_t$ is thereby in both cases of demagnetization considered a constant value. The results for optimum designs of both demagnetization cases are inserted as dash-dotted curves in Figures 12 and 17, and permit the determination of that value of c which corresponds to a given value of k, Figure 12, and vice versa, Figure 17.

It is obvious that the value of c equivalent to a value of k is always smaller than k. The difference between k and c is thereby influenced by the characteristics of the material.

Final Remarks

The presented design charts and their evaluation are demonstrative examples for several permanent-magnet materials, based on the particular magnetic characteristics as listed before. The given analytical relations enable the designer to develop similar design charts for the same types of material, but having different magnetic characteristics, or for any other material, or for any other desired range of demagnetization. By using the actual magnetic characteristics of the materials, the design accuracy may approach the limits which are given by the tolerances of the material.

Appendix I

Equation for λ, Case A

Using Figure 5, the abscissa values $\mathfrak{F}_2$ and $\mathfrak{F}_3$ of the intersection points 2, between the straight lines $\mathcal{R}_o$ and m_s, and 3, between the straight line $\mathcal{R}_o$ and the main demagnetization curve M_{so}, can be calculated as functions of the shape factor s and parameters k. After simplifications and introduction of the terms

$$z=(s/s_o)/k \tag{23}$$

$$b=\mu_a\mathbf{H}_c/\mathbf{B}_r \tag{47}$$

μ_a is always a negative value, therefore b is always negative. The final relation for $\lambda=\mathfrak{F}_2/\mathfrak{F}_3$ reads

$$\lambda=\frac{z-b/k}{2z(z-b)}\left(1+z+\sqrt{(1+z)^2-4az}\right) \tag{48}$$

Equation for λ, Case B

Using Figure 7, the abscissa values $\mathfrak{F}_2$ and $\mathfrak{F}_3$ of the intersection points 2, between the straight lines $\mathcal{R}_{ta}$ and m_s, and 3, between the shifting auxiliary line $\mathcal{R}_a$, connecting points 2 and 0, and the main demagnetization curve M_{so}, can be calculated as functions of the shape factor s and parameters c. After simplifications and introduction of the term b, according to equation 47 the final relation for $\lambda=\mathfrak{F}_2/\mathfrak{F}_3$ reads

$$\lambda=\frac{1}{2\left(\frac{s}{s_o}-b\right)}\left\{c(1+b)+\left(1-b\frac{s_o}{s}\right)\left(1+\frac{s}{s_o}\right)+\sqrt{\left[c(1+b)+\left(1-b\frac{s_o}{s}\right)\left(1+\frac{s}{s_o}\right)\right]^2-4ab\left[c+\left(1-b\frac{s_o}{s}\right)\right]\left[c-\left(1-\frac{s}{bs_o}\right)\right]}\right\} \tag{49}$$

Appendix II

Relation for $\mathbf{B}_{or}$, Case A

Using Figure 5, the value $\mathbf{B}_{or}$ can be derived from the ordinate value of point 2, as the intersection of the optimum minor loops with the line of the open-circuit reluctance $\mathcal{R}_o$. The equation of the optimum minor loop is thereby determined by point 1 and the slope μ_{as} which corresponds to the optimum shape factor s_m. The result is then

$$\mathbf{B}_{or}=\frac{\mathbf{B}_r}{\lambda_m}\;\frac{1/k-z_m/b}{1-z_m/b} \tag{50}$$

Relation for $\mathbf{B}_{or}$, Case B

Using Figure 7, the value $\mathbf{B}_{or}$ can be found with the same method except that the line of the open-circuit reluctance must be replaced by the line $\mathcal{R}_{ta}$. The result yields

$$\mathbf{B}_{or}=\frac{B_r}{\lambda_m}\;\frac{1-c-(s_m/s_o)/b}{1-(s_m/s_o)/b} \tag{51}$$

Appendix III

Interrelations Between k and c for Optimum Designs

Using Figure 7, the interrelations between k and c can be derived from the reluctance value which corresponds to the shifting auxiliary line $\mathcal{R}_a$ for point 2 of the optimum magnet. It is then $k=\mathcal{R}_a/\mathcal{R}_t$ for the corresponding value of c. The result is

$$k=\frac{1+c-(s_o/s_m)b}{1+(s_o/s_m)b(c-1)} \tag{52}$$

$$c=\frac{z_m-b/k}{z_m-b}(k-1) \tag{53}$$

(By replacing s_o/s_m by s_o/s and z_m by z, the relations can be used also for magnets not representing optimum designs.)

Optimum designs obtained for specified values of k or c do not necessarily represent optimum designs for their interrelated c and k values.

◆

Discussion

P. P. Cioffi (Bell Telephone Laboratories, Murray Hill, N. J.): I have also been concerned with the problem of optimum design of permanent magnets when stabilized against demagnetizing forces.[1] My paper discussed three aspects of the problem: Optimum operation under conditions of (a) external variable reluctance; (b) applied external demagnetizing force; and (c) the interrelationship between the two methods of stabilization. It was shown that for either method the state of magnetization, as represented by the terminus of the tip of the minor loop on the air-gap line, is dependent upon the reversible permeability, the degree of demagnetization, and the slope of the air-gap line. The locus of this point, as the air-gap line slope changes from zero to infinity, is a curve passing through $\mathbf{H}_c$ and $\mathbf{B}_r$. This curve, which I called the secondary demagnetization curve, can be used with its associated energy-product curve identically as the main demagnetization and energy-product curves are used in design problems. The point of intersection of this curve with the air-gap line defines the state of magnetization of the permanent-magnet material for the given degree of stabilization. Analytical and graphical methods were developed for determining the secondary demagnetization curves for the two methods of stabilization, and families of such curves with their associated energy-product curves were presented for the four most important permanent-magnet materials for various degrees of stabilization.

The present paper by H. K. Ziegler appears to present identically the same aspects of the problem as the three mentioned. The novelty of the method rests chiefly on the use of new terms and nomenclature introduced by the author such as "ideal magnet," "magnification factor," and "shape factor ratio." The nature of the proposed method obscures the physical significance of the problem and yields results which have no advantage in application.

Reference

1. See reference 5 of the paper.

George C. Uchrin (Signal Corps Engineering Laboratories, Fort Monmouth, N. J.): The paper presented has brought out the results that the proper choice of the slope of the minor hysteresis loops is of vital importance for the design economy. This fact can be seen still more clearly if, for instance, in the simplified relation for alnico V, as given by equation 40 of the paper, the value of the average slope μ_a is introduced as a design parameter, instead of the numerical value which applies for that particular chosen value of $\mu_a=-5.0$.

The outcome of such an investigation with variable values of μ_a has given the following relation for the optimum magnet volume v_{op} per-unit external magnetic energy, for alnico V

$$v_{op}=\frac{k}{\mathbf{B}_o\mathbf{H}_o}\left[1-0.076\left(\frac{k-1}{k}\right)|\mu_a|\right]\quad\frac{\text{centimeters}^3}{\text{maxwell-gilberts}}$$

where

k = demagnetization degree $\mathcal{R}_o/\mathcal{R}_t$ for demagnetization by reluctance increase from $\mathcal{R}_t$ to $\mathcal{R}_o$

$\mathbf{B}_o\mathbf{H}_o$ = maximum external energy product of main demagnetization curve

$|\mu_a|$ = absolute value of average slope of straight-line replacement for minor hysteresis loops, in the zone to which optimum designs are confined

This equation was found to be correct within approximately 1 per cent of the values of the charts. This equation contains, as a design parameter, the average value μ_a of the slope of the minor hysteresis loops. Also contained are the values of the maximum energy product $\mathbf{B}_o\mathbf{H}_o$, and a factor 0.076 which depends upon the fullness factor of the main demagnetization curve. This confirms the fact that for permanent magnets subjected to demagnetizing effects, the slope of the minor hysteresis loops is an important factor, in addition to the maximum-energy product, for judging the over-all qualities of a permanent-magnet material. It is evident that materials having a large slope μ_a in the zone which applies to optimum designs offer smaller magnets than materials with smaller slopes. This is well understood, because a material with a steep slope of the minor loops gives a better recovery after demagnetization. For a general conclusion that materials with a large slope are more desirable than those with a small slope, it must be considered that for some applications the slope of the minor loops also influences the final operating characteristic of the magnetic circuit of which the permanent magnet is a part.

Hans K. Ziegler: Mr. Cioffi's paper has been given recognition by reference 5 of the author's paper. In reply to his discussion, it is necessary to compare both papers in order that important differences and results of the presented methods can be clearly understood:

In concurrence with reference 4 of his paper Mr. Cioffi advocates, for all practical design purposes, the assumption of a constant slope of the minor hysteresis loops. As he does not specify any value for such constant slope, it must be assumed that he also agrees with reference 4 in choosing a value equal to the differential permeability at the point $\mathbf{B}_r$. His paper includes the grade of alnico V.

The author's paper has brought out, as a new result, the practical significance of the variation of the slope of the minor hysteresis loops and of the proper choice of an average constant value upon the design economy. Alnico V, as a material with very large slope variations, was thereby singled out to expose the consequences originating from the previous lack of information regarding the significance of these factors. It is deemed by the author that weight savings for alnico V, of the order of 25 per cent, for frequently occurring practical demagnetization factors of $k=5$, obtainable through the utilization of the new results, represent a worth-while improvement. Of course, for materials with small slope variations, the savings will be smaller or even negligible, but it should be kept in mind that presently alnico V is the most important and widely used alloy.

In view of the fact that the author's paper employs an unprecedented method of attack to the problem, it is a logical consequence that certain new terminology would be introduced. The author does not agree to the inference of Mr. Cioffi's discussion that such new terminology disguises the physical significance of the subject involved. The design method is a step-by-step logical engineering procedure which is as feasible for the designer as the application of maximum-energy product considerations from a physical point of view. Designers have been using the method successfully for the past 6 years without difficulties. Regardless of the merits of the one or the other design procedure, it has always been considered a healthy research policy to exploit all possible means of attack for the solution of a problem in a relatively new field. As a rule, some new results associate themselves with each new approach. The uncovering of the presented new relations between the minor hysteresis loops and the design economy are an example of such associated results. It is an interesting coincidence that Mr. Cioffi's and the author's methods have been developed completely independent of each other. Mr. Cioffi's paper was presented in October 1948, while the author's method was filed with the Signal Corps Engineering Laboratories in June 1947, and was released only recently.

With reference to the working efforts for the execution of either method for the development of design charts, it is seen that two basic curves are needed for both. In Mr. Cioffi's paper these are the secondary demagnetization and the related energy product curves, whereas in the author's paper these are the magnification factor and the related optimum volume curves. In Mr. Cioffi's method a combined graphical and analytical procedure is employed for deriving the secondary demagnetization curve, utilizing a graph of a main demagnetization curve to select pairs of B_1 and H_1 values. The author uses a completely analytical procedure for the calculation of the magnification-factor curve, whereby the analytical relation of the main demagnetization curve is incorporated. This accounts for the more complicated analytical expression. The further evaluation of the curves and the necessary efforts are, for both methods, quite similar. In addition to the method for the development of design charts, the author's paper has produced simple analytical relations for the direct precalculation of optimum magnet dimensions for alnico V and VI. They represent satisfactory approximations for a wide range of practical applications, and have proved to be a very expeditious means for designing permanent-magnet apparatus.

It should be understood that Mr. Cioffi's method of design, when modified by using the actual μ_r values associated with each selected pair of values B_1 and H_1, or by the introduction of proper average values of the slope of minor hysteresis loops, as emphasized in the author's paper, will eventually lead to results which are identical with those obtained from the author's method. It will be up to the designer to decide which method offers best aid for his particular design problems.

The relation quoted by Mr. Uchrin is gratefully acknowledged as a contribution to further support the significance of the proper choice of the average-slope value of the minor hysteresis loops on the design economy.

Electronic Frequency Changer Used as Nonsynchronous Tie Between A-C Power Systems

HAROLD WINOGRAD
FELLOW AIEE

EARLY in 1943 a 6,667-kw electronic frequency changer, using mercury-arc rectifiers, was installed in the Gary Sheet and Tin Mill of the United States Steel Corporation, at Gary, Ind., to provide a nonsynchronous tie between the 25-cycle and 60-cycle power systems, for the controlled interchange of power in either direction.[1] All the 25-cycle power is generated in the steel company's plants in the Chicago district. The 60-cycle system is supplied by the steel company's generating equipment and by the Northern Indiana Public Service Company. The generating capacity of each system is over 200,000 kw.

The interconnection had to be made through a nonsynchronous tie because of the frequency variations on the 25-cycle system. The electronic-type frequency changer was selected by the engineers of the United States Steel Corporation after investigating several alternative methods, including the Scherbius system, two a-c-to-d-c motor-generator sets, and two rotary converters. Preference was given to the mercury-arc frequency changer, in spite of its higher first cost and the pioneering involved, for the following reasons:

1. It consists of stationary equipment and requires no special foundation.
2. There are no slip rings, commutators, and brushes, and the maintenance cost was expected to be lower.
3. It is easy to start without any shock on the system and it requires no synchronizing. It does not feed into a fault on the a-c system.
4. The power flow can be controlled easily.
5. It has a higher all-day efficiency.

In the original installation, multianode-type mercury-arc rectifiers were employed. In 1948 these were replaced by single-anode type excitron rectifiers and the rating was increased to 8,000 kw. A second 8,000 kw unit was installed in 1949, bringing the capacity of the installation to 16,000 kw, with a 2-hour rating of 20,000 kw.

In the electronic frequency changer a d-c link serves as the tie between the two power systems. A power rectifier converts power from one a-c system to d-c power, which is in turn converted to a-c power into the other system by a power inverter.

Before describing the Gary frequency-changer installation, the operating principles of a power inverter and an electronic frequency changer will be explained. The term "rectifier unit" is applied to the physical equipment consisting of a rectifier transformer, rectifier, and associated auxiliaries and switching equipment. The terms "power rectifier" and "power inverter" are applied to the power-conversion functions of a rectifier unit.[2]

Operation of Power Inverter

Basic Principles

The operation of a power inverter is basically the same as that of a power rectifier, and a rectifier unit can be used alternately for either conversion function. The rectifier tubes are connected to a multiphase winding of a rectifier transformer, and conduct the direct current of the unit in sequence during each cycle. The current can flow through the tubes in one direction only, from anode to cathode.

Paper 53-53, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted November 7, 1952; made available for printing November 20, 1952.

Harold Winograd is with the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

The author gratefully acknowledges the valuable contributions made to this development by R. W. Holman, United States Steel Corporation, and by E. Bender, I. K. Dortort, J. Kiefer, and A. D. Millikin, present and former associates of the author.

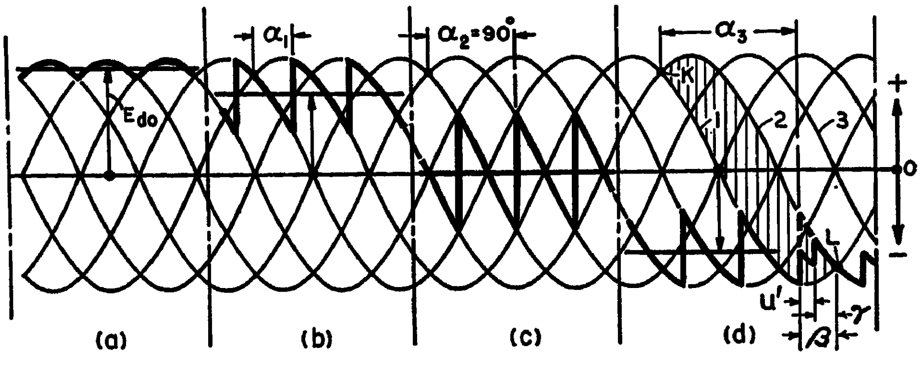

Figure 1. Transition from power rectification to power inversion by phase control

The essential difference between the two functions is that in a power rectifier the tubes conduct during the positive half-cycles of their phase voltages, and the average direct voltage is positive and in the same direction as the current; in a power inverter the tubes conduct during the negative half-cycles of their voltages, so that the average direct voltage of the unit is negative and opposite to the direction of the current.

The firing time in the cycle is controlled by the control grids of the tubes. A tube is permitted to fire when its grid voltage with respect to the cathode is changed from negative to positive. The control of the firing point in the cycle, called "phase control," is used also for regulating the magnitude of the direct voltage.

The operation of phase control and the transition from power rectification to inversion are illustrated in Figure 1. The sine waves represent the phase voltages of a 6-phase star-connected rectifier unit, as shown in Figure 2. In section (a) of Figure 1, the tubes are permitted to fire when their phase voltages are highest. Each tube conducts for 1/6 of a cycle (neglecting the commutating period), and the direct voltage, indicated in heavy outline, has a maximum value. In section (b) the firing point of each tube in its voltage cycle is retarded by the phase-control angle α_1, and the average value of the direct voltage is reduced. In section (c), with a 90-degree angle of retard, the average direct voltage is zero. It is assumed that the d-c circuit has sufficient inductance to maintain the flow of direct current. In section (d) the firing of the tubes has been retarded by an angle α_3, so that they conduct during the negative half-cycles of the phase voltages, and the average direct voltage is negative. The direct current continues to flow in the same direction, and the reversal of the voltage represents a reversal of power flow, which was effected entirely by phase control.

To permit the flow of direct current through a rectifier unit in the opposite direction from its voltage, an external direct voltage has to be applied in the same direction as the current and of sufficient magnitude to overcome the negative voltage. The external voltage could be supplied by another rectifier unit which might be connected to another a-c system.

Such an arrangement is shown in Figure 2, in which are indicated the directions of the current, voltages, and power. This is the basic circuit of an electronic frequency changer. Either unit may be operated as a power rectifier or a power inverter, and the direction of power flow can be changed by phase control without interrupting the d-c circuit. The magnitude of the direct current and the transmitted power is determined by the relative values of the direct voltages, which can be regulated also by phase control. The negative direct voltage of a power inverter is comparable to the back electromotive force of a d-c motor.

The operation of a power inverter depends on the ability to delay the conducting period of the tubes and to commutate (transfer) the direct current between tubes of successive phases. Commutation is possible only when the incoming phase has a higher voltage than the outgoing phase. Referring to Figure 1, this condition for a pair of successive phases prevails between the intersection point K of the positive half-cycles and the intersection point L of the negative half-cycles of their voltages. If, for example, the current is not commutated from phase 1 to phase 2 before point L is reached, phase 1 will continue to conduct beyond L and into its positive half-cycle. The back-voltage of the power inverter would then disappear, and the external d-c power supply would be short-circuited through phase 1 of the inverter transformer and the tube connected to it. Point L is the commutation-limit point, and commutation must be completed before it is reached.

OPERATING REQUIREMENTS

In Figure 3 are shown the circuit relations of a power inverter with a 6-phase double-wye connection which is the most generally used rectifier connection and is employed for the Gary frequency changer. It consists of two 3-phase commutating groups paralleled through an interphase transformer. Each group conducts the direct current I_c, which is one-half of the total current I_d. Because of the phase displacement between the groups, the direct voltage of the unit has a 6-phase wave shape.[3]

At the right of Figure 3 are shown the phase-voltage sine waves of one commutating group. During each cycle, the direct current I_c is conducted in sequence by the three phases and their tubes. Each tube is fired by its control grid at a point on its voltage wave advanced by the angle β from the commutation-limit point L. The current is commutated from the outgoing to the incoming phase during an angle u', and the commutation is completed short of point L by the angle

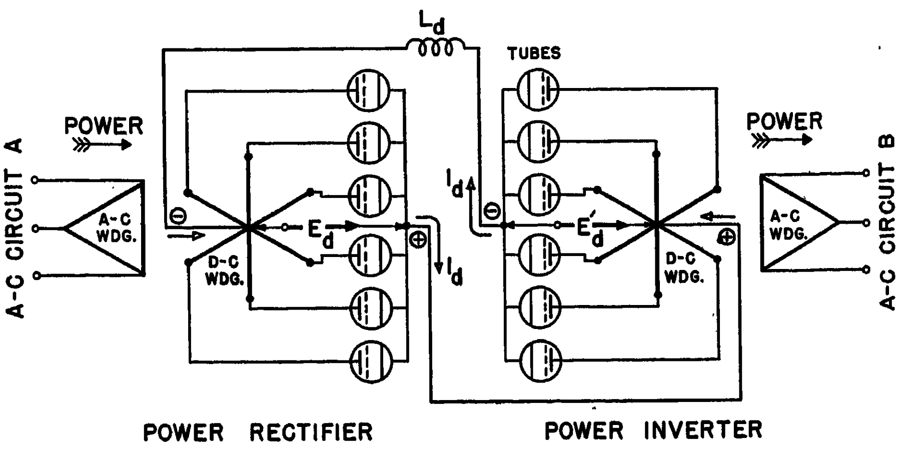

Figure 2. Elementary circuit of electronic frequency changer, showing directions of direct current, direct voltages, and power

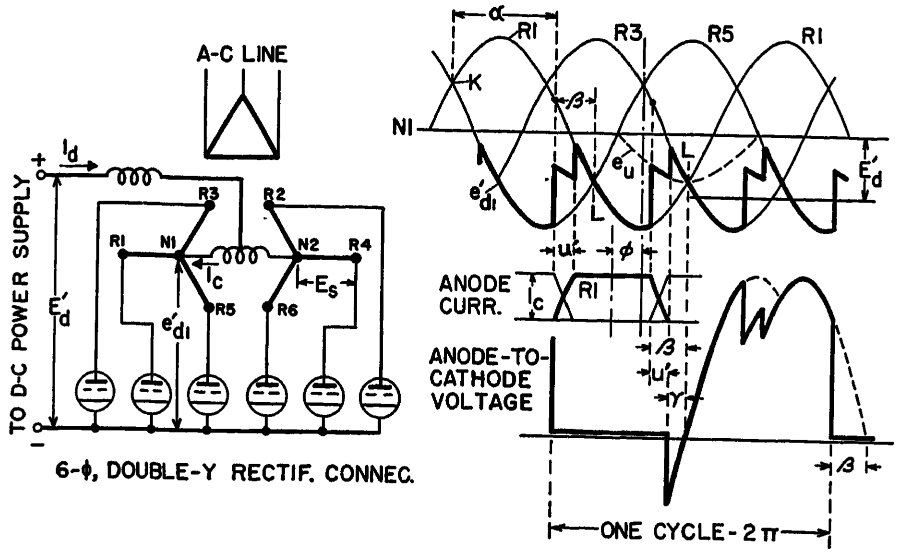

Figure 3. Current and voltage relations of power inverter with 6-phase double-wye connection

γ, which is called the "margin angle." The direct voltage e_{d1}' of the commutating group, shown in heavy outline, is equal to the voltage of the conducting phase. During the commutating period it is equal to the average of the overlapping phase voltages e_u. The average direct voltage of a group E_a' is also the average voltage of the unit, since the two groups are paralleled.

The duty on a tube of a power inverter is indicated by its anode-to-cathode voltage, as shown in Figure 3 for the tube of phase $R1$. It is obtained by taking the difference between the voltage of phase $R1$ and the cathode voltage e_{d1}'. During the conducting period of the tube, the voltage is equal to the arc drop and is low. It is negative during the margin angle γ, and positive beyond point L until the start of the next conducting period. It attains peak positive values equal to the peak value of the phase-to-phase voltage. The margin angle is needed for deionization of the control grid so that it will regain control and block the anode during the positive period. The commutating angle u' increases as the load current is increased, and the angle of advance β has to be sufficiently large to provide the needed margin angle for the highest current to be commutated.[4]

It should be noted in Figure 3 that the center of the anode current of $R1$ is advanced by an angle φ from the center of the negative half-cycle of the phase voltage, as a consequence of requiring an angle of advance. The significance of this is that the fundamental component of the line alternating current, which is a reflection of the anode currents, leads the output line-to-neutral voltage of the power inverter (which is equal and opposite to the applied voltage). The a-c system must therefore be able to receive current of leading power factor. In practice this means that the system should have sufficient synchronous machine capacity, or static capacitors, capable of supplying lagging kilovars to compensate for the leading kilovars put out by the power inverter, in addition to the kilovars required by the load.

On the basis of the preceding discussions, there are two system requirements for the operation of a power inverter:

1. The system must provide the alternating voltages which are required for producing the negative direct voltage of the inverter and for commutating the direct current between tubes. The required voltages can be provided by a-c generators or a synchronous condenser.

2. The system must be capable of supplying the lagging kilovars required by the load and the power inverter. This can be provided by a-c generators, a synchronous condenser, or static capacitors.

Both of these requirements were satisfied for the Gary frequency-changer installation by existing system conditions.

Regulation of Power Flow

The flow of power through an electronic frequency changer may be regulated by phase control of the output voltage of the power rectifier, or the back-voltage of the power inverter, or both. On the Gary frequency changer, the power inverter operates at a fixed angle of advance, and the power flow is controlled by regulating the voltage of the power rectifier only. This method is illustrated by the voltage regulation characteristics of Figure 4.

The terminal direct voltage of a power rectifier is given by the expression[2]

$$E_d = E_{d0} \cos \alpha - (E_x + E_r + E_a) \qquad (1)$$

where

E_{d0} is the theoretical no load voltage, and is equal to $1.17E_s$ for the circuit of Figure 3
E_s = phase voltage of rectifier transformer d-c winding
α = phase-control angle of retard
E_x = voltage drop due to commutating reactance
E_r = voltage drop due to resistance losses in rectifier transformer and any other elements of the unit
E_a = arc-drop voltage of rectifier

The voltage drops E_x and E_r are directly proportional to the load current, while E_a is nearly constant. The voltage regulation characteristic is therefore a straight line sloping downward at increasing load. The maximum voltage is obtained when α is zero, as shown by line E_{dm} in Figure 4. For other values of α, regulation lines are obtained, such as E_{d1} and E_{d2}, which are parallel to E_{dm}.

For a power inverter, the terminal direct voltage is the voltage required to overcome the theoretical back-voltage, plus the voltage drops produced by the

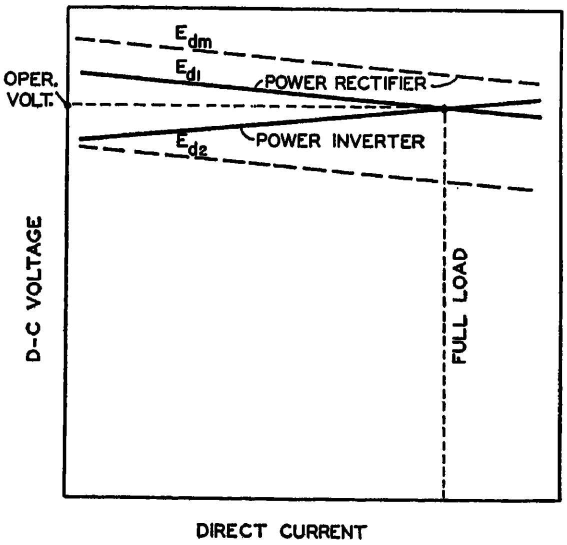

Figure 4. Voltage regulation characteristics of power rectifier and power inverter, illustrating load control of electronic frequency changer

flow of current, and is given by the expression

$$E_d' = E_{d0} \cos \beta + (E_x + E_r + E_a) \qquad (2)$$

in which β is the angle of advance. The voltage regulation characteristic is therefore a straight line sloping upward at increasing current, as shown in Figure 4. The position of this line is determined by the value of β.

Since the terminal voltages of the power rectifier and the power inverter of the frequency changer must be equal, the direct current is determined by the intersection point of their voltage-regulation characteristics. This point can be shifted to control the direct current and the transmitted power by varying the phase-control angle α, which shifts the voltage regulation line of the power rectifier. The inherent voltage regulation of the Gary frequency changer, between full load and light load, is about 5 per cent.

Operating Faults

The anode-to-cathode voltage of a power rectifier is similar to that shown in Figure 3, when viewed upside down. It is negative during the greater part of the nonconducting period in the cycle. The major fault of a power rectifier is an arc-back, which results when a cathode spot develops on an anode during the inverse period. Reverse current flows to the faulted tube from the tubes connected to the other phases, resulting in an unbalanced short-circuit on the rectifier transformer with a high reverse current through the phase of the faulted tube.

An arc-back may be cleared by interrupting the circuit of the faulted tube, by interrupting the a-c supply to the unit, or by applying negative blocking voltage to the grids of the rectifier tubes. The last method, called arc suppression, blocks the tubes feeding into the faulted tube after their currents fall to zero in sequence. There is no back-feed from the power inverter into an arc-back on the power rectifier of the frequency changer. The load current drops off.

The major fault of a power inverter is an arc-through, which results if a tube fails to remain blocked and conducts during the positive nonconducting period in the cycle (see Figure 3). An arc-through may be caused by one of the following conditions:

1. When the current is not commutated away from the tube before the commutation-limit point L, or if the margin angle is too small for deionization of the grid.
2. Interruption or single-phasing of the a-c system voltage, so that the back-voltage of the power inverter disappears or is noncontinuous.
3. A fault in the grid-control circuit.
4. Failure to commutate away the current of a tube because of a misfire on the tube of the succeeding phase.
5. An arc-back on a tube during the margin angle, when the anode is negative to the cathode, may cause the tube to conduct when the anode voltage reverses.
6. Random and transient loss of control by a grid. This is the most common cause of arc-throughs, and may occur at any point of the positive period.

When an arc-through occurs, the back-voltage of the power inverter disappears, with the result that the power rectifier is short-circuited through the faulted tube and its transformer phase winding. The ultimate current of such a fault is determined by the resistance of the circuit and the voltage-regulation characteristic of the power rectifier, and can attain a high value. Its initial rate of rise is determined by the inductance of the circuit. The fault current has an a-c component, produced by the voltage of the faulted phase. The current through the faulted tube flows in the normal forward direction.

An arc-through can be cleared by removing the d-c power supply. This may be effected by one of the following methods:

1. Interrupting the d-c circuit.
2. Applying arc suppression to the power rectifier by grid blocking.
3. Interrupting the a-c supply to the power rectifier.

An arc-through produced by a random nonsustained cause may clear itself by recommutation. The tube of the succeeding phase, fired in its normal sequence, can commutate the current away from the faulted tube, if the current attained at that point is sufficiently low so that the commutating angle is smaller than the

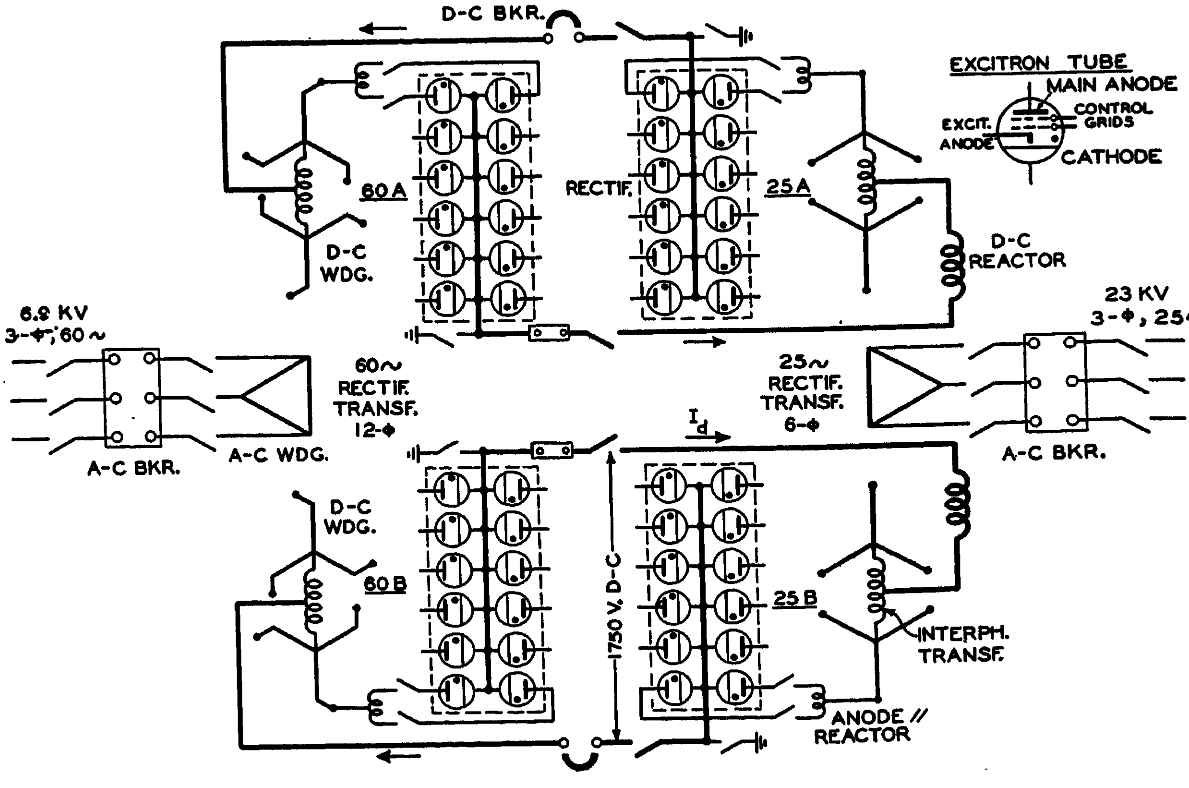

Figure 5. Power-circuit diagram of 8,000-kw electronic frequency-changer unit installed at Gary

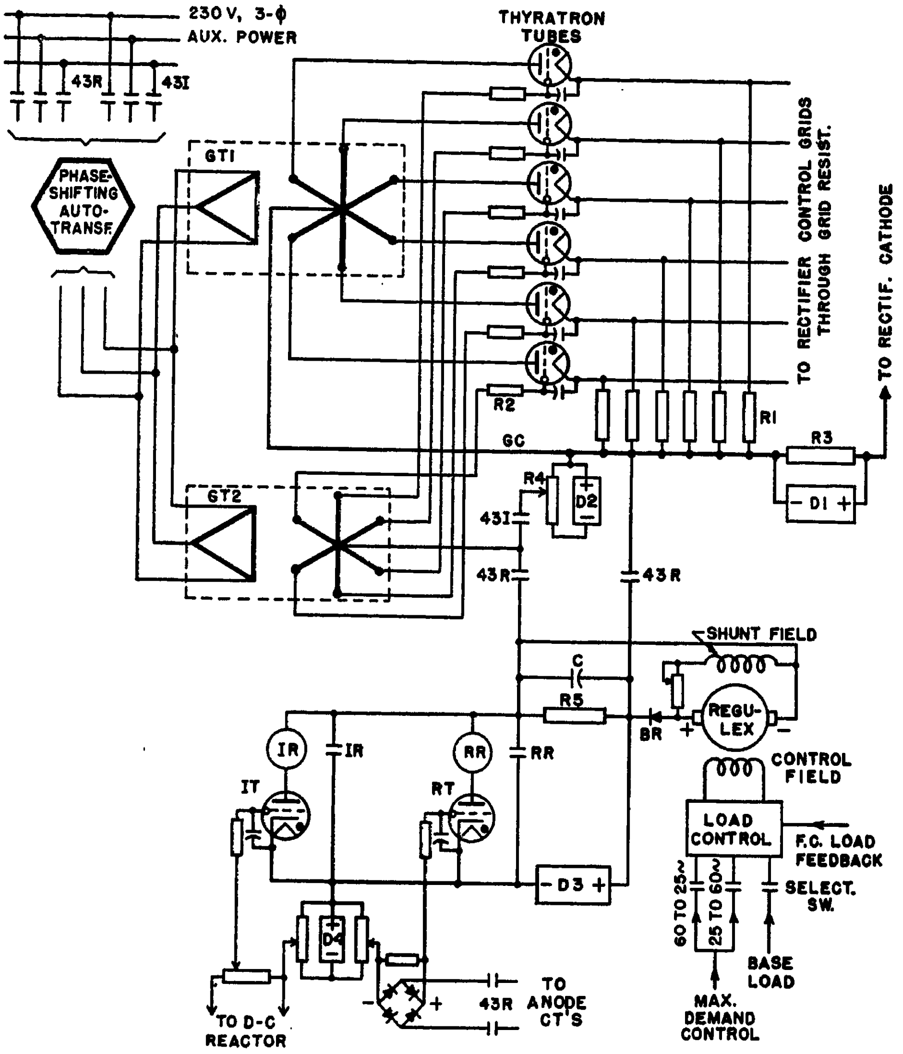

Figure 6. Grid-control and load-regulating circuit of Gary frequency changer

angle of advance. This could happen if the fault occurs late in the positive period. The same result can be obtained for arc-throughs occurring at any point of the positive period by inserting into the d-c circuit sufficient inductance to slow up the rate of rise of the current, so that it does not reach the commutation-limit value at the firing point of the succeeding tube. The d-c inductance is also beneficial in keeping down the magnitude of the current resulting from sustained faults, which are cleared by one of the other methods.

The several protective measures discussed, including d-c reactors, are incorporated in the protection system of the Gary frequency changer.

Gary Frequency Changer

Power Circuit

The power circuit diagram of one unit of the Gary frequency changer installation is shown in Figure 5. The a-c windings of the 25-cycle and 60-cycle rectifier transformers are connected to their respective systems through an oil circuit breaker.

The unit consists of two 4,000-kw sections, each comprising a 25-cycle and a 60-cycle rectifier group, which are connected in series on the d-c side. One group operates as a power rectifier, the other as a power inverter; their functions depend on the desired direction of power flow. Each group consists of a 12-tube pumped excitron rectifier connected to a 6-phase d-c winding of the rectifier transformer. A pair of tubes is connected to each phase through an anode-paralleling reactor, which consists of a circular-wound iron core, through which the anode cables are looped in opposite directions.

The d-c circuit operates at 1,750 volts. It is provided with a d-c breaker and an oil-immersed d-c reactor. Grounding switches are provided for the cathode terminals. Only the grounding switches of the power rectifiers are closed in service, which makes it possible to operate the load-regulating equipment close to ground potential. Disconnecting switches in the d-c and anode circuits permit inspection or servicing the rectifiers of one section while the other section remains in operation.

The d-c reactor, besides suppressing arc-throughs and limiting the fault currents, assists the load regulator by slowing up changes of the load current resulting from variations of the a-c system voltages. It also suppresses the harmonic components in the direct current. The reactors of unit *1* have an inductance of 15 millihenrys. Unit *2* has 12 millihenry reactors which operate on a 10-millihenry tap.

The 6-phase d-c windings of the 60-cycle transformer are zig-zagged to produce a 12-phase combination. The 60-cycle transformer of unit *2* consists of two cores with wye and delta a-c windings, and 6-phase double-wye d-c windings, producing a 12-phase combination displaced by 15 degrees from that of unit *1*. The two units combined therefore constitute a 24-phase system on the 60-cycle side, and the resulting line alternating current has a wave shape closely resembling a sine wave.

On the 25-cycle side, both units have 6-phase transformers, one with a delta-connected, the other with a wye-connected a-c winding, producing a 12-phase combination. A larger number of phases was provided for the 60-cycle side to avoid the possibility of telephone interference on the power system of the Northern Indiana Public Service Company.

Grid-Control and Load-Regulating Circuit

Figure 6 shows a simplified diagram of the grid-control circuit for each rectifier. A negative blocking voltage is applied to the control grids of the rectifier tubes by a direct-voltage supply *D1*, through resistors *R1*. (Circuit elements *D1* to *D4* are selenium rectifiers.) The grids are fired, in the correct sequence and at the

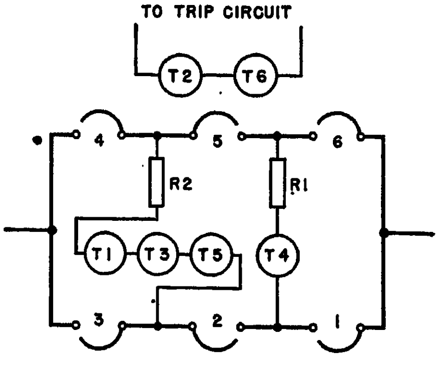

Figure 7. Connection diagram of d-c circuit breaker used for the electronic frequency changer

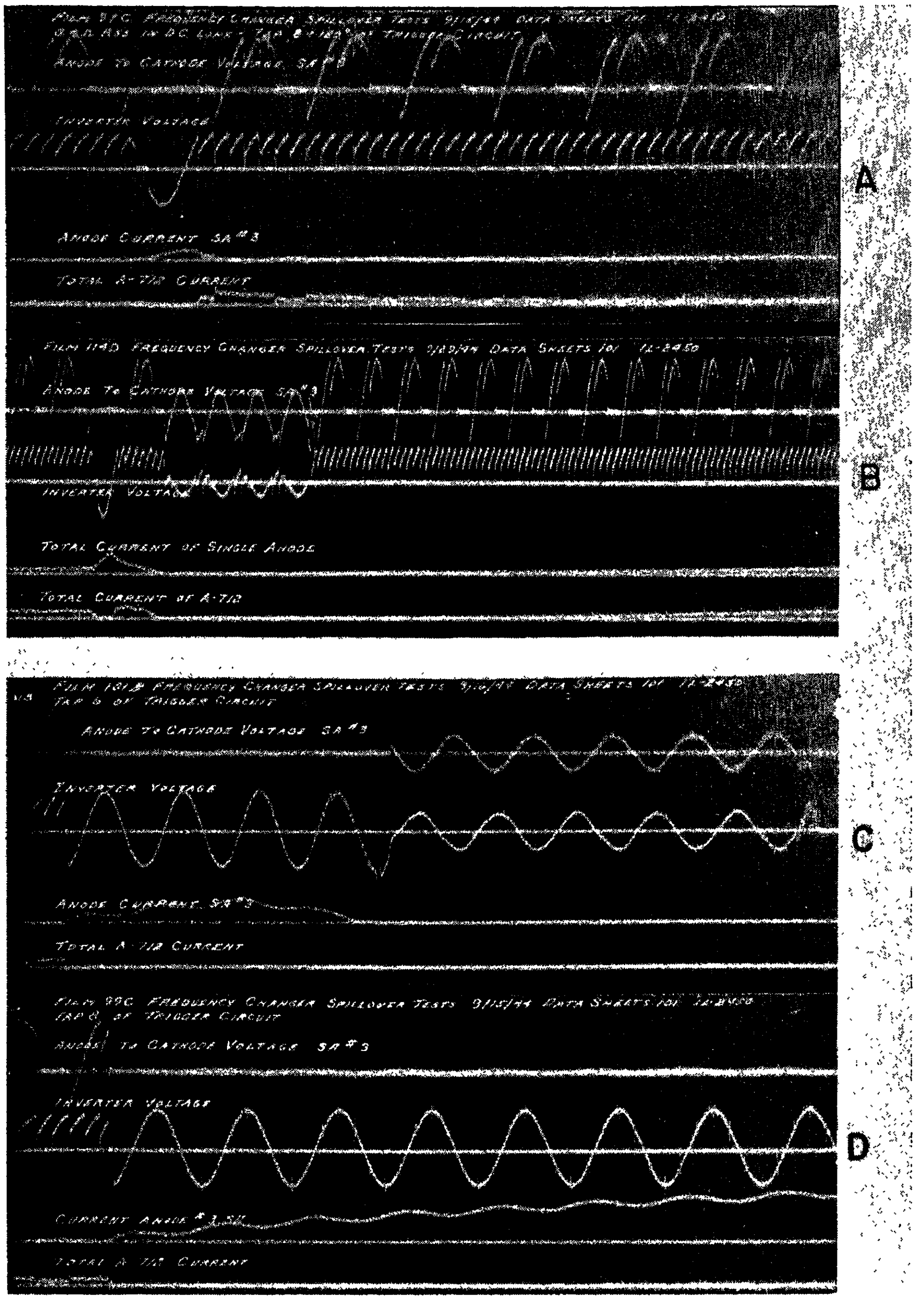

Figure 8. Oscillograms of arc-throughs in power inverter of electronic frequency changer, illustrating several methods of clearing the fault

proper point of the cycle, by means of thyratron tubes. They apply positive voltages from a 6-phase winding of grid transformer *GT1*, of sufficient magnitude to overcome the blocking voltage of *D1*. The resistors *R1* serve as individual loading resistors for the tubes, and the firing voltages appear across them. The average current of each tube is about 0.25 ampere. The connection *GC* is the common reference terminal for the cathodes of the thyratron tubes.

The grids of the thyratron tubes are controlled by the 6-phase winding of grid transformer *GT2* and a negative bias voltage between the neutral point of the grid transformer and terminal *GC*. The firing point of the thyratron tubes, and of the corresponding rectifier tubes, is determined by the phase position of the grid alternating voltages and the magnitude of the bias voltage.

The phase position of the grid-firing voltages in relation to the anode voltages of the rectifier unit, which determines its operation as a power rectifier or a power inverter, is set by a tapped phase-shifting autotransformer, and contactors *43R* and *43I*. The contactors are operated by a selector control switch, which establishes the direction of power flow.

For power inverter operation, a contact of *43I* connects the neutral point of grid transformer *GT2* to *GC* through a negative bias voltage provided by *D2*. This bias is used for a closer setting of the angle of advance, which remains fixed. The power transmitted by the frequency changer is regulated by phase control of the power rectifier only.

For operation as a power rectifier, contacts *43I* are open and *43R* closed. One pair of contacts connects a source of variable-bias voltage between the neutral point of *GT2* and *GC*, for controlling the firing point of the tubes. The bias voltage is supplied by a Regulex rotating-type amplifier. Its output voltage is regulated by its control field in response to a feedback load-control system, indicated by a block in Figure 6, to maintain the direct current in the d-c link of the frequency changer at a value dictated by power requirements.

The frequency changer may be operated to carry a preset adjustable base load, or to control the maximum demand of purchased 60-cycle power supplied to the steel mill, depending on the position of a selector switch. When on maximum-demand control, the load is allowed to swing between preset limits under control of the demand-meter contacts. To reduce the demand, the frequency changer load has to be reduced when transmitting power from the 60- to the 25-cycle system, and has to be increased for the reverse direction of power flow.

The thyratron tubes *IT* and *RT* serve as relays to apply arc suppression to the power rectifier upon occurrence of an arc-through or an arc-back. Tube *IT* is triggered on an arc-through in the power inverter by a voltage from a secondary winding of the d-c reactor. An arc-back in the power rectifier triggers tube *RT* with a voltage pulse from anode current transformers. The firing of either tube applies to the grids of the control tubes a blocking bias voltage from *D3*, which exceeds the maximum value of the grid alternating voltages. The blocking circuit is opened, after a short time delay, by the series relays *IR* and *RR;* their contacts short-circuit the tubes and coils, thereby extinguishing the tubes and resetting the relays. A blocking rectifier *BR* prevents the flow of current from *D3* through the Regulex amplifier.

One set of load-control and blocking equipment is provided for each section of the frequency changer. The selector switches and the demand control are common for both sections.

PROTECTION

The units are provided with overcurrent protection on the a-c side of each rectifier transformer. Overcurrent relays, with

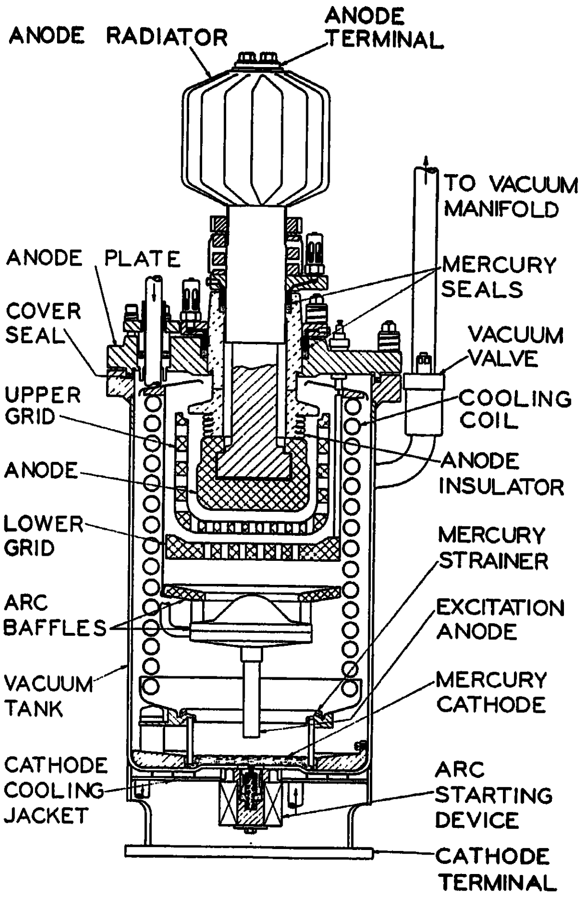

Figure 9. Cross section of excitron rectifier tube used for the Gary frequency changer

time-delay and instantaneous elements, are used for this purpose and are connected to trip the a-c breakers. On an arc-back in the power rectifier, arc-suppression by grid blocking is applied to the faulted rectifier, as previously described. This is backed up by tripping of the a-c breaker. Arc suppression provides fast interruption of the fault current, but cannot be relied on for absolute protection in all cases.

An arc-through in the power inverter is usually suppressed by the d-c reactor, supplemented by application of arc suppression to the power rectifier, as has been described. A sustained arc-through is cleared by the d-c breaker, which is tripped at a preset overcurrent in the d-c circuit. Because of the inductance of the d-c reactor, a standard d-c breaker was not available for interrupting the circuit during a fault. A 6-pole anode breaker,[5] used for other rectifier applications, was adapted for this purpose.

A circuit diagram of the breaker is shown in Figure 7. The six poles are connected in series parallel. The breaker is closed by a motor. Each pole is held closed by an electromagnet (not shown) against the pull of a spring; it is tripped by a d-c trip coil which bucks the flux at the pole faces of the electromagnet and releases the holding armature. The series reverse-current trip coils of the standard anode breaker were replaced by suitable coils designated in Figure 7 by *T1* to *T6*, for the breaker poles of corresponding numbers.

The poles are tripped in sequence, cutting in two steps of current-limiting resistors before final interruption. On an overcurrent in the d-c circuit, tripping current is applied to coils *T2* and *T6* from the station battery. The opening of poles 2 and 6 inserts resistor *R1* into the d-c circuit, in series with trip coil *T4*. The opening of pole 4 inserts resistor *R2*, in series with the trip coils of the remaining poles, which interrupt the d-c circuit. The d-c breaker can be tripped manually by opening the coil circuit of the holding electromagnets.

The oscillograms of Figure 8 illustrate several methods of clearing an arc-through in a power inverter. The tests were made on one section of unit *1*, with the 60-cycle side as the power inverter. The arc-throughs were produced by pulsing the grids of an excitron tube during the positive nonconducting period. For the oscillograms in Figures 8(A), 8(B), and 8(D) the tube was connected in parallel with one anode of an operating rectifier (*A-712* in the oscillograms), but did not itself carry normal load current. For the oscillogram in Figure 8(B) the faulting tube was one of a 6-tube rectifier, which carried about one-half the load current of the section.

The top trace of each oscillogram is the anode-to-cathode voltage of the faulting tube; the second trace is the terminal d-c

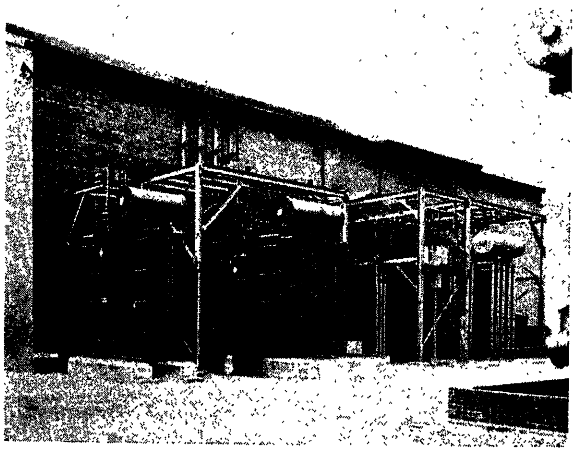

Figure 10. View of 60-cycle side of frequency-changer building at Gary Sheet and Tin Mill

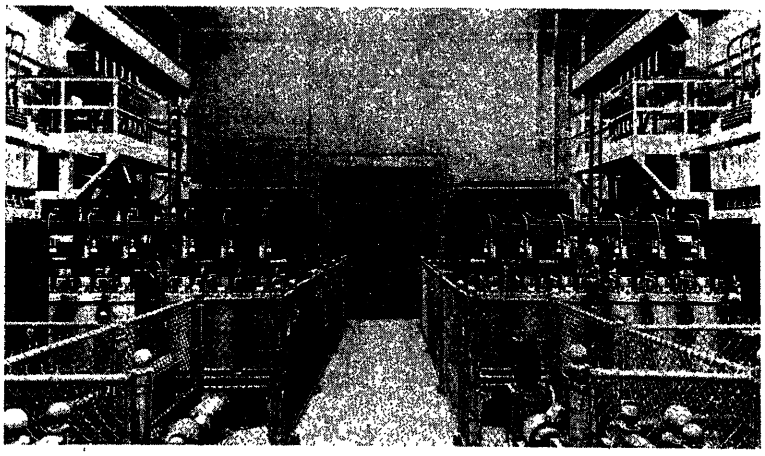

Figure 11. Interior view of frequency-changer installation, showing the equipment of unit 2

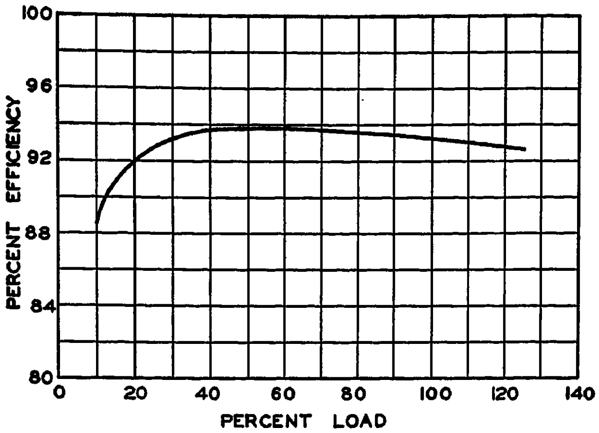

Figure 12 (left). Over-all efficiency of 8,000-kw electronic frequency-changer unit 2

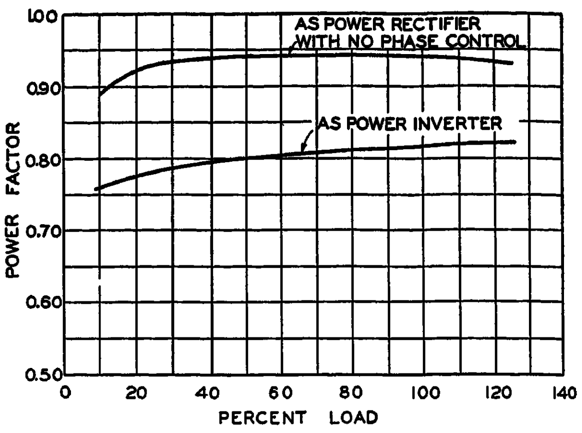
Figure 13 (right). Power factor on the 60-cycle side of 8,000-kw electronic frequency change



voltage of the power inverter (negative above the zero line); the third trace shows the fault current; the bottom trace is the current of the parallel rectifier.

In the oscillogram in Figure 8(A) the arc-through was suppressed by recommutation. Besides the reactor, there was a current-limiting resistor in the d-c circuit. There was no resistor in the tests recorded by the other oscillograms. The anode-to-cathode voltage is equal to the arc drop while the current is flowing, and is close to the zero line. During the arc-through, the inverter voltage is the voltage of the faulted phase, which accounts for the loop in the positive direction, produced by the positive half-cycle of the voltage.

Arc suppression was applied to the power rectifier (25 cycles) in the oscillogram in Figure 8(B), but it took effect only after the arc-through was suppressed by recommutation, due to the influence of the d-c reactor in slowing up the rise of fault current. After the removal of arc suppression, the direct current was gradually restored to normal, as indicated by the lower traces.

The fault current was interrupted by the d-c breaker in the oscillogram in Figure 8(C). The inverter voltage is the voltage of the faulted phase. The voltage traces after the breaker opened are due to the potentiometer connections for the oscillograph elements.

In the oscillogram in Figure 8(D) the fault was cleared by tripping the a-c breaker of the power rectifier. Unfortunately, the opening of the breaker was not recorded on the oscillogram. The peak value of the current near the right end of the trace is 10,100 amperes. The current scale is the same for all the oscillograms. The a-c component of the fault current was produced by the voltage of the faulted phase.

The d-c component of the ultimate fault current resulting from an arc-through was calculated to be about 37,000 amperes, which is over 50 times the current rating of the faulted phase winding. This emphasizes the importance of limiting the current by fast clearing of the fault.

Besides the protection against faults, the rectifier units have the usual protective devices and circuits for protection against overtemperature of the transformer, and for overtemperature, poor vacuum, stoppage of water circulation, and sustained excitation failure of the rectifiers. Annunciators are provided for indicating operation of protective devices.

Rectifiers and Their Auxiliaries

A cross-section view of an excitron tube used for the Gary frequency changer is shown in Figure 9. It has the same general design as the tubes used for other rectifier applications.[6] Its main features are:

1. A d-c excitation arc is maintained continuously at the cathode while in operation, and the firing of the anode is controlled by grids.
2. The active part of the tube is enclosed by a cooling coil, which is insulated from the tank and serves the dual purpose of shielding the tank walls from the arc and conducting the cooling water in series with the cathode jacket. The tank is solidly connected to the cathode, and the tank support is the cathode terminal.
3. The tube has two control grids. This was found necessary for power-inverter service, to provide the required blocking reliability.

The excitation current, of about 10 amperes per tube, is supplied by a selenium rectifier. The excitation arc is started by connecting the excitation anode to the cathode with a jet of mercury, ejected by a nozzle plunger which is pulled down by a solenoid.

The 12 tubes of each rectifier are mounted on a base which is supported on insulators. They are connected to the vacuum pumps by a vacuum manifold through shut-off valves on the individual tubes. By closing these valves, a tube can be removed and replaced without breaking the vacuum on any of the tubes.

Each rectifier is cooled by a recirculating water cooling system with a water-to-water heat exchanger. The flow of raw water through the heat exchanger is regulated by a thermostatically-controlled valve, to maintain the rectifier at about 48 degrees centigrade. The cooling equipment is insulated from ground.

All the rectifier auxiliaries and control equipment which operate at, or close to, the cathode potential are supplied with voltage through an insulating transformer. The excitation and grid-control equipments, the vacuum meter, and other rectifier control devices are mounted in a cubicle, which is also insulated from ground.

Equipment is also provided for preheating the rectifiers with current at low voltage following a prolonged shut-down.

Operating Controls

The operating and load-regulating control equipment of each unit, as well as the indicating and recording instruments, are mounted on a control switchboard.

To put a unit in operation, the selector switches are set for the desired direction of power flow and method of load control. A "start" push button is operated to energize the grid-control and excitation circuits of the four rectifiers. The a-c breakers are then closed by control switches, followed by closing of the d-c breakers. The filaments of the thyratron tubes are energized continuously. The unit is shut down by a "stop" push button, which trips the a-c and d-c breakers.

When the unit is shut down, the load regulator is set automatically to pick up a light load when the unit is restarted. When operating on base-load control, the load of each section can be set by a hand-operated rheostat on the switchboard.

INSTALLATION

The frequency-changer installation is located midway between a 69/23-kv 25-cycle substation and a 132/6.9-kv 60-cycle substation, which are about 200 feet apart. The a-c breakers, rectifier transformers, and d-c reactors are placed outdoors. The rest of the equipment is installed in a 44- by 115-foot 1-story brick building.

A view of the 60-cycle side of the building is shown in Figure 10. The 60-cycle transformer of unit *2* and one of the d-c reactors are at the left. Figure 11 is a view of the building interior, showing the equipment of unit *2*. The 60-cycle rectifiers are at the left of the aisle, the 25-cycle rectifiers are at the right. The control cubicles are placed behind the fence between the rectifiers. The cores of the anode-paralleling reactors and anode-current transformers are mounted above the rectifiers. The d-c breakers are located on balconies. The control switchboards and the operator's desk are at the opposite end of the building, adjacent to unit *1*.

The station also has a conditioning stand with three spare excitron tubes, the necessary auxiliaries, degassing equipment, and facilities for reconditioning tubes. These facilities are utilized also for reconditioning and degassing excitron tubes for 250-volt rectifier units installed in other parts of the plant.

EFFICIENCY AND POWER FACTOR

The efficiency curve for unit *2* of the Gary frequency-changer installation is given in Figure 12. It is the calculated over-all efficiency between the 25-cycle and 60-cycle line terminals, including the losses of the rectifier auxiliaries. The curve is fairly flat over the greater part of the load range, which is typical for rectifier units.

The calculated power-factor curves on the 60-cycle side of a rectifier unit, when operating as a power rectifier and a power inverter, are given in Figure 13. The power factor is the ratio of kilowatts to kilovolt-amperes, which includes the effect of the harmonic components in the current. As was explained in another part of the paper, the output current of the power inverter has a leading power factor, while the input to the power rectifier has a lagging power factor. The increase in the power factor of the inverter at increasing load is due to an increase in the commutating angle. Referring to Figure 3, as the commutating angle increases with an increase in the current, the center of the anode current wave shifts to the right, and the angle ϕ decreases.

The power factor of the power rectifier is lowered when its output voltage is reduced by phase control, in approximately the ratio of the voltages. Its power factor is therefore variable, depending on the amount of phase control required for regulating the load of the frequency changer.

OPERATION

The Gary frequency changer has been operated mostly for transmitting power from the 25-cycle to the 60-cycle system. At times it operates in the opposite direction for extended periods, when some of the 25-cycle generating equipment is shut down for maintenance or for other reasons. On some days the direction is alternated.

The units are operated generally on base-load control, and the load level is set by the operator, at the direction of the steel company's power dispatcher, to meet the varying power requirements. Sections of the voltage and kilowatt graphic charts for one of the units are shown in Figure 14. The recording wattmeters have a zero-center scale, for recording either direction of power flow. The kilowatt records for the two sides of the frequency changer are therefore a reflection of each other, and the small difference in their magnitudes is due to the losses in the unit.

The transmitted power is kept steady, at the levels set by the operator, through the action of the load regulators, in spite of the voltage fluctuations on both systems. The rapid dips in the 60-cycle voltage were caused by the load of a large rolling mill. A "pip" in the kilowatt chart near 2 a.m. was produced by a suppressed arc-through on the power inverter.

Since the excitron rectifiers were installed, unit *1* of the frequency changer has been in operation a little over 4 years, and unit *2* over 3 years. During that time 12.5 per cent of the excitron tubes were reconditioned. The thyratron tubes used for firing the rectifier grids have been the major maintenance item, because of their relatively short useful life, averaging 4 to 5 months. It is expected that improvements in the tubes will lengthen their life considerably. They are operated at a fraction of their rated current.

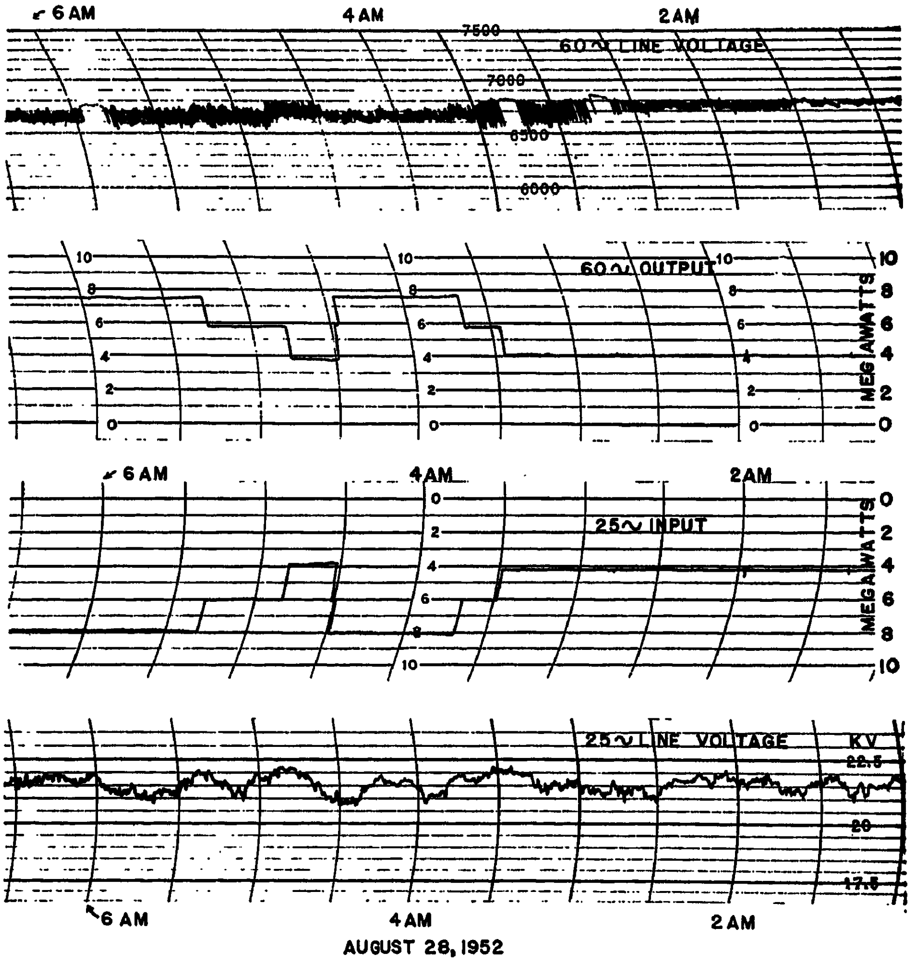


Figure 14. Graphic charts of line alternating voltages and kilowatts for one 8,000-kw unit of Gary frequency-changer installation

There have been occasional trip-outs of a unit caused by arc-backs, but it is restarted immediately, and the outage time is usually less than a minute.

Inductive co-ordination tests were conducted in 1945 to study the influence of the frequency changer on the power systems from the viewpoint of telephone interference. The voltage telephone influence factor (TIF) on the 60-cycle transmission and distribution system of the Northern Indiana Public Company was not appreciably affected by the operation of the frequency changer.

Summary

The electronic frequency changer has proved itself as a practical and highly flexible tie between a-c power systems. The interchange of power can be controlled easily and accurately, unaffected by frequency and voltage variations. However, its application opportunities are limited. Because of its higher first cost, it can be applied economically only where a synchronous-synchronous frequency changer cannot be used,[7] as was the case for the Gary installation.

Besides the Gary installation, the United States Steel Corporaton has an electronic frequency changer operating in a steel mill near Pittsburgh. It is rated at 20,000 kw and employs a different type of rectifier tube.[8] It was also installed in 1943. The engineers of the steel company are to be commended for pioneering these applications.

◆

Discussion

W. E. Gutzwiller (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): Mr. Winograd covered, in a very thorough manner, the principle of operation, design, protection, and electrical characteristics of this 16,000-kw electronic frequency-changer installation.

This discussion deals briefly with the economic aspects of this installation as they prevailed at the time the order for the original equipment was placed.

This electronic frequency changer was purchased mainly for 60-cycle power demand control. The power generated in the 25-cycle system by the United States Steel Corporation was then low-cost by-product power. The 60-cycle system, using purchased utility power, carried heavy mill loads, such as hot-strip, cold-reduction, and temper mills, causing wide fluctuations in the 60-cycle power demand. The purchased power was metered on a 1/2-hour demand basis.

For best utilization of power under the power contract, it was necessary to control closely the 60-cycle power demand. Without such control the mills could frequently exceed the normal controlled demand by 15 to 20 per cent.

There was a definite need to utilize in the 60-cycle system some of the low-cost 25-cycle power produced by unstorable by-product fuel, in order to control the purchased power demand. This called for a frequency changer tie between the two power systems, whose input into the 60-cycle system could be controlled quickly and automatically, depending on the metered 60-cycle power.

The 25-cycle system at that time had ±1.5-cycle, and the 60-cycle system ±0.1-cycle frequency variations. Each system had over 200,000-kw generating capacity. All these conditions still prevail more or less today.

A frequency changer of the nonsynchronous tie type only could be considered. It was then estimated that for the initial installation a set of approximately 7,000 kw would show the maximum economy for demand control. The set also had to provide for operation, in emergency, from 60 to 25 cycles, to take care of temporary shortages of generating capacity in the 25-cycle system.

After careful consideration of all aspects by the engineers of the United States Steel Corporation, an electronic frequency changer was chosen. The original set was rated 6,667 kw, with provision for doubling the capacity of the installation at a later date. This expansion was carried out about 5 years later, when the capacity was increased from 6,667 kw to 16,000 kw.

The system requirements essential for operation of an electronic frequency changer, that is, the a-c voltage for inverter commutation, the kilovars of the power system, and the excitation kilovars of the frequency changer set, which must be supplied from the synchronous machines of the two systems, were met at Gary.

The following characteristic features of the electronic frequency changer were factors in the choice of this equipment for the Gary installation:

1. High over-all conversion efficiency is maintained over a wide range of load.
2. Relatively wide frequency fluctuations in both systems do not affect power transfer or stability of the electronic frequency changer.
3. The kilowatt rating of the set can be chosen independently of the respective system capacities.
4. The electronic frequency changer does not contribute to the short-circuit capacity of the two systems.
5. Starting, loading, and unloading of the set is easy and relatively quick.
6. Maintenance cost of the station is low.
7. Installation, building, and ventilation costs are low because of relatively light weights, absence of heavy rotating masses, and water cooling.
8. Total installed cost of the electronic set was favorable in comparison with similarly rated nonsynchronous-type rotating frequency-changer sets.

The operating records of this installation as of today indicate that most, if not all of the original expectations were realized.

P. A. Jeanne (Bell Telephone Laboratories, Inc., New York, N. Y.): The installation described in Mr. Winograd's paper and the one in reference 8 of the paper afforded an excellent opportunity to study the inductive co-ordination aspects of electronic frequency changers. Extensive observations of inductive influence were made by representatives of the Joint Subcommittee on Development and Research of the Edison Electric Institute and Bell System with the co-operation of the manufacturers and users of the equipment and the interested utilities. As stated in the paper under discussion, the frequency changer did not appreciably affect the TIF of the 60-cycle transmission system supplying it. A review of the test data indicates that there was a very substantial increase in inductive influence on the 6.9-kv bus directly supplying the frequency changer. However, the distribution of harmonics among the various transmission circuits forming the power network supplying the 6.9-kv bus resulted in only a small effect on the influence of the transmission circuits. If there had been any extensive telephone-circuit exposures to lines fed directly from the 6.9-kv bus, noise problems may have been encountered. The inductive influence for a given load condition was somewhat higher on the power system when it was receiving power from the frequency changer than on the same system when it was supplying power to the frequency changer. This is attributable to the greater amount of grid control used with the inverter, which causes more distortion than when the same unit is operating as a rectifier unit.

These observations are based on tests made at the time of the original installations.

Doubling of the frequency changer capacity of the Gary installation might be expected to increase the inductive influence. However, the second unit was so connected that when both are operating, the equivalent of a 24-phase rectifier in place of a 12-phase rectifier is obtained on the 60-cycle side, and a 12-phase rectifier in place of a 6-phase rectifier on the 25-cycle side. This is quite beneficial in reducing the inductive influence because it reduces by one-half the number of theoretically unsuppressed harmonics and they are of higher harmonic order, where their magnitudes are less.

Both this installation and that of reference 8 of the paper are excellent examples of the employment of the multiphasing principle to reduce wave-shape distortion and thus the inductive influence of rectifiers. We in the communication field greatly appreciate the attention given to this matter by both manufacturers and users of large rectifier installations.

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): The author has covered the subject very completely and there is nothing I can add except to point out a few pitfalls.

The voltage charts of the two a-c systems shown in Figure 14 of the paper are typical, but more violent fluctuations occur than can be seen on these charts. If, in Figure 4 of the paper, a line parallel to E_{d1}, indicating the output voltage of the rectifier at maximum a-c voltage and no control and another line representing minimum a-c voltage and maximum phase control were drawn, and then two similar lines parallel to the inverter voltage were drawn, there would be formed a parallelogram including the area of operation possible when both system voltages vary violently between the limits indicated. It must be remembered that no stable regulator, even of the electronic type, can, in practice, be depended on to correct the power transfer for very sudden changes in voltage since corrective action must be taken within a small fraction of a cycle. The d-c reactors can be made large enough, at considerable expense, to slow up the rate of change and give the regulator a chance to catch up. Taking into account the speed of the regulator and the flywheel effect of the d-c reactor, the parallelogram defining the limits of operation can be constricted. For safe operation, however, the right-hand corner of the parallelogram must fall within the safe-load limit of the inverter and the left-hand corner must be greater than the minimum load limit imposed by the stability of the inverter, the system, or particular relaying schemes.

Although not mentioned in this paper, static condensers can be used to supply the commutating voltage, making it possible for the frequency changer to supply an independent load. While this method is possible, difficulties in starting and lack of stability under widely varying operating conditions make the system impractical for large installations.

Power factor of the inverter has been clearly defined in several different ways throughout the paper and yet, it seems to me, more emphasis is needed to correct erroneous thinking on this matter.

It is demonstrated that the inverter must operate at leading power factor in order to commutate successfully; that is to say, the connected system must accept leading current. It is clear that a leading power-factor load is, at the same time, a source of lagging reactive power. In other words, lagging kilovars must be supplied to the inverter by connected generators, or other rotating equipment capable of performing this function, or by static condensers. An electronic frequency changer does not improve the power factor of a system.

E. W. Brewer (General Electric Company, Pittsburgh, Pa.): Mr. Winograd's excellent paper is particularly interesting to many in the Pittsburgh district. A similar installation, which was mentioned in the paper, has been operating for 10 years at the Edgar Thomson Works of the United States Steel Corporation at Braddock, Pa. A few comments on the field experience with this unit may be of interest, as it confirms the practicality of this type of equipment.

The system conditions are similar to those of Gary in that power is generated at both 25 cycles and 60 cycles, supplemented with purchased power at 60 cycles.

The electronic, reversible, nonsynchronous tie consists of two units having a combined rating of 20,000 kw continuously, with overload ratings up to 40,000 kw for 1 minute. A-c power from the 60-cycle 66-kv system is converted by the rectifier to d-c power at approximately 15,000 volts, and then inverted to a-c power in the 25-cycle 44-kv system.

The amount and direction of power flow is remotely controlled. The usual system requirements are such that about 10,000 to 15,000 kw is supplied through the frequency changer to the 25-cycle side. At times as high as 24,000 kw is supplied for approximately 1 hour, and on one occasion, over 30,000 kw was supplied for 1 hour, with a close watch being maintained on tube temperatures. It is operated on standby at loads as low as 500 kw per unit, and during emergencies, 60-cycle power is supplied. Commutating reactors were used originally, but were eliminated when it was found they were not necessary.

Each 10,000-kw unit contains 24 type *GL-506* sealed-pentode ignitron-type tubes. It was expected originally that the tube life might be only 10,000 hours. The latest survey (in January 1953) disclosed, however, that 16 of the original tubes were still in service. The average age (based on actual operating time) of the 48 tubes now installed in the two units was 5.6 years. The average age of the tubes being used has been increasing and, as more of the original tubes reach the end of their life, accurate values of average tube life can be calculated. These values will exceed the average age of tubes in service by a substantial margin.

The river water side of the heat exchangers is cleaned once or twice a year. As with tube changes, this operation is performed on one unit while the other unit is operating.

Harold Winograd: Mr. Gutzwiller has supplied additional background information on the economic factors of the Gary frequency changer installation. Reference 1 of the paper contains interesting data on the application of the frequency changer for controlling the maximum demand.

Mr. Jeanne has pointed out correctly that there was a substantial increase in the voltage TIF at the 6.9-kv 60-cycle terminals of the frequency changer, which was due to the reactance of the 132/6.9-kv step-down transformer bank. This was of no consequence in the Gary installation because the 6.9-kv circuit was inside the plant and no exposures of telephone circuits were involved. From the viewpoint of inductive co-ordination, the significant fact is that an electronic frequency changer has the same effect and can be treated in the same way as any other rectifier installation of comparable size and operating with a corresponding amount of phase control. Where an inductive co-ordination problem is expected, corrective measures, such as phase multiplication, can be applied in the same manner as for rectifier installations in electrochemical service.

The problem of load control due to variations of the a-c line voltages is nowhere near as critical as indicated by Mr. Dortort. It is neither necessary nor desirable to set the angle of advance of the power inverter for extreme and infrequent swings of the a-c voltages. Such a setting would have an adverse effect on the power factors and on the performance of the frequency changer. The load regulator or the protection system can take care of these conditions.

The d-c reactors, of the size used in the Gary installation, have a decided stabilizing effect, and the regulator does not have to take corrective action "within a small fraction of a cycle." For example, with a 10-millihenry reactor in the d-c circuit, a sudden 20-per-cent dip in the inverter voltage will produce an initial rate of increase in the direct current of about 25 per cent of rated current, per cycle (on a 60-cycle basis). Assuming an angle of advance of 35 degrees and a transformer commutating reactance of 6 per cent, the commutation-limit load during such a voltage dip would be reached in about 4 cycles, allowing a margin angle of 15 degrees for deionization of the tube grids. Such a large voltage dip on either system, or a combined simultaneous voltage change in opposite directions on the two systems, would be unusual, but there is sufficient time for a reasonably good regulator to take corrective action.

Electronic frequency changers of relatively low rating, in which the commutating voltage is generated by capacitors in combination with an inductive load, have been applied for conversion of 60-cycle power to about 1,000 cycles for induction heating. As stated by Mr. Dortort, this type of frequency changer would not be very stable under fluctuating load conditions.

Regarding the power factor and kilovars, it has been explained in the paper that the output current of the power inverter has a leading power factor and that the a-c system "must be capable of supplying the lagging kilovars required by the load and the power inverter." Putting out leading kilovars is the same as receiving lagging kilovars.

Mr. Brewer has given some interesting information on the operation of the electronic frequency changer in the Edgar Thomson Works, which was installed in the same year as the first unit at Gary. Besides using different types of rectifier tubes, the two installations have several notable differences in their power circuits.

The rectifier transformers of the Edgar Thomson units have a considerably higher reactance, provided by series a-c reactors. This increased the variation of the commutating angle with load and made it necessary to control the angle of advance of the power inverter in function of the load. The higher reactance also tends to lower the power factor on the input and output sides.

In the Gary installation two rectifier tubes are connected in parallel to each phase of a rectifier transformer, while the Edgar Thomson units have one tube per phase. By paralleling two tubes, a misfire or excitation interruption on one tube of the power inverter is not likely to cause an arc-through because the parallel tube continues to commutate the current, even though it has to conduct the phase current alone during the misfire interval.

The d-c reactors of the Gary units tend to limit the fault current during arc-throughs and aid in suppressing them. The switching equipment in the d-c circuits, independent cooling systems for the individual rectifiers, and individual current regulators for each section permit operating one section of a Gary unit while the other is out of service. This provides greater operating flexibility.

The use of a double-way rectifier circuit for the Edgar Thomson units made it possible to employ simpler rectifier transformers, although some complication was added to the installation because the tubes of each rectifier had to be insulated from each other, and insulating transformers had to be used for the excitation and grid-control circuits of the individual tubes.

This is a rather brief and possibly 1-sided comparison of a few salient technical differences in the two installations. It is interesting that successful solutions of an engineering problem were attained from different approaches.

Oscillatory Circuits Containing Iron-Cored Inductances

ABD EL-SAMIE MOSTAFA
NONMEMBER AIEE

M. EL-SHISHINI
NONMEMBER AIEE

Synopsis: The purpose of the present paper is the development of a theory for analyzing nonlinear iron-cored inductance oscillatory circuits where the forced behavior of the system is considered.

The methods of superposition and successive approximation are applied to the solution of circuits having periodically varying capacitances and the results are directly applied to the present nonlinear problem. The solution obtained gives the harmonics present, a matter which has not been considered by previous authors.

A complete analysis of the properties of oscillatory circuits containing iron-cored inductances is given. Performance and design of static stabilizers using such circuits are also given. Experimental verification has been carried out, and the results agree well with the theoretical predictions.

ELECTRIC circuits containing iron-cored inductances have become of increasing importance due to their extension into many fields of electrical engineering. The property of sudden variation, the so-called critical points, makes ferroresonant circuits useful as sensitive elements in relay and control apparatus.[1–7] Magnetic generation of a group of harmonics,[8] for supplying carrier currents to various multichannel carrier telephone systems and for frequency comparison and standardization, employ such circuits. Static stabilizers are good examples of these circuits.. Therfore, a need is felt for a rigorous but simplified treatment for quantitative evaluation of oscillatory circuits containing iron-cored inductances.

Several papers for the explanation and predetermination of the oscillations in these circuits have been written.[1–8] In all of these papers, the nonlinear characteristic of the iron-cored inductance was treated from the point of view of effective values and not from the point of view of instantaneous values. Therefore, previous authors' analysis is similar to the secant method used in the determination of the amplitude of oscillation in a simple electron tube oscillator and which was proved to be unsatisfactory.[9] Moreover, previous writers ignore the harmonics which may be of considerable amplitudes.

In the present analysis, the nonlinear inductance characteristic is treated from the point of view of instantaneous values and the solution obtained contains the harmonics as well.

Analysis of Iron-Cored Reactor Oscillatory Circuits

The circuit to be analyzed is the ferroresonant parallel circuit, see Figure 1. In most of the iron-cored reactors used in this connection, both the hysteresis and eddy-current losses can be approximately represented by a constant resistance R' shunting the inductor, so long as the frequency of operation is low.

According to Kirchhoff's first law

$$\sum i=0 \text{ at point } P$$

therefore

$$i_C+i_{R'}+i_L=i$$

giving

$$Cdv/dt+v/R_{\text{tot}}+\left(\int vdt\right)/L_t$$
$$=(V_s/R)\sin(\omega t+\theta) \quad (1)$$

where, i_C=current flowing through condenser$=Cdv/dt$; v=voltage across coil$\cong d\phi/dt=d(L_ti_L)/dt$, neglecting winding resistance of coil; ϕ=coil flux linkage; L_t= instantaneous inductance$=\phi/i_L$; $i_L=(\int vdt)/L_t$=current flowing through the iron-cored reactor; i=current passing through load resistance $R=(v_s-v)/R$; v_s=supply voltage$=V_s\sin(\omega t+\theta)$; $i_{R'}=v/R'$=current corresponding to iron loss; $1/R_{\text{tot}}=(1/R)+(1/R')$.

Figure 2 shows instantaneous (that is, d-c) $i\rightarrow\phi$ characteristic passing through the tips of the magnetizing cycles as well as the $(1/L_t)\rightarrow\phi$ characteristic. The first portion of the $i\rightarrow\phi$ characteristic can be satisfactorily considered linear as shown by the dotted line. The corresponding portion in the $(1/L_t)\rightarrow\phi$ characteristic is also shown dotted. $(1/L_t)\rightarrow\phi$ characteristic can be represented by either a power series or a trigonometric series. However, Fourier representation is general and can be used whether the representation is a function of ϕ or i. In the latter case, the power series is very tedious as it requires a large number of terms for satisfactory representation. The characteristic is symmetrical about the vertical axis, and therefore only cosine terms will appear in the Fourier analysis, giving

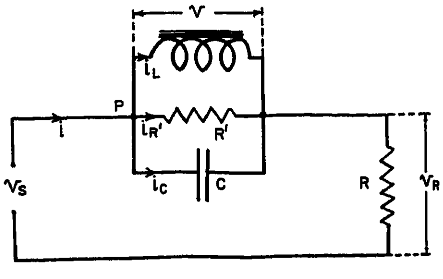

Figure 1. Ferroresonant circuit to be analyzed

Paper 53-156, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted April 3, 1951; made available for printing December 4, 1952.

ABD EL-SAMIE MOSTAFA is with the Alexandria University, Alexandria, Egypt. M. EL-SHISHINI is a member of the Egyptian Senate, Cairo, Egypt.

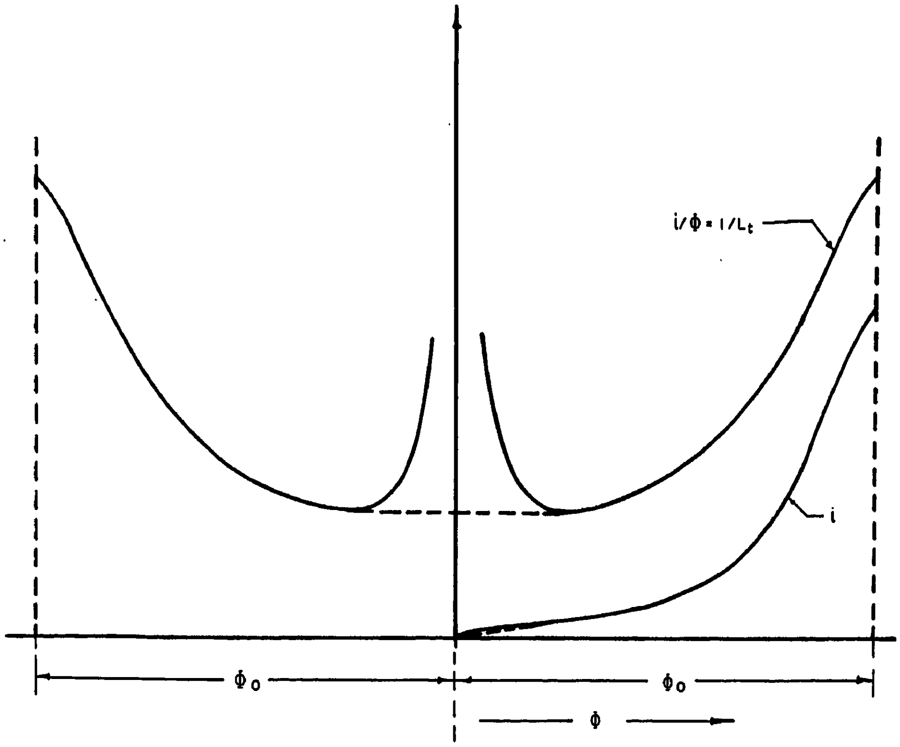

Figure 2. Current as well as $(1/L_t)$ versus flux linkage

$$1/L_t = a_0 + \sum_{n=1} a_n \cos(n\pi\phi/\phi_0)$$

where $a_0, a_1, a_2, \ldots a_n$ are constants to be determined from Fourier analysis. The upper limit of the summation depends on the number of terms in the expansion required for satisfactory representation, but generally it is infinity.

From the nature of the problem, the steady-state flux must contain only odd harmonics. Let the steady-state flux linkage ϕ be given by

$$\phi = -\phi_m \cos \omega t + \phi_3 \cos(3\omega t + \theta_3) + \phi_5 \cos(5\omega t + \theta_5) + \ldots$$

giving

$$v = d\phi/dt = \phi_m \omega \sin \omega t - \phi_3 3\omega \sin(3\omega t + \theta_3) - \phi_5 5\omega \sin(5\omega t + \theta_5) + \ldots$$

The angle θ will consequently be the phase angle between the supply voltage v_s and the fundamental of v at the steady state. The negative sign in ϕ is simply used to give a positive sign, for the fundamental of v, on differentiation.

For the solution of equation 1 to the first power of the parameters a_n of the nonlinear inductance, it is sufficient to substitute $-\phi_m \cos \omega t$ for ϕ in the Fourier analysis. This approximation is sufficient for most practical cases. The resulting solution will contain the harmonics to a satisfactory degree of approximation. Substitution gives

$$\begin{aligned} 1/L_t &= a_0 + \sum_{n=1} a_n \cos(\phi_n \cos \omega t) \\ &= (1/L_0)(1 + K_2 \cos 2\omega t + K_4 \cos 4\omega t + \ldots) \quad (2) \end{aligned}$$

where

$$1/L_0 = a_0 + \sum_{n=1} a_n J_0(\phi_n)$$

$$\phi_n = n\pi\phi_m/\phi_0$$

$$K_2 = \left\{-2\sum_{n=1} a_n J_2(\phi_n)\right\} / (1/L_0)$$

$$K_4 = \left\{2\sum_{n=1} a_n J_4(\phi_n)\right\} / (1/L_0) \ldots$$

$J_0, J_2, J_4 \ldots$ are Bessel functions of zero, 2nd, 4th, … orders respectively.[10]

In most of the iron-cored reactors used, equation 2 is highly convergent in the normal operating ranges and usually terms up to K_4 are sufficient for satisfactory results. Substituting equation 2 in 1 gives

$$C dv/dt + v/R_{\text{tot}} + (1/L_0)(1 + K_2 \cos 2\omega t + K_4 \cos 4\omega t + \ldots) \int v\,dt = (V_s/R) \times \sin(\omega t + \theta) \quad (3)$$

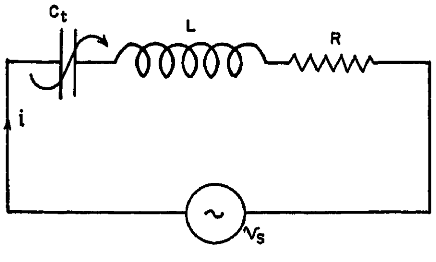

Figure 3. Series oscillatory circuit having a periodically varying capacitance

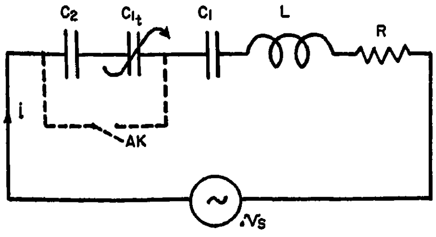

Figure 4. Connection diagram for equation 5

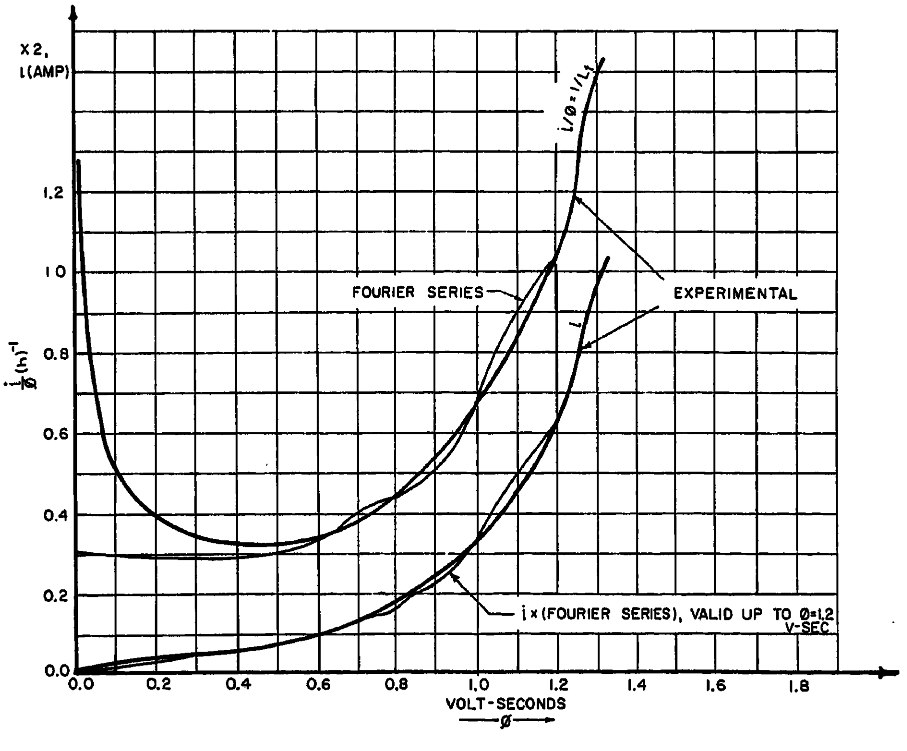

Figure 5. Fourier representation of $i-\phi$ as well as $(i/\phi)-\phi$ characteristics

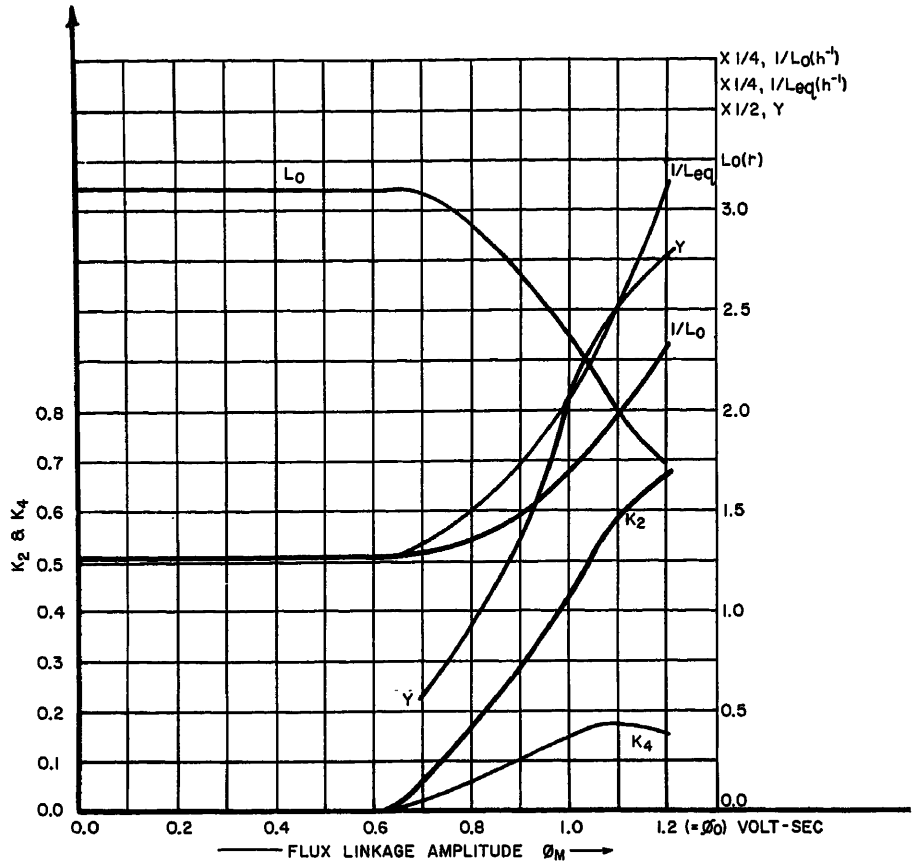

Figure 6. Core characteristics

In this way, the nonlinear differential equation 1 has been transformed to a linear one with periodically varying coefficients. This linearization concerns only the differential equation. On the other hand, the solution of equation 3 will not give the amplitude ϕ_m explicitly. For given values of V_s, R, C, and a certain iron-cored inductance, the solution can be obtained by assuming several values of ϕ_m and solving[11] for V_s, as will be shown later.

For the solution of equation 3, the methods of superposition and successive approximation will be adopted. Although these methods can be directly applied to equation 3, yet a better understanding of the nature of the solution can be obtained when solving the dual series circuit, Figure 3, where C_t is a periodically varying capacitance and given by

$$C_t = C/\left\{1+\sum_{n=1}^{\infty} h_{2n}\cos 2n\omega t\right\}$$

while the inductance L and the resistance R are constants. Here the amplitudes of the capacitance variation h_2, h_4, and so forth of Figure 3 are constants while the corresponding amplitudes K_2, K_4, and so forth of equation 3 are functions of the required solution. Misunderstanding may result if equation 3 is directly analyzed using the methods of successive approximation. The series forming C_t of Figure 3 is assumed convergent, which is the case of equation 3.

The circuit is supplied with a voltage v_s given by $V_s \sin(\omega t+\theta)$ and $(\theta-\pi/2)$ is the phase angle between the applied voltage v_s and the fundamental of the capacity variation. The differential equation for the current i in the circuit is

$$L\,di/dt + Ri + (1/C)\left\{1+\sum_{n=1}^{\infty} h_{2n}\cos 2n\omega t\right\}\times \int i\,dt = V_s \sin(\omega t+\theta) \quad (4)$$

Let

$$\omega_0 = \omega(1+d)$$

where

$$\omega_0^2 = 1/LC$$

d = amount of detune

giving

$$\omega_0^2 = \omega^2(1+d)^2 = (1/LC_1)+(1/LC_2)$$

$$1/C_1 = \omega^2 L,$$

$$1/C_2 = (2d+d^2)/C_1 = \omega^2 L(2d+d^2)$$

Substitution in equation 4 gives

$$L\,di/dt + Ri + \left\{(1/C_1)+(1/C_2)+(1/C)\times \sum_{n=1}^{\infty} h_{2n}\cos 2n\omega t\right\}\int i\,dt = V_s \sin(\omega t+\theta) \quad (5)$$

This means that the condenser C is split up into two condensers C_1 and C_2 in series. The connection diagram giving the current i of equation 5 will be as shown, Figure 4, where

$$1/C_{1t} = (1/C)\sum_{n=1}^{\infty} h_{2n}\cos 2n\omega t$$

The reason for splitting up the capacity C is in order that the resonant frequency of the $L-C_1-R$ circuit would equal the supply frequency; this will result in simplifying the analysis when using the methods of successive approximations.

As will be shown in the Appendix I, the current i of equation 5 is given by

$$i = (V_s/R)\{\sqrt{M^2+N^2}/(1-a)\}\times [\sin(\omega t+\theta_1) + (\sqrt{A_3^2+B_3^2}/\times \sqrt{R^2+(8\omega L/3)^2})\cos(3\omega t+\theta_3-\phi_3) + (\sqrt{A_5^2+B_5^2}/\sqrt{R^2+(24\omega L/5)^2})\times \cos(5\omega t+\theta_5-\phi_5)+\ldots] \quad (6)$$

where

$$a = (h_2/2\omega CR)^2 - \{(2d+d^2)/\omega C_1 R\}^2 = (\omega L/R)^2[\{(h_2/2)(1+d)^2\}^2-(2d+d^2)^2]$$

$$M = \cos\theta + (\omega L/R)\{(h_2/2)(1+d)^2 - (2d+d^2)\}\sin\theta$$

$$N = \sin\theta + (\omega L/R)\{(h_2/2)(1+d)^2 + (2d+d^2)\}\cos\theta$$

$$\tan\theta_1 = N/M$$

$$A_3 = \{(h_2+h_4)/2\omega C\}\cos\theta_1$$

$$B_3 = \{(h_2-h_4)/2\omega C\}\sin\theta_1$$

$$\tan\theta_3 = B_3/A_3$$

$$\tan\phi_3 = 8\omega L/3R$$

$$A_5 = (h_4/2\omega C)\cos\theta_1$$

$$B_5 = (h_4/2\omega C)\sin\theta_1$$

$$\tan\theta_5 = B_5/A_5 = \tan\theta_1$$

$$\tan\phi_5 = 24\omega L/5R$$

Now, equation 4 is similar to equation 3 with the substitution of i, R, L, C, h_2, h_4 ..., and V_s for v, $(1/R_{tot})$, C, L_0, K_2, K_4, ... and (V_s/R) respectively. However, the voltage v of equation 3 must be of the same form as assumed and which is $v=\phi_m\omega \sin\omega t+\ldots$ Therefore, a possible solution for equation 3 can be obtained from equation 6 provided $\theta_1=0$, that is

$$N = 0 = \sin\theta + (\omega L/R)\{(h_2/2)(1+d)^2 + (2d+d^2)\}\cos\theta$$

giving

$$\tan\theta = (\omega L/R)\{(h_2/2)(1+d)^2+(2d+d^2)\} = \{\omega L-(1/\omega C_{eq})\}/R$$

where

$$C_{eq} = C/(1+h_2/2)$$

Therefore, the voltage v of equation 3 will be given satisfactorily by

$$v=V_s(R_{tot}/R)\cos\theta[\sin\omega t+\{(K_2+K_4)/\times 2\sqrt{(\omega L_0/R_{tot})^2+(8\omega^2/3\omega_0^2)^2}\}\times \cos(3\omega t-\phi_3)+\{(K_4/\times 2\sqrt{(\omega L_0/R_{tot})^2+(24\omega^2/5\omega_0^2)^2})\times \cos(5\omega t-\phi_5)+\ldots] \quad (7)$$

where

$\tan\theta=R_{tot}\{\omega C-(1/\omega L_{eq})\}$,

$R_{tot}=RR'/(R+R')$

$L_{eq}=L_0/(1+K_2/2)$

$\tan\phi_3=(8/3)\omega CR_{tot}$

$\tan\phi_5=(24/5)\omega CR_{tot}$

$\omega_0^2=1/L_0C$

The flux linkage

$$\phi=\int v\,dt \quad (8)$$

The voltage across the load resistance R will be given by

$$v_R=v_S-v=V_S\cos\theta[\sqrt{\tan^2\theta+(R_{tot}/R')^2}\times \sin(\omega t+\theta')-\{(R_{tot}/R)(K_2+K_4)/\times 2\sqrt{(\omega L_0/R_{tot})^2+(8\omega^2/3\omega_0^2)^2}\}\times \cos(3\omega t-\phi_3)+\{(R_{tot}/R)(K_4/2)/\sqrt{(\omega L_0/R_{tot})^2+(24\omega^2/5\omega_0^2)^2}\} \cos(5\omega t-\phi_5)+\ldots] \quad (9)$$

where

$\tan\theta'=(R'/R_{tot})\tan\theta=R'\{\omega C-1/\omega L_{eq}\}$

The load current is given by

$i=v_R/R$

As stated before, the solutions of equations 7, 8, and 9 are not direct. For given values of V_s, R, C and a certain iron-cored inductance, equation 8 can be solved by assuming several values of ϕ_m and solving for V_s. Interpolation or otherwise is normally required.

It should be noted that the predicted harmonics arrived at in equations 7, 8, and 9 are practically satisfactory estimates of the harmonic contents. For a closer approximation resubstitute $\{-\phi_m\cos\omega t+\phi_3\sin(3\omega t-\phi_3)+\phi_5\sin(5\omega t-\phi_5)+\ldots\}$ for ϕ in the Fourier analysis of $1/L_t$ where ϕ_3, ϕ_5 and so forth, ϕ_3, ϕ_5, and so forth are the amplitudes and phases of the harmonics given by equation 8; the resulting values of K_2, K_4, and so forth will now be modified, and solutions 7, 8, and 9 will still hold.

To test that the amplitudes and phases of the harmonics given by equations 7 and 9 are reliable estimates, the following examples will be calculated and checked experimentally by oscillograms. The examples are intentionally chosen where the nonlinearity is large.

From the $\phi\rightarrow i$ characteristic passing through the tips of the cycles of a given iron-cored inductance, the $(1/L_t)\rightarrow\phi$ characteristic is obtained, see Figure 5; harmonic analysis gives

$$1/L_t=0.4465-0.253665\cos(\pi\phi/\phi_0)+0.1481\cos(2\pi\phi/\phi_0)-0.0715\cos\times(3\pi\phi/\phi_0)+0.04275\cos(4\pi\phi/\phi_0)-0.03285\cos(5\pi\phi/\phi_0)+0.014665\times\cos(6\pi\phi/\phi_0)$$

where

$\phi_0=1.2$ volt-seconds

Putting $\phi=-\phi_m\cos\omega t$ in the harmonic analysis gives

$$1/L_t=(1/L_0)(1+K_2\cos 2\omega t+K_4\times\cos 4\omega t+\ldots)$$

$$1/L_0=0.4465-0.253665J_0(\pi\phi_m/\phi_0)+0.148085J_0(2\pi\phi_m/\phi_0)-0.0715\times J_0(3\pi\phi_m/\phi_0)+0.04275J_0(4\pi\phi_m/\phi_0)-0.03285J_0(5\pi\phi_m/\phi_0)+0.014665\times J_0(6\pi\phi_m/\phi_0)$$

$$K_2=2L_0\{-0.253665J_2(\pi\phi_m/\phi_0)+0.148085\times J_2(2\pi\phi_m/\phi_0)-0.0715J_2(3\pi\phi_m/\phi_0)+0.04275J_2(4\pi\phi_m/\phi_0)-0.03285\times J_2(5\pi\phi_m/\phi_0)+0.014665J_2(6\pi\phi_m/\phi_0)\}$$

$$K_4=2L_0\{-0.253665J_4(\pi\phi_m/\phi_0)+0.148085\times J_4(2\pi\phi_m/\phi_0)-0.0715J_4(3\pi\phi_m/\phi_0)+0.04275J_4(4\pi\phi_m/\phi_0)-0.03285\times J_4(5\pi\phi_m/\phi_0)+0.014665J_4(6\pi\phi_m/\phi_0)\}$$

The coefficients higher than K_4 were very

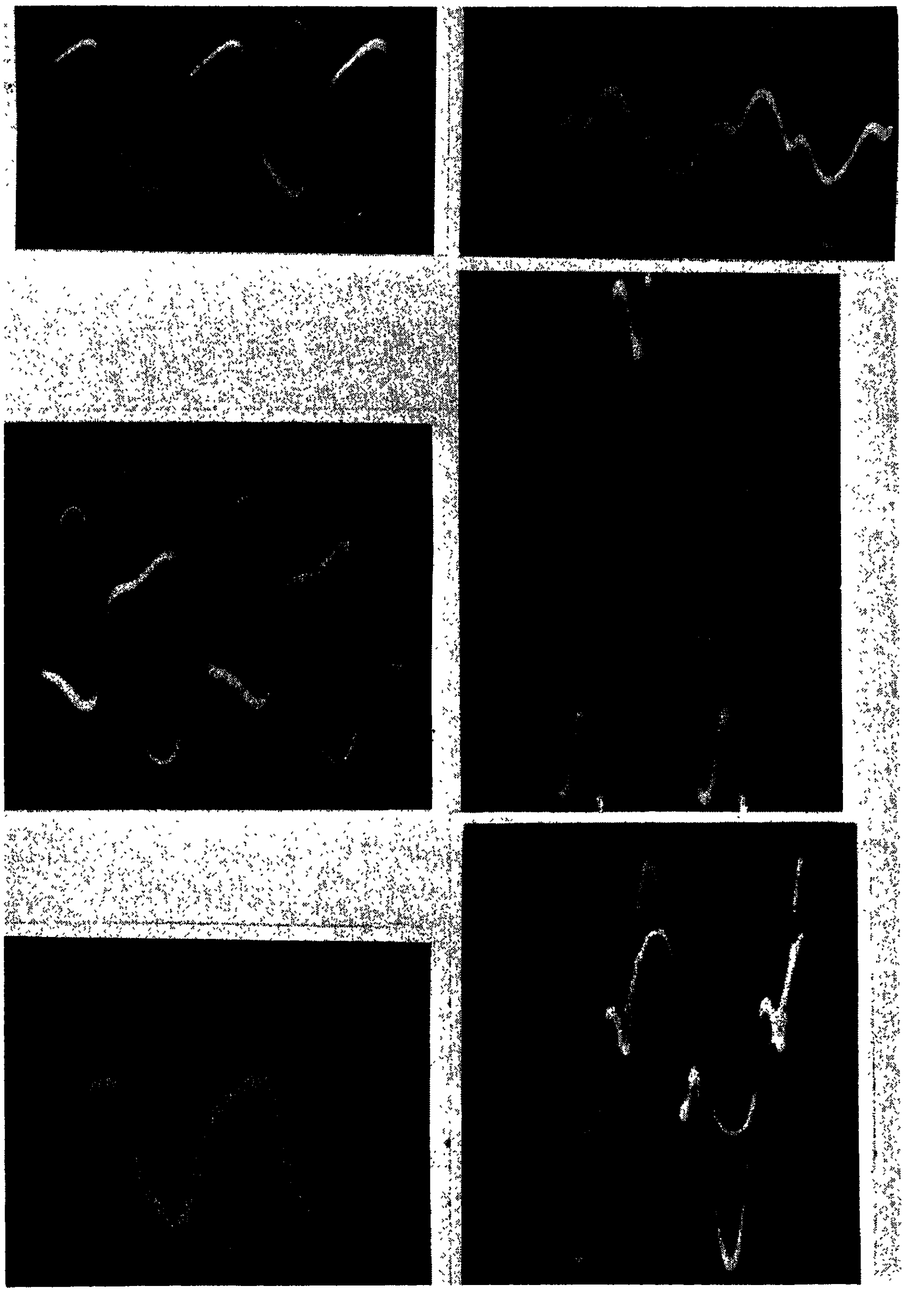

Figure 7. Experimental oscillograms of load voltage v_R and voltage v across reactor

Bottom: C=10 microfarads, V_s (rms)=240 volts, R=500 ohms

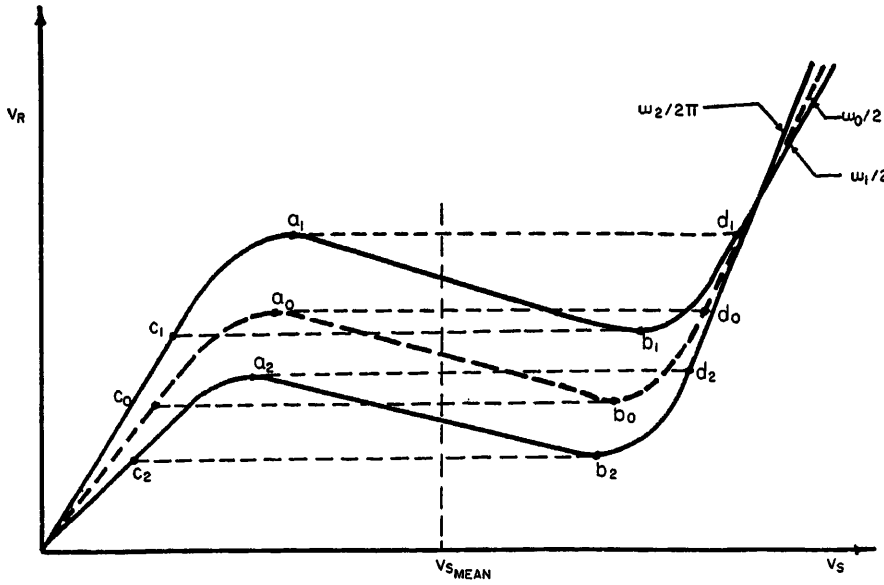

Figure 9. Load voltage versus supply voltage for three frequencies $\omega_0/2\pi$, $\omega_1/2\pi$, and $\omega_2/2\pi$ ($\omega_1>\omega_0>\omega_2$)

small and hence they were neglected. From the Bessel coefficients, the values of $1/L_0$, K_2, and K_4 can be obtained for any value of ϕ_m.

The characteristics of the core which are, $1/L_0$, K_2, K_4, L_0, $1/L_{eq}\{=(1+K_2/2)/L_0\}$ against ϕ_m are shown, see Figure 6.

The shunt resistance R' representing the iron loss of the present core = 1,780 ohms.

EXAMPLE 1

Capacitance $C=12$ microfarads, resistance $R=500$ ohms, supply voltage $V_s=264$ volts rms, and supply frequency = 40 cycles per second.

It is clear from equations 7 and 8 that the amplitude ϕ_m of the fundamental of the flux linkage is given by

$$\phi_m=(1/\omega)V_s(R_{tot}/R)\cos\theta$$

where

$$\tan\theta=R_{tot}\{\omega C-(1/\omega L_{eq})\}$$

$$R_{tot}=RR'/(R+R')$$

and

$$L_{eq}=L_0/(1+K_2/2)$$

substitute the given values of C, R, ω, and R' and assume several values for ϕ_m until one is found which is consistent; this value of $\phi_m=1.153$ volt-seconds. Using Figure 6, we get

$$L_0=1.836h$$

$$K_2=0.638$$

$$K_4=0.1716$$

$$1/L_{eq}=0.718h^{-1}$$

Substituting in equations 7 and 9 we get

$$v=290\{\sin\omega t+0.104\cos(3\omega t-72°)+0.0126\cos(5\omega t-80°)\}$$

$$v_R=84.8\{\sin(\omega t+15°)-0.356\cos\times(3\omega t-72°)-0.041\cos(5\omega t-80°)\}$$

$$v_s=373\sin(\omega t+3°20')$$

EXAMPLE 2

$C=8$ microfarads, $R=500$ ohms, $V_s=300$ volts rms, and supply frequency = 40 cycles per second. Following the same lines as before we get

$$\phi_m=1.2 \text{ volt-seconds}$$

$$L_0=1.725h$$

$$K_2=0.675$$

$$K_4=0.153$$

$$1/L_{eq}=0.776h^{-1}$$

$$v=303\{\sin\omega t+0.164\cos(3\omega t-64°48')+0.018\cos(5\omega t-75°)\}$$

$$v_R=187\{\sin(\omega t-62°24')-0.2675\cos\times(3\omega t-64°48')-0.029\cos(5\omega t-75°)\}$$

$$v_s=424\sin(\omega t-23°)$$

EXAMPLE 3

$C=10$ microfarads, $R=500$ ohms, $V_s=240$ volts rms, and supply frequency = 40 cycles per second, giving

$$v=264.8\{\sin\omega t+0.091\cos(3\omega t-69°)+0.013\cos(5\omega t-77°57')\}$$

$$v_R=77.7\{\sin(\omega t+16°40')-0.31\cos\times(3\omega t-69°)-0.044\cos(5\omega t-77°57')\}$$

$$v_s=340\sin(\omega t+3°48')$$

Figure 7 shows experimental oscillograms for v and v_R for the previous calculated cases. In the same figure the supply voltages are also shown, noting that they are 180 degrees out of phase in the v-oscillograms. The theoretical curves are drawn to the scale of the oscillograms and shown together for comparison in Figure 8; there is satisfactory agreement indicating that the amplitudes and phases of the harmonics given by Figures 7 and 8 are reliable estimates.

Some Properties of the Circuit

In order to simplify the analysis when getting the properties of the circuit, only the fundamental of the wave will be considered; it is clear from the previous examples that a discrepancy of the order of 10 per cent between experimental values (rms) and theoretical values (fundamental) is to be expected at the portions of the characteristics where the nonlinearity is high. However, most design data obtained in this way will be practically satisfactory. It should be noted here that considering only the fundamental and using the present analysis is totally different from the standard prac-

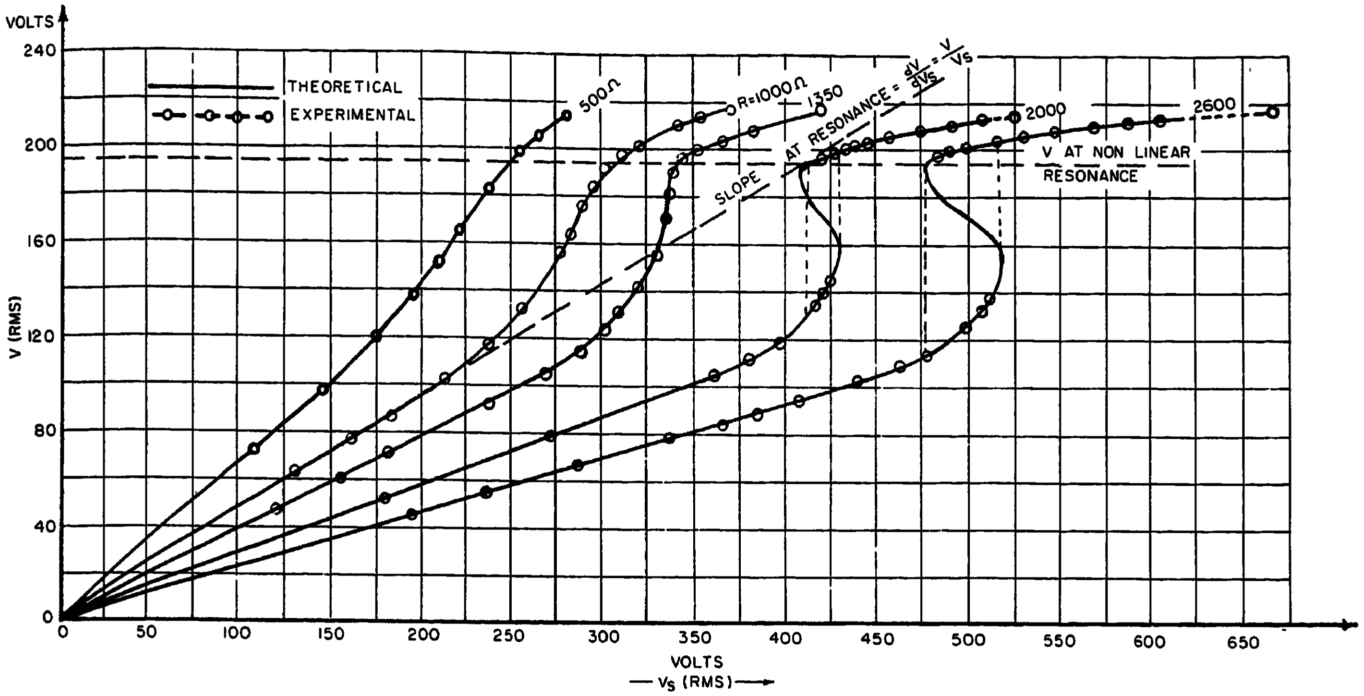

Figure 10. Characteristics of voltage V across reactor versus supply voltage V_s, $C=10$ microfarads

tice used by previous authors, namely, treating the nonlinear characteristic of the iron-cored inductance from the point of view of effective values.

The important properties of the circuit are the unstable regions and the point of nonlinear resonance.

The point of nonlinear resonance, is that at which v_s and the fundamentals of v and v_R are in phase, and hence $\theta = 0 = \theta'$, giving $\omega^2 C = 1/L_{eq}$. The corresponding value of ϕ_m is therefore independent of R, and can be obtained from $(1/L_{eq}) \rightarrow \phi_m$ characteristic given in Figure 6. It can be shown easily that at the resonant point

$$V_s = (1 + R/R')\omega\phi_m$$

$$V_R = (R/R')\omega\phi_m$$

$$dV_s/dV = 1 + R/R'$$

$$dR/dV = -(R+R')/V$$

where V is the amplitude of the fundamental of v. The unstable region is the region bounded by the locus $fV/dV_s = \infty$, that is, $dV_s/dV = 0$. It can also be shown that

$$dV_s/dV = (1/\omega)dV_s/d\phi_m = (1+R/R')\times [1 + R_{tot}^2\{(1/\omega L_{eq}) - \omega C\}^2 + \phi_m R_{tot}^2\{(1/\omega L_{eq}) - \omega C\}\, Y/\omega]/\times [1 + R_{tot}^2\{(1/\omega L_{eq}) - \omega C\}^2]$$

where $Y = d(1/L_{eq})/d\phi_m$ characteristic is given in Figure 6.

For

$$dV_s/dV = 0$$

$$1/R_{tot}^2 = -\{(1/\omega L_{eq}) - \omega C\}\times \{(1/\omega L_{eq}) - \omega C + \phi_m Y/\omega\} \quad (10)$$

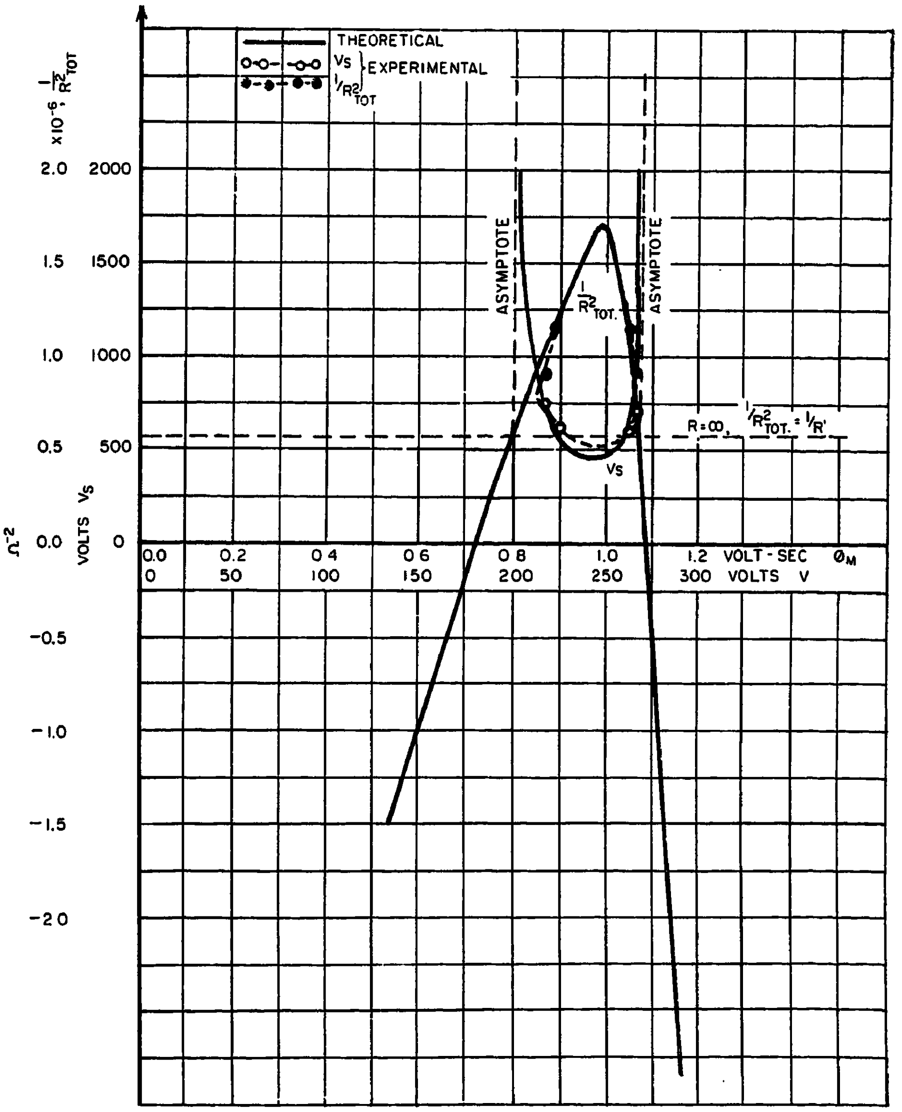

Figure 11. Unstable region, $C=10$ microfarads

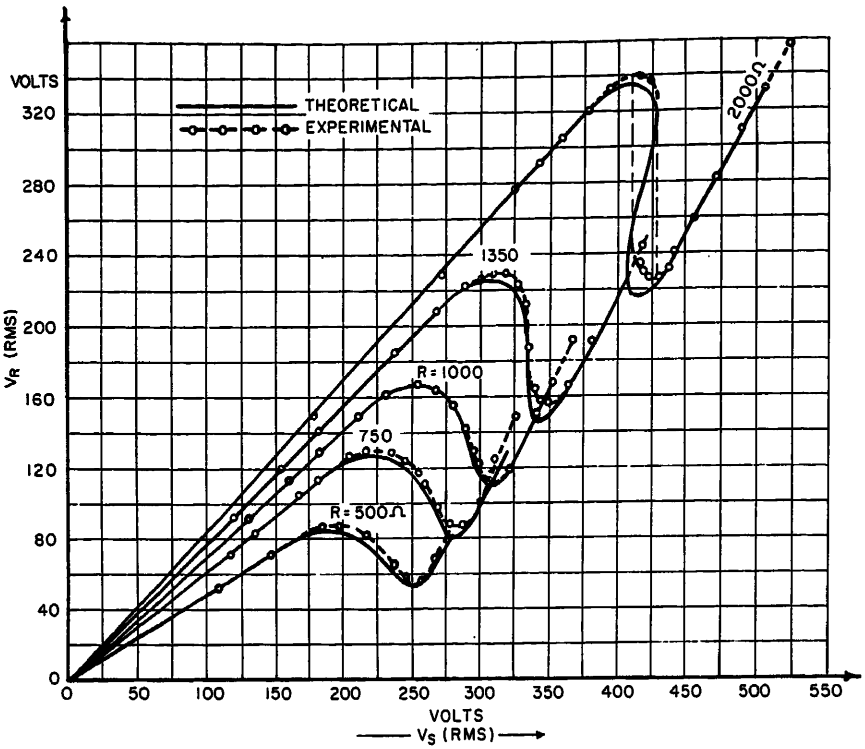

Figure 12 (above). Characteristics of load voltage V_R versus supply voltage V_s, C=10 microfarads

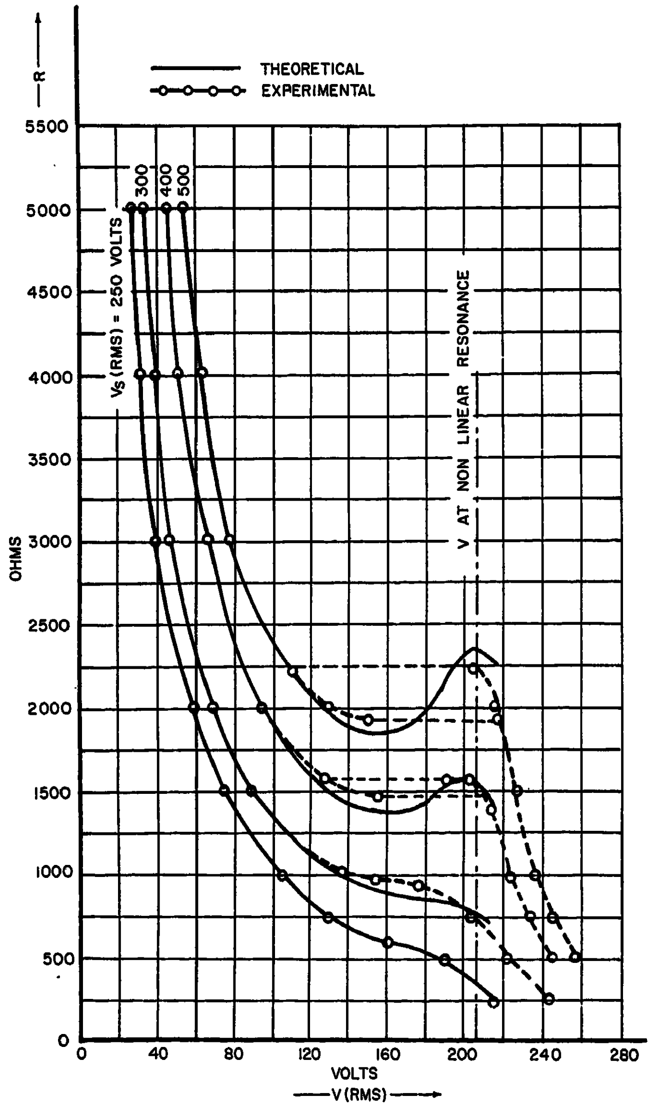

Figure 13 (left). Characteristics of load resistance R versus voltage V across reactor, C= 12 microfarads

Figure 14 (below). C—ϕ_m characteristics, loci of points a, b, and c, d

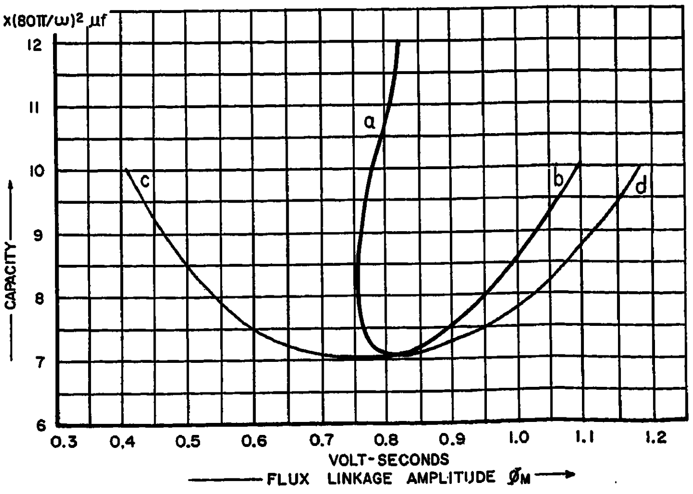

Figure 11 shows the relation between the right-hand side of equation 10 and ϕ_m or V giving the unstable region. Using equation 10, it can be shown that the corresponding values of V_s are obtained from the relation

$$V_s=\omega\phi_m R\sqrt{\phi_m(Y/\omega)\{\omega C-(1/\omega L_{eq})\}},$$

Figure 11. As $(\partial R/\partial V)_{V_s}=(\partial R/\partial V_s)_V(\partial V_s/\partial V)_R$, therefore $(\partial R/\partial V)_{V_s}=0$ when $(\partial V_s/\partial V)_R=0$, indicating that points of sudden variation in the $V\rightarrow V_s$ characteristic, Figure 10, correspond to those of the $R\rightarrow V$ characteristic, Figure 13.

Performance and Design of a Static Stabilizer

From the study of the characteristics of parallel iron-cored oscillatory circuits, it is evident that the region which can be used as a stabilizer is that between points c and d, Figure 9. It can be shown that

$$V_R=\omega\phi_m R\sqrt{\{(1/\omega L_{eq})-\omega C\}^2+(1/R'^2)}$$

indicating that the line current I, given by $(I=V_R/R)$, depends only on ϕ_m and C, and is independent of R. It can also be shown that

$$V_s=\omega\phi_m\sqrt{\{(R+R')/R'\}^2+R^2\{(1/\omega L_{eq})-\omega C\}^2}$$

The points a and b are determined from the relation

$$dV_R/dV_s=0=(\partial V_R/\partial\phi_m)(\partial\phi_m/\partial V_s)$$

that is, from the relation, $dV_R/d\phi_m=0$, giving

$$\{(1/\omega L_{eq})-\omega C\}^2+(1/R'^2)+\{(1/\omega L_{eq})-\omega C\}\,Y\phi_m/\omega=0$$

showing that the flux linkages ϕ_{m_a} and ϕ_{m_b} at points a and b are independent of R. Again, as Y is positive as shown in Figure 6, $\{(1/\omega L_{eq})-\omega C\}$ must be negative in the region between a and b.

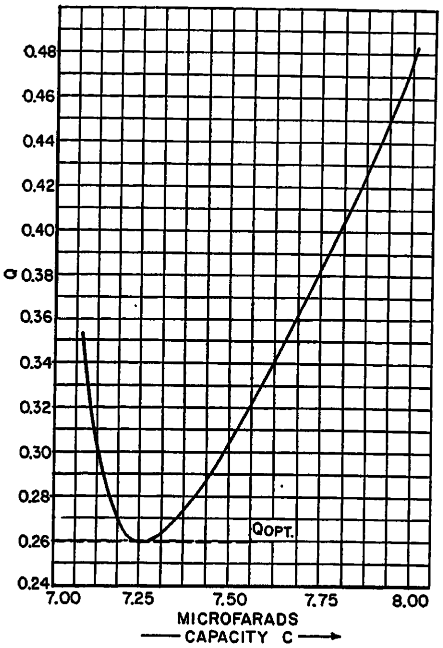

Figure 15. Q—C characteristic, optimum capacity for good stabilization

Therefore, it can be shown that the voltages across R, namely, V_{R_a} and V_{R_b} at points a and b increase with the increase of frequency, R and C being kept constants. When the variation of the supply voltages V_{s_c} and V_{s_d} at points c and d with frequency is comparatively small and can be neglected (Figure 9), the values at normal frequency $\omega_0/2\pi$ will be used. The relation between V_R and V_s for $\omega_0/2\pi$ and for other two frequencies $\omega_1/2\pi$ and $\omega_2/2\pi$ slightly higher and lower than $\omega_0/2\pi$ respectively are shown in Figure 9.

The relation between the capacitance C and the amplitude of the flux linkage ϕ_m for $dV_R/dV_s=0$ and the relation between C and (ϕ_{m_c}, ϕ_{m_d}) are shown, Figure 14, the frequency $\omega/2\pi$ being constant; both relations are independent of R. ϕ_{m_c} and ϕ_{m_d} are the values at points c and d respectively.

From conditions of similarity, it can be shown that if the frequency increases from $\omega_2/2\pi$ to $\omega_1/2\pi$, the capacitance should be reduced by the factor ω_2^2/ω_1^2 to have the same values of ϕ_m.

CHOICE OF R AND C FOR GOOD STABILIZATION

Our choice is such that for certain ratio changes in the supply frequency and supply voltage $\pm K_f$ and $\pm K_s$ respectively, the stabilization in the load voltage is the best possible provided that the load voltage with respect to the supply voltage is reasonable. An approximate relation to satisfy these conditions is that the quantity Q given by

$$\{(V_{R_{a_1}}-V_{R_{b_2}})V_{s_{\text{mean}}}/2V_{R_{\text{mean}}}{}^2K_s=Q\} \quad \text{is minimum}$$

where

$V_{s_{\text{mean}}}$ = mean supply voltage $=(V_{s_{c_0}}+V_{s_{d_0}})/2$

$V_{R_{\text{mean}}}$ = mean load voltage $=(V_{R_{a_1}}+V_{R_{b_2}})/2$

K_s = ratio change in the supply voltage $=(V_{s_{d_0}}-V_{s_{c_0}})/(V_{s_{d_0}}+V_{s_{c_0}})$

$V_{s_{c_0}}$ and $V_{s_{d_0}}$ are the supply voltages at points c_0 and d_0 of Figure 9, while $V_{R_{a_1}}$ and $V_{R_{b_2}}$ are the load voltages at points a_1 and b_2 respectively. The ratio of the supply voltages $V_{s_{c_0}}$ and $V_{s_{d_0}}$ at points c_0 and d_0 of Figure 9 is given by

$$V_{s_{d_0}}/V_{s_{c_0}}=(1+K_s)/(1-K_s)=K=\omega_0\phi_{m_{d_0}}\times \sqrt{(1+R/R')^2+R^2\{(1/\omega_0L_{eq_{d_0}})-\omega_0C\}^2}/\omega_0\phi_{m_{c_0}}\sqrt{(1+R/R')^2+R^2\{(1/\omega_0L_{eq_{c_0}})-\omega_0C\}^2}$$

The last relation gives

$$R=1/(\sqrt{M}-1/R')$$

where

$$M=[\{(1/\omega_0L_{eq_{c_0}})-\omega_0C\}^2(K\phi_{m_{c_0}}/\phi_{m_{d_0}})^2-\times\{(1/\omega_0L_{eq_{d_0}})-\omega_0C\}^2]/\{1-(K\phi_{m_{c_0}}/\phi_{m_{d_0}})^2\}$$

The indices 0, 1, and 2 refer to values at frequencies $\omega_0/2\pi$, $\omega_1/2\pi$, and $\omega_2/2\pi$ respectively.

For a certain value of C, $\phi_{m_{c_0}}$, $\phi_{m_{d_0}}$, and hence $L_{eq_{c_0}}$ and $L_{eq_{d_0}}$ can be obtained.

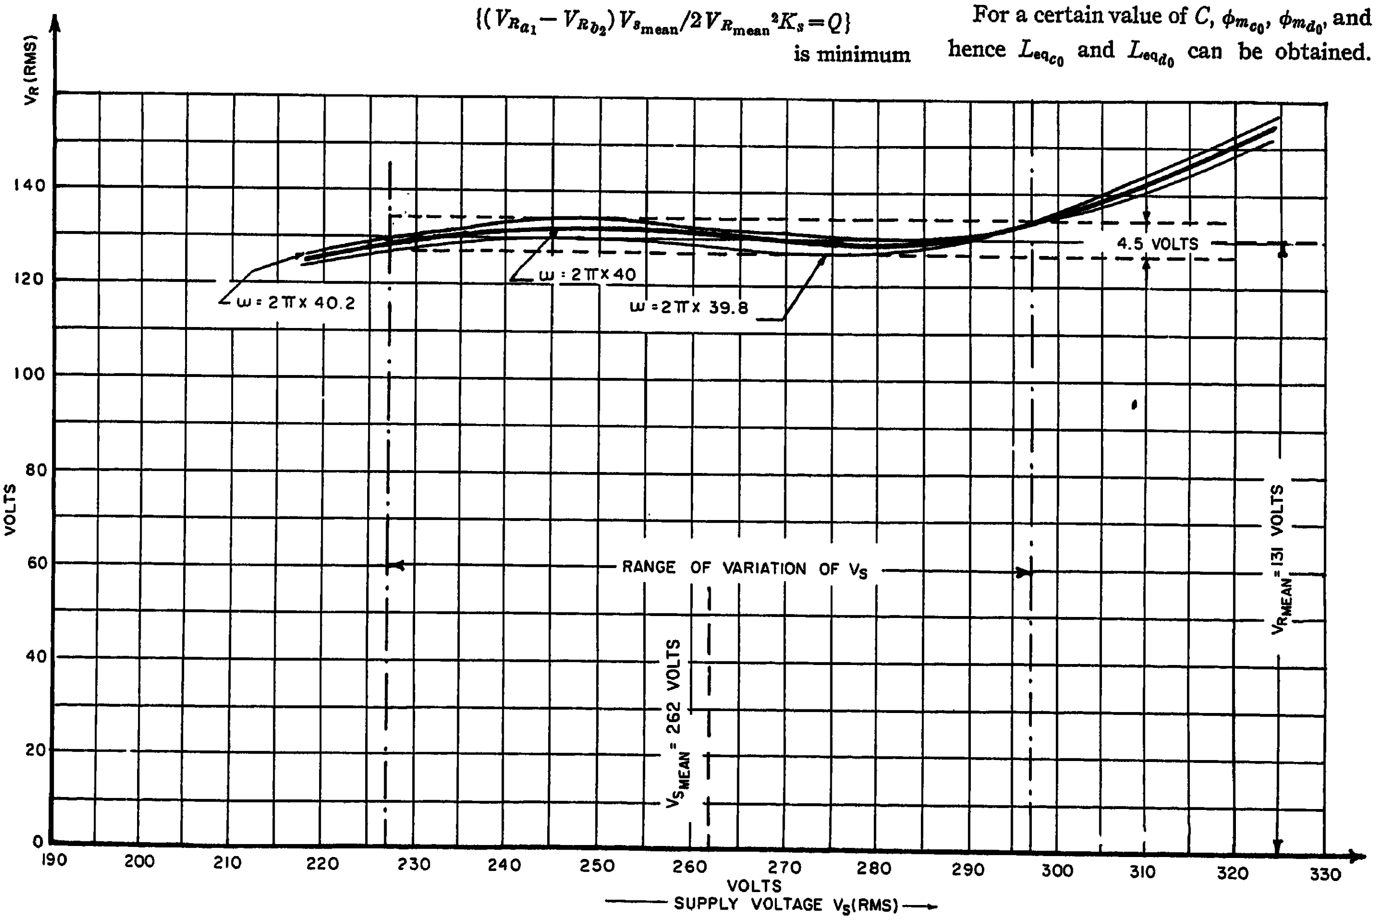

Figure 16. Voltage stabilizer characteristics

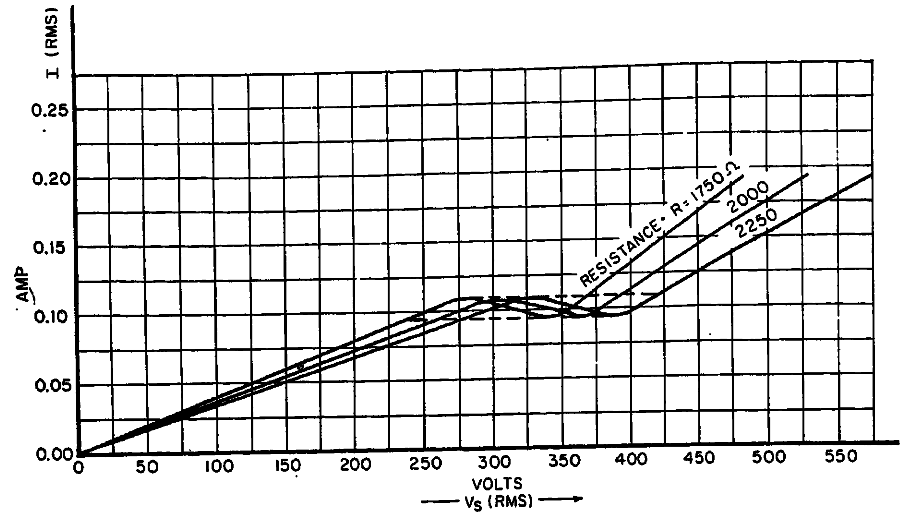

Figure 17. Current stabilizer characteristics

Substitution gives the corresponding value of R, from which the corresponding value of Q can be obtained. Similarly, for other values of the capacity C, the corresponding values of Q are obtained. The $Q \rightarrow C$ characteristic will show a minimum, giving the optimum capacity $C_{\text{opt.}}$ required for good stabilization, Figure 15, the corresponding values $R_{\text{opt.}}$ and $V_{s\,\text{opt.}}$ are consequently obtained.

For any other core of different dimensions, but of the same iron grade, the values of C, R, V_s and the rating for good stabilization can be obtained by applying the conditions of similarity. It can be shown that if the core volume, area, and length vary from τ_0, A_0, and l_0 to τ, A, and l respectively, and the number of turns of the iron-core coil and the supply frequency vary from n_0 and $\omega_0/2\pi$ to n and $\omega/2\pi$ respectively, the values of C, R, and V_s and the rating will be given by

$$C=(n_0^2/n^2)(A_0l/Al_0)(\omega_0^2/\omega^2)C_0$$

$$R=(l_0/l)(An^2/A_0n_0^2)(\omega/\omega_0)R_0$$

$$V_s=(nA/n_0A_0)(\omega/\omega_0)V_{s_0}$$

and the rating = (rating)$_0(\tau/\tau_0)(\omega/\omega_0)$.

Experimental Verification

In order to test the validity of the foregoing theoretical relations and conclusions regarding iron-cored inductance oscillatory circuits, the following experimental work was carried out.

The iron-cored inductance used in the experiments is the one whose characteristics are given in Figure 5 and 6.

Figure 10 shows the voltage V across the iron-cored reactor against the supply voltage V_s for several values of the load resistance R and for $C=10$ microfarads, both theoretical and experimental curves are indicated. As in section entitled "Some Properties of the Circuit," only the fundamental of the wave is used in the theoretical curves while rms values are used in the experimental curves. The value of V at nonlinear resonance, and which is independent of the load resistance R, is shown. The slopes dV_s/dV at such nonlinear points are also shown. The values of V and hence ϕ_m at which $dV/dV_s=$— are obtained experimentally from such curves. The boundaries at which $dV/dV_s=\infty$ for $C=10$ microfarads both theoretical and experimental are shown, see Figure 11. Figure 12 shows the load voltage V_R against the supply voltage V_s for several values of the load resistance R and for $C=10$ microfarads, both experimental and theoretical curves are shown. Figure 13 shows the load resistance R against V for several values of the supply voltage V_s, C being equal to 12 microfarads. The value of V at nonlinear resonance is shown.

To get the values of C, R and V_s for good stabilization, the following theoretical curves are drawn. The relation between C and ϕ_m at points c and d as well as points a and b is shown in Figure 14. Figure 15 shows the relation between the quantity Q and the capacity C for variations of ±12.5 per cent and ±0.5 per cent in the supply voltage and frequency respectively from which the optimum value of the capacity $C=C_{\text{opt.}}=7.25$ microfarads for good stabilization is obtained.

Figure 16 shows the relation between the load voltage V_R and the supply voltage V_s at $C=7.25$ microfarads and $R=$ 1,450 ohms, that is, near optimum values; the frequency $f=40$, 40.2 and 39.8 cycles per second. With these values, a stabilization as good as ±1.75 per cent in the load voltage or current which will be reduced at ±0.96 per cent if the frequency remains constant at 40 cycles per second; the supply voltage V_s varies between 227 and 297 volts.

Figure 17 shows the relation between the line current I and the supply voltage V_s for $C=8$ microfarads and for several values of the load resistance R and shows that good stabilization can be obtained with variable load resistance.

Appendix I. Determination of the Current *i* of Equation 5

According to the well-known "compensation theorem," if C_2 and C_{1_t} are short-circuited by closing the artificial key and replaced instead by a generator of zero internal impedance having an electromotive force $-\{(1/C_2)+(1/C_{1_t})\}\int i\,dt$, where i is the actual current flowing in the circuit, i would be unchanged; but the actual current flowing in the circuit is unknown; therefore, successive approximations will be adopted as follows

Closing the artificial key, the current would be given by

$$i_1=(V_s/R)\sin(\omega t+\theta)$$

i_1 gives the current to a first approximation, steady state only being considered.

For a second approximation, replace C_2 and C_{1_t} by a generator of zero internal impedance and having an electromotive force

$$\begin{aligned} v_1 = -\{(1/C_2)+(1/C_{1_t})\}\int i_1 dt = (V_s/R)\times \\ [\{(2d+d^2)/\omega C\}\cos(\omega t+\theta)+ \\ \sum_{n=1}^{\infty}(h_{2_n}/2\omega C)\{\cos((2n+1)\omega t+\theta)+ \\ \cos((2n-1)\omega t-\theta)\}] \\ = v_{1_\omega}+v_{1_{3\omega}}+v_{1_{5\omega}}+\cdots \end{aligned}$$

The voltage v_1 consists of components of frequencies $\omega/2\pi$, $3\omega/2\pi$, $5\omega/2\pi$, and so forth. To get the effect of v_{1_ω}, close the artificial key of Figure 4, and apply such a voltage, the current is given by

$$\begin{aligned} i_2=(V_s/R)[\{(2d+d^2)/\omega C_1R\}\cos(\omega t+\theta)+ \\ (h_2/2\omega CR)\cos(\omega t-\theta)] \end{aligned}$$

When this is added to i_1, it gives a second approximation for the current in the circuit so long as the effects of the voltage components of frequency $\omega/2\pi$ are considered.

Following the same lines, other approximations can be obtained and which are given by

$$\begin{aligned} i_3=(V_s/R)[(h_2/2\omega CR)^2-\{(2d+d^2)/\omega C_1R\}^2] \\ \sin(\omega t+\theta) \end{aligned}$$

$$\begin{aligned} i_4=(V_s/R)[(h_2/2\omega CR)^2-[\{(2d+d^2)/ \\ \omega C_1R\}^2]\{(2d+d^2)/\omega C_1R\}\cos(\omega t+\theta)+ \\ (h_2/2\omega CR)\cos(\omega t-\theta)] \end{aligned}$$

$$\begin{aligned} i_5=(V_s/R)[(h_2/2\omega CR)^2-\{(2d+d^2)/ \\ \omega C_1R\}^2]^2\sin(\omega t+\theta) \end{aligned}$$

Therefore, the fundamental component of the current, excluding the effects of the 3rd, 5th, . . . harmonic voltages, will be given by

$$
\begin{aligned}
i_{\text{Fund.}} &= i_1+i_2+i_3+i_4+i_5+\dots \\
&= (V_s/R)[\sin(\omega t+\theta)+\{(h_2/2\omega CR)\times \cos(\omega t-\theta)+((2d+d^2)/\omega C_1R)\times \cos(\omega t+\theta)\}+\{(h_2/2\omega CR)^2- ((2d+d^2)/\omega C_1R)^2\}\sin(\omega t+\theta)+ \\
&\quad \{(h_2/2\omega CR)^2-((2d+d^2)/\omega C_1R)^2\}\times \{((2d+d^2)/\omega C_1R)\cos(\omega t+\theta)+ (h_2/2\omega CR)\cos(\omega t-\theta)\}+\{(h_2/2\omega CR)^2- ((2d+d^2)/\omega C_1R)^2\}^2\sin(\omega t+\theta)+\dots] \\
&= (V_s/R)(1+a+a^2+a^3+\dots)\times \{\sin(\omega t+\theta)+(h_2/2\omega CR)\cos(\omega t-\theta)+ ((2d+d^2)/\omega C_1R)\cos(\omega t+\theta)\} \\
&= (V_s/R)\{\sqrt{M^2+N^2}/(1-a)\}\times \sin(\omega t+\theta_1) \qquad (11)
\end{aligned}
$$

where

$$a=(h_2/2\omega CR)^2-\{(2d+d^2)/\omega C_1R\}^2$$

$$=(\omega L/R)^2[\{(h_2/2)(1+d)^2\}^2-(2d+d^2)^2]$$

$$M=\cos\theta+(\omega L/R)\{(h_2/2)(1+d)^2-(2d+d^2)\}\sin\theta$$

$$N=\sin\theta+(\omega L/R)\{(h_2/2)(1+d)^2+(2d+d^2)\}\cos\theta$$

and

$$\tan\theta_1=N/M$$

For a better approximation of $i_{\text{Fund.}}$, the effects of the components of the voltages v_2, v_3, et cetera of frequencies other than $\omega/2\pi$ would be considered. However, the approximation given by equation 11 is sufficient for the present nonlinear problem.

Harmonics other than the fundamental can be obtained using the method of successive approximation and following the same lines as before.

Therefore, the current i, to a satisfactory degree of approximation, will be as given in equation 6 in the text.

A New Method for Treating Electron Tubes When Used as Superregenerative Detectors

Part II. Superregenerative Circuits Under Signal Conditions

ABD EL-SAMIE MOSTAFA
NONMEMBER AIEE

M. EL-SHISHINI
NONMEMBER AIEE

Synopsis: This is the second of a series of papers dealing with a comprehensive study of superregenerative detection. In the first paper[1] the analysis under no-signal condition was given. In this paper, the analysis of superregenerative circuits under signal condition is presented. It is shown that the amplitude to which the oscillation under signal condition builds up, depends fundamentally on the quenching source and the nonlinearity of the tube characteristic. The automatic volume control action, the sensitivity, the selectivity, the stability, and the synchronization with the signal voltage or the semisynchronization (the synchronization with one of the equivalent side bands) of the signal voltage are clearly explained. The existing idea that the effect of the signal is merely to start a free oscillation with an amplitude depending on the signal is erroneous and does not conform with the fact. What actually happens when the signal is present, is that the system must, in general, be in some state of synchronization with the signal frequency or with one of the equivalent side bands. This latter is defined as semisynchronization. In order to have satisfactory reception, the free oscillation is generally suppressed. In general, no previous author has mentioned such synchronization or semisynchronization processes. Numerical examples are given for clarification.

Theoretical Analysis

Figure 1 shows a schematic diagram for a separately quenched superregenerative detector acted upon by an external source e of amplitude E and frequency $\omega_1/2\pi$ in series with the inductive branch.

Applying Kirchhoff's first law for the currents meeting at P we get

$$i_C+i_G+i_p+i_L=0$$

giving after differentiation

$$d^2v/dt^2+(1/C)(Gdv/dt+di_p/dt)+\omega_0v=\omega_0^2e \qquad (1)$$

where i_C, i_L, and i_G represent the alternating components of the currents in the capacitive, inductive, and conductive branches respectively, i_p, being the deviation of the plate current from its steady value, can be represented as a power series of the lumped voltage e' as follows

$$i_p=\alpha e'+\beta e'^2+\gamma e'^3$$

Near resonance, the amplitude E of the signal voltage will be too small compared with the amplitude of the output voltage v, therefore e' can be very approximately given by

$$e'=(1-\mu M/L)v+v_q$$

where v_q = quench voltage = $N\cos pt$

Differentiating i_p and neglecting dv_q/dt compared with dv/dt and substituting in equation 1 we get

---

Paper 53-157, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted March 10, 1952; made available for printing December 3, 1952.

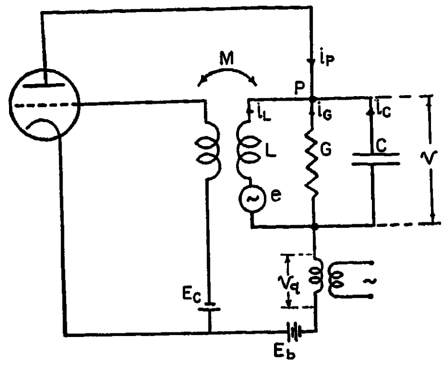

Figure 1. Separately quenched superregenerative detector with an applied signal

$$d^2v/dt^2+(1/C)\{G+\alpha(1-\mu M/L)+ 2\beta(1-\mu M/L)^2v+2\beta(1-\mu M/L)v_q+ 3\gamma(1-\mu M/L)^3v^2+6\gamma(1-\mu M/L)^2\times v_qv+3\gamma(1-\mu M/L)v_q^2\}dv/dt+\omega_0^2v =\omega_0^2e \quad (2)$$

As will be shown later in the experimental part (part III of this series[2]), the type of oscillation under signal condition depends on the amount of detune between $\omega_0/2\pi$ and $\omega_1/2\pi$ and on the amplitude E of the signal, where $\omega_0^2=1/LC$. If $\omega_0/2\pi$ is near $\omega_1/2\pi$, synchronization at the signal frequency takes place provided the conditions for stable synchronization are fulfilled; in this case, only synchronized oscillation of frequency $\omega_1/2\pi$ will be present, the free oscillation is suppressed. If $\omega_0/2\pi$ is near $(\omega_1\pm np)/2\pi$, synchronization at $(\omega_1\pm np)/2\pi$ takes place provided the conditions of the stability for such synchronization are fulfilled, n being an integer and $p/2\pi$ the quench frequency. Such synchronization does not take place at the signal frequency $\omega_1/2\pi$, but it takes place at an equivalent sideband frequency $(\omega_1\pm np)/2\pi$ and therefore it may be called semisynchronization. In this case, besides the semisynchronized oscillation of frequency $(\omega_1\pm np)/2\pi$, the tube also operates at frequency $\omega_1/2\pi$; however, free oscillation will be suppressed. In any case, such synchronization or semisynchronization is essential for satisfactory reception; the characteristic noise is generally suppressed. If the conditions of stable synchronization are not fulfilled, forced as well as free oscillations will be present, and in this case, the characteristic noise exists and the reception is poor. The two possible cases for satisfactory reception will now be treated.

SYNCHRONIZED OSCILLATION IF FREQUENCY $\omega_1/2\pi$ ONLY IS PRESENT, $\omega_0/2\pi$ IS NEAR $\omega_1/2\pi$

Assume v to be of the form $(V_t\cos\omega_1t+\ldots)$, where V_t is slowly varying compared with the frequency of oscillation. Therefore $dv/dt\approx-V_t\omega_1\sin\omega_1t+\ldots$ Let the signal voltage $e=E\cos(\omega_1t+\phi_t)$, then

$$e\approx k_tv\cos\phi_t+(1/\omega_1)(dv/dt)\sin\phi_t$$

Where $k_t=E/V_t$, it is a slow function of time, and where $\phi_t=$ the instantaneous phase angle between e and v, it is also a slow function of time. Substitution in equation 2 gives

$$d^2v/dt^2+(G_t/C)(1+h_{pt}\cos pt+h_{2pt}\times \cos 2pt+\ldots+h_{1t}\cos\omega_1t+h_{2t}\times \cos 2\omega_{1t}+\ldots)dv/dt+\omega_0^2\times (1-k_t\cos\phi_t)v=0 \quad (3)$$

where

$$G_t=G+\alpha(1-\mu M/L)-(\omega_0^2/\omega_1)Ck_t\sin\phi_t+ (3\gamma/2)(1-\mu M/L)^3V_t^2+(3\gamma/2)\times (1-\mu M/L)N^2$$

$$h_{pt}=(1/G_t)2\beta(1-\mu M/L)N$$

$$h_{2pt}=(1/G_t)(3\gamma/2)(1-\mu M/L)N^2$$

$$h_{1t}=(1/G_t)(2\beta+6\gamma N\cos pt)(1-\mu M/L)^2V_t$$

and

$$h_{2t}=(1/G_t)(3\gamma/2)(1-\mu M/L)^3V_t^2$$

In this way, the nonlinear differential equation 2 has been transformed to a linear one with periodically varying coefficients.

In the present analysis, as in the preceding paper,[1] it is assumed that the amount of nonlinearity is small, that is each of (G_t/ω_1C), $(G_t/\omega_1C)h_{pt}$, $(G_t/\omega_1C)h_{2pt}$ and so forth, and $(G_t/\omega_1C)h_{1t}$, $(G_t/\omega_1C)h_{2t}$, and so forth is much less than unity (this is equivalent to saying that the present work is limited to small signals).

Equation 3 is similar to the differential equation 3 of paper 1,[1] of the periodically varying resistance, with the substitution

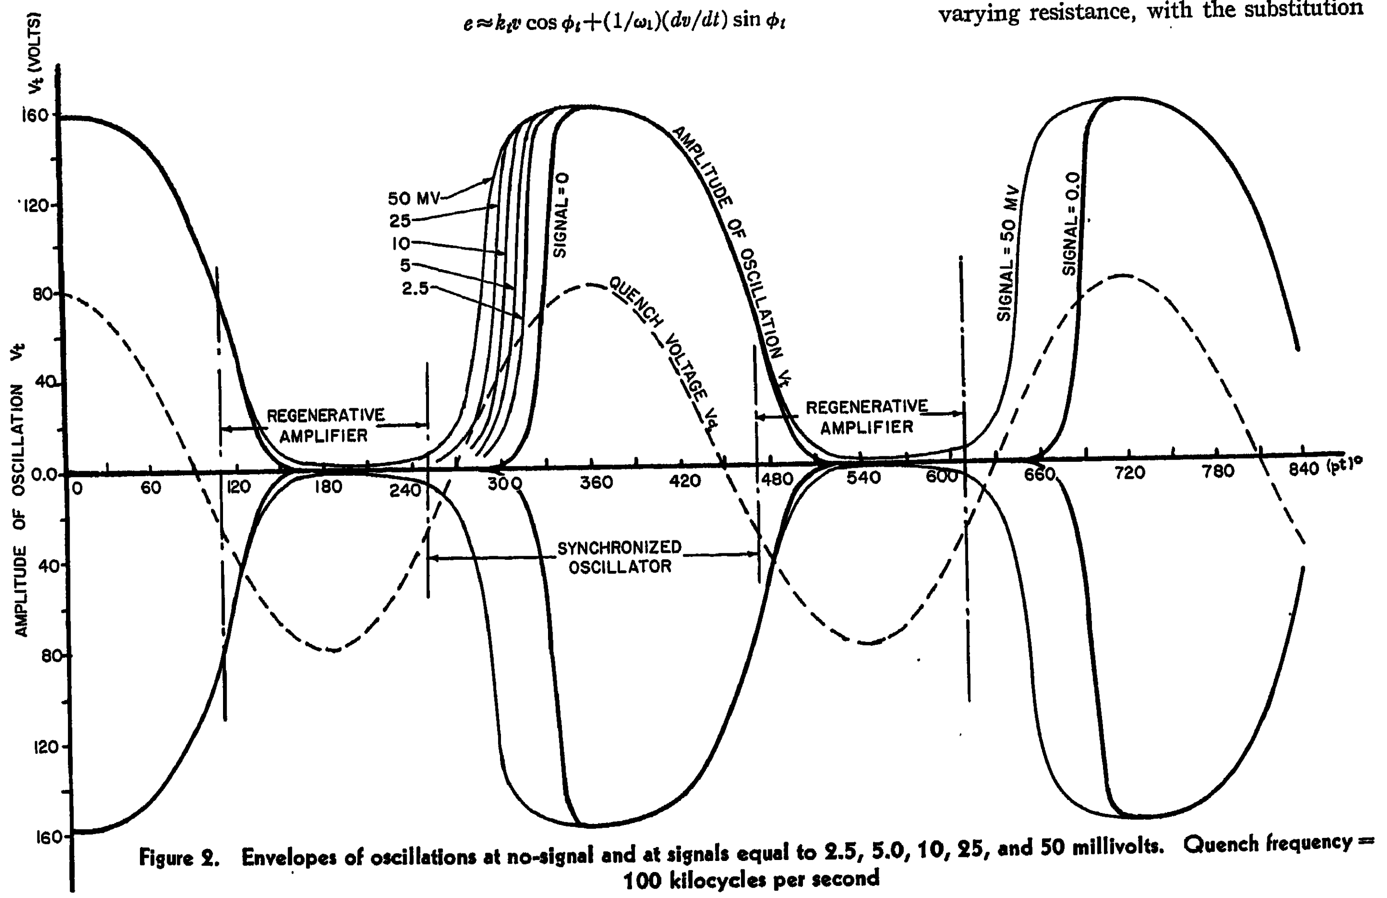

Figure 2. Envelopes of oscillations at no-signal and at signals equal to 2.5, 5.0, 10, 25, and 50 millivolts. Quench frequency = 100 kilocycles per second

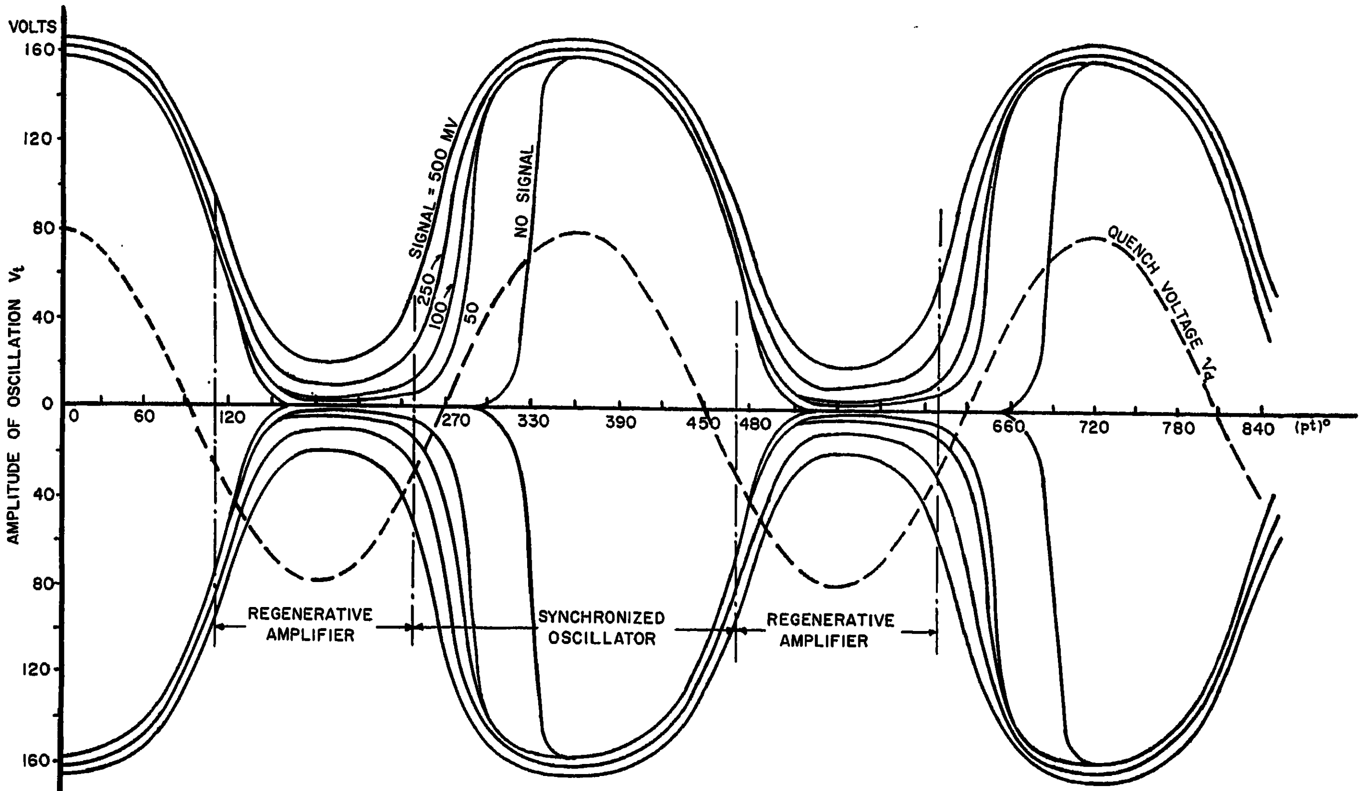

Figure 3. Envelopes of oscillations at no-signal and at signals equal to 50, 100, 250, and 500 millivolts. Quench frequency = 100 kilocycles per second

of v, G_t, L, and C for Q, R_{0t}, C, and L respectively. Also the assumptions made for the solution of the equation of the periodically varying resistance are satisfied in equation 3. However, the voltage v must be of the same form as assumed and which is $v = V_t \cos \omega_1 t + \ldots$ Therefore a possible solution for equation 3 can be obtained from equation 7 of paper 1[1] provided $\phi' - \theta' = \pi/2$ that is $d \approx 0$; therefore

$$\begin{aligned} v = V_s \epsilon^{\int X dt} \{ & \cos \omega_1 t - (1/6\omega_1 C)(2\beta - 6\gamma' N \times \\ & \cos pt)(\mu M/L - 1)^2 V_t \sin 2\omega_1 t - \\ & (1/8\omega_1 C)(3\gamma'/4)(\mu M/L - 1)^3 V_t^2 \times \\ & \sin 3\omega_1 t - \ldots \} \end{aligned} \tag{4}$$

where

$$\begin{aligned} X = (1/2C)\{ & \alpha' - G + \omega_1 C k_t \sin \phi_t - (3\gamma'/4) \times \\ & (\mu M/L - 1)^3 V_t^2 - (3\gamma'/2) \times \\ & (\mu M/L - 1) N^2 + (\mu M/L - 1) \times \\ & (2\beta N \cos pt - (3\gamma'/2) N^2 \cos 2pt)\} \end{aligned} \tag{4A}$$

$$\omega_1^2 \approx \omega_0^2 \{1 - (E/V_t) \cos \phi_t\} \tag{5}$$

$$\gamma' = -\gamma, \ \alpha' = \alpha(\mu M/L - 1)$$

and

$$V_t = V_s e^{\int X dt}$$

giving the steady-state solution, there is no transient. V_s is the amplitude of oscillation at the instant at which X just starts to be positive. From equation 5 $\cos \phi_t = \{1 - \omega_1^2/\omega_0^2\} V_t/E$, showing that for ω_1 slightly less than ω_0, ϕ_t varies from slightly less than $\pi/2$ to slightly higher than zero as V_t increases; for ω_1 slightly higher than ω_0, ϕ_t varies from slightly higher than $\pi/2$ to slightly less than π as V_t increases. Now

$$\sin \phi_t \approx \sqrt{1 - (Z/\omega_1)^2/(E/V_t)^2}$$

where Z = amount of detune $= 2(\omega_0 - \omega_1)$; substitution in equation 4(A) gives

$$\begin{aligned} X \approx (1/2C)[& \alpha' - G + \omega_1 C(E/V_t) \times \\ & \sqrt{1 - (Z/\omega_1)^2/(E/V_t)^2} - \\ & (3\gamma'/4)(\mu M/L - 1)^3 V_t^2 - \\ & (3\gamma'/2)(\mu M/L - 1) N^2 + (\mu M/L - 1) \times \\ & \{2\beta N \cos pt - (3\gamma'/2) N^2 \cos 2pt\}] \end{aligned}$$

The frequency of oscillation is that of the signal voltage, but the phase angle between the signal voltage e and the output voltage v and which is ϕ_t is varying according to equation 5; the phase angle ϕ_t is modulated with a fundamental frequency = frequency of quench source = $p/2\pi$.

Again, as in the first paper,[1] when there is no signal applied, multiple resonance phenomena exists, but in this case, the equivalent side bands are of frequencies $(\omega_1 + np)/2\pi$ and $n = \pm$integer.

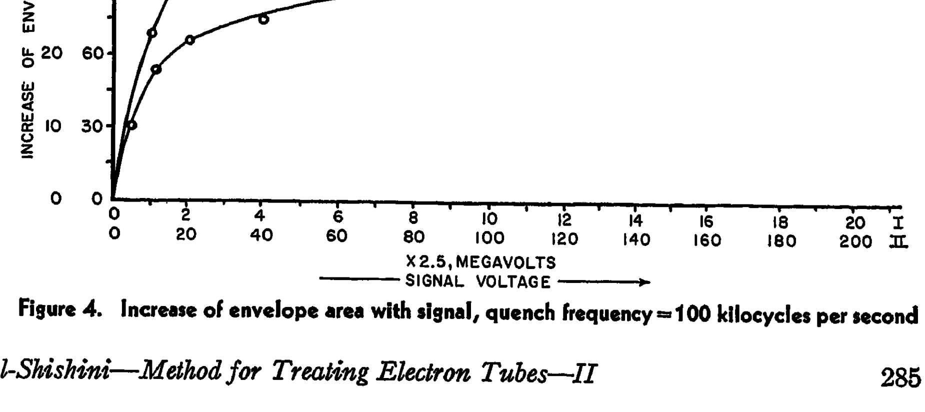

Figure 4. Increase of envelope area with signal, quench frequency = 100 kilocycles per second

Amplitude of Oscillation V_t and the Rate of Variation dv_t/dt

$$V_t = V_s \epsilon^{\int X dt}$$

giving

$$
\begin{aligned}
dV_t/dpt = {} & (\epsilon/2)[1+(1/\epsilon)(E/V_t) \\
& \sqrt{1-\{(Z/\omega_1)(V_t/E)\}^2 -} \\
& (V_t^2/V_0^2)-\{(3\gamma'/2)(\mu M/L-1)/ \\
& (\alpha'-G)\}N^2(1+\cos 2pt)+ \\
& \{2\beta(\mu M/L-1)/(\alpha'-G)\}N\cos pt]\times \\
& V_t(\omega_1/p) \qquad (6)
\end{aligned}
$$

where $\epsilon=(\alpha'-G)/\omega_1 C$ and as the amount of nonlinearity is assumed small, $\epsilon << 1$

$$V_0^2=(\alpha'-G)/(3\gamma'/4)(\mu M/L-1)^3$$

X can be written as

$$
\begin{aligned}
X = {} & (1/2C)\{(\alpha_{eq}'-G)+\omega_1 C(E/V_t)\times \\
& \sqrt{1-\{(Z/\omega_1)(V_t/E)\}^2 -} \\
& (3\gamma'/4)(\mu M/L-1)^3 V_t^2\}
\end{aligned}
$$

where

$$
\begin{aligned}
\alpha_{eq}' = {} & (\mu M/L-1)\{(1/\rho)-(3\gamma'/2)N^2+ \\
& 2\beta N\cos pt-(3\gamma'/2)N^2\cos 2pt\}
\end{aligned}
$$

It is clear that X depends not only on the amplitude N and frequency $p/2\pi$ of the quench source and the nonlinearity of the tube characteristic and the amplitude of oscillation V_t, but also on the signal voltage E and the amount of detune Z. The effect of the signal is equivalent to a reduction in the load conductance G, the amount of reduction depends on V_t. The effect of the detune Z is equivalent to a reduction in the signal voltage E by an amount which depends on V_t. This latter characteristic explains how a superregenerative detector can be used for the reception of frequency modulated waves. The effect of increasing the quench frequency $p/2\pi$ is to reduce the rate of variation dV_t/dpt. If $p/2\pi$ is increased beyond a certain value, the amplitude of oscillation cannot attain the saturation value and the detector will operate in the linear mode instead of the logarithmic mode as shown in the characteristics of Figure 7 having $p/2\pi=$ 200 and 300 kilocycles per second. It is clear therefore, that there is a certain quench frequency at which the sensitivity of the detector is maximum, Figure 8, other parameters being the same.

When the exponent X is positive, Figure 5, the oscillation builds up exponentially with a rate which depends on the amount of coupling, amplitude, and frequency of the quench source, and the nonlinearity of the tube characteristic. This rate also depends on E and Z.

When the exponent X is negative, Figure 5, the amplitude of oscillation decreases. During the interval at which $(\alpha_{eq}'-G)$ is positive, the system works as a synchronized oscillator with variable regeneration. When $(\alpha_{eq}'-G)$ is negative, the system works as a regenerative amplifier whose regeneration varies as the amplitude of $(\alpha_{eq}'-G)$ varies, Figures 2, 3, and 5. From the relation $V_t = V_s \epsilon^{\int X dt}$, it can easily be shown that V_t is maximum or minimum when $X=0$. The minimum value occurs during the operation as an amplifier, Figure 5. The maximum value takes place during the operation as a synchronized oscillator. It should be noted that the minimum amplitudes are linearly related with the signal amplitudes, Figure 6. This linear relationship explains the possibility of using a superregenerative detector for the reception of amplitude modulated waves.

When $(\alpha_{eq}'-G)$ enters the positive region, the tube starts to work as a synchronized oscillator. The same process is repeated for each cycle of the quenching source. It should be noted that so long as the signal voltage E and the amount of detune Z are satisfying the condition of stability, the oscillation will start in the synchronized state and remain synchronized during the building up and the dying down of the oscillation, see Figures 2 and 3. Therefore, the starting condition will no longer be irregular, the oscillation will always continue with definite amplitudes and frequency, and the characteristic noise will be suppressed.

SYNCHRONIZATION WITH ONE OF EQUIVALENT SIDE BANDS OR SEMISYNCHRONIZATION

As mentioned before, if the free oscillation frequency $\omega_0/2\pi$ is near $(\omega_1+np)/2\pi$, where $n=\pm$integer, synchronization at $(\omega_1+np)/2\pi$ takes place provided the conditions of stability for such synchronization are fulfilled. As this synchronization does not take place at the signal frequency $\omega_1/2\pi$ but it takes place at an equivalent side-band frequency

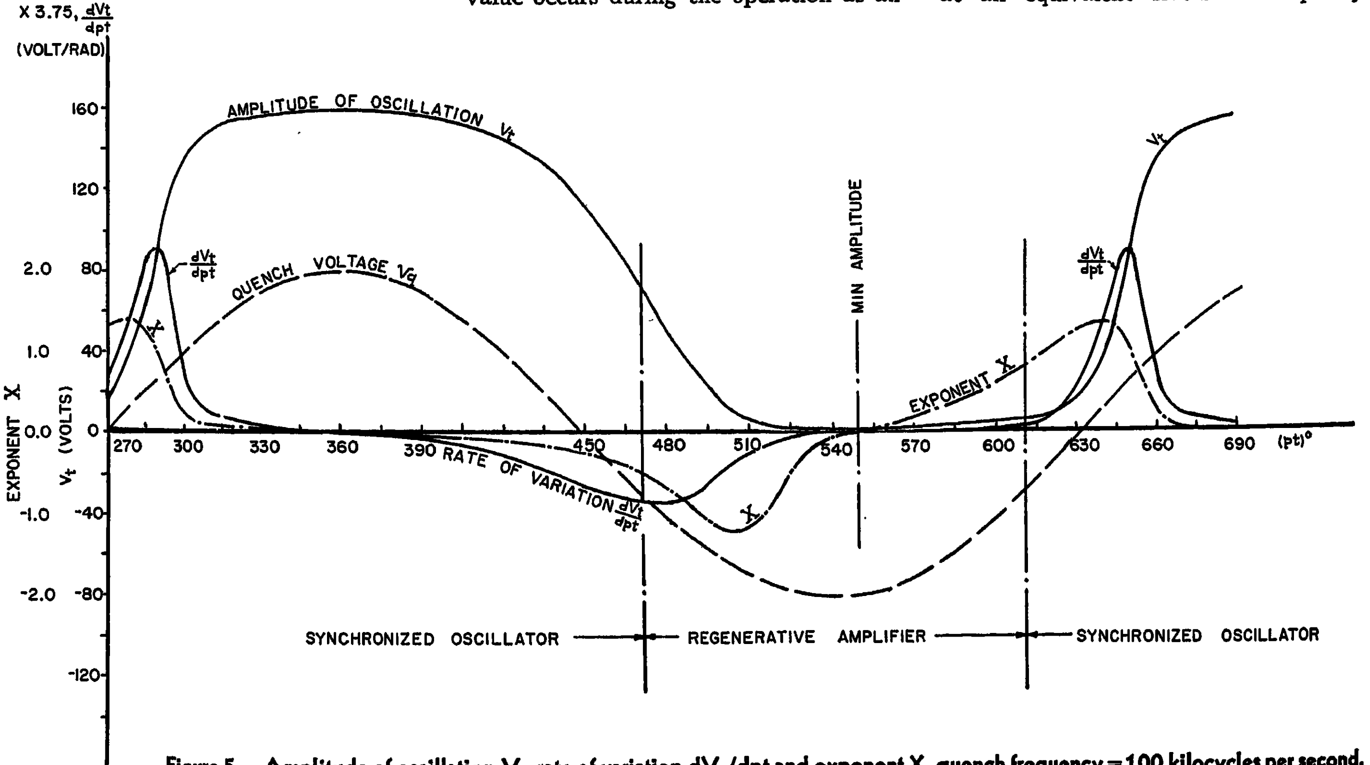

Figure 5 Amplitude of oscillation V_t, rate of variation dV_t/dpt and exponent X, quench frequency = 100 kilocycles per second. Signal voltage = 50 millivolts

$(\omega_1+np)/2\pi$, therefore, it may be termed semisynchronization. The output voltage will consist of two components, namely, the forced oscillation v_1 of frequency $\omega_1/2\pi$ and the semisynchronized oscillation v_{0_1} which can also be considered forced, where $v_1=V_{t_1}\cos\omega_1 t+\ldots$ and $v_{0_1}=V_{t_{0_1}}\cos(\omega_1+np)t+\ldots$, and zero time is chosen such that the phase angle between v_1 and v_{0_1} is zero; $v=v_1+v_{0_1}$. Therefore, in this case also the free oscillation will be suppressed; the semisynchronized oscillation of frequency $(\omega_1+np)/2\pi$ which is near $\omega_0/2\pi$ will exist instead. The amplitudes V_{t_1} and $V_{t_{0_1}}$ are slow functions of time. The signal voltage

$$\begin{aligned}e=E\cos(\omega_1 t+\phi_t)=E\cos\{(\omega_1+np)t+\\ (\phi_t-npt)\}=k_t\{V_{t_{0_1}}\cos(\phi_t-npt)+\\ (dv_{0_1}/dt)(1/(\omega_1+np))\sin(\phi_t-npt)\}\end{aligned}$$

where

$$k_t=E/V_{t_{0_1}}$$

is a slow function of time; $\phi_t-npt=$ instantaneous phase angle between e and v_{0_1}, it is also a slow function of time.

In order to simplify the analysis and not to lose its generality, the plate current i_p will be taken as $i_p=\alpha' e+\gamma e'^3$, in which case all terms containing β will be omitted. Again, substitution of $v=v_1+v_{0_1}=V_{t_1}\cos\omega_1 t+V_{t_{0_1}}\cos(\omega_1+np)t$ in the coefficient of dv/dt in equation 2 gives

$$\begin{aligned}&[d^2v_{0_1}/dt^2+(1/C)[G-\alpha'-(\omega_0^2/(\omega_1+np))\times\\ &Ck_t\sin(\phi_t-npt)+3\gamma'(\mu M/L-1)^3\times\\ &\{V_{t_1}\cos\omega_1 t+V_{t_{0_1}}\cos(\omega_1+np)t\}^2+\\ &3\gamma'(\mu M/L-1)N\cos pt\{V_{t_1}\cos\omega_1 t+\\ &V_{t_{0_1}}\cos(\omega_1+np)t\}+(3\gamma'/2)\times\\ &(\mu M/L-1)N^2(1+\cos 2pt)]dv_{0_1}/dt+\\ &\omega_0^2\{1-k_t\cos(\phi_t-npt)\}v_{0_1}]+\\ &[d^2v_1/dt^2+(1/C)[G-\alpha'+3\gamma'\times\\ &(\mu M/L-1)^3\{V_{t_1}\cos\omega_1 t+V_{t_{0_1}}\cos(\omega_1+\\ &np)t\}^2+3\gamma'(\mu M/L-1)N\cos pt\times\\ &\{V_{t_1}\cos\omega_1 t+V_{t_{0_1}}\cos(\omega_1+np)t\}+\\ &(3\gamma'/2)(\mu M/L-1)N^2(1+\cos 2pt)]\times\\ &dv_1/dt+\omega_0^2 v_1]=0 \qquad (7)\end{aligned}$$

Equation 7 is composed of two differential equations, the first one when equated to zero gives the semisynchronized oscillation v_{0_1} while the second one when equated to zero gives the oscillation v_1.

Therefore, the semisynchronized oscillation is represented by the equation

$$\begin{aligned}&d^2v_{0_1}/dt^2+(G_t/C)[1+h_{2p_t}\cos 2pt+h_{np_t}\times\\ &\cos npt+h_{1_t}\cos\{(\omega_1+np)t-\theta_{1_t}\}+h_{2_t}\\ &\cos\{2(\omega_1+np)t-\theta_{2_t}\}]dv_{0_1}/dt+\omega_0^2\times\\ &\{1-k_t\cos(\phi_t-npt)\}v_{0_1}=0 \qquad (8)\end{aligned}$$

where

$$\begin{aligned}G_t=&\{G-\alpha'-(\omega_0^2/(\omega_1+np))Ck_t\\ &\sin(\phi_t-npt)+(3\gamma'/2)(\mu M/L-1)^3\times\\ &(V_{t_1}^2+V_{t_{0_1}}^2)+(3\gamma'/2)(\mu M/L-1)N^2\}\end{aligned}$$

$$h_{2p_t}=(1/G_t)(3\gamma'/2)(\mu M/L-1)N^2$$

$$h_{np_t}=(1/G_t)(3\gamma')(\mu M/L-1)^3V_{t_1}V_{t_{0_1}}$$

$$\begin{aligned}h_{2_t}=&(1/G_t)(3\gamma'/2)(\mu M/L-1)^3\times\\ &(V_{t_1}^2+V_{t_{0_1}}^2+2V_{t_1}V_{t_{0_1}}\cos npt)\end{aligned}$$

and

$$\begin{aligned}\tan\theta_{2_t}=&\{V_{t_1}^2\sin 2npt+2V_{t_1}V_{t_{0_1}}\sin npt\}/\times\\ &\{V_{t_1}^2\cos 2npt+V_{t_{0_1}}^2+2V_{t_1}V_{t_{0_1}}\cos npt\}\end{aligned}$$

The differential equation 8 is similar to equation 3 of paper 1,[1] of a series oscillatory circuit having a periodically variable resistance. The only difference is that the component of frequency $2(\omega_1+np)/2\pi$ in the coefficient of dv_{0_1}/dt contains a phase angle θ_{2_t} and therefore the resulting phase angle in the solution must be modified; a phase angle $\theta_{2_t}/2$ must be added to it. The solution can therefore be obtained from equation 7 of paper 1, putting $h_{1_t}=0$ and modifying the phase angle $(\phi'-\theta')$ to $\{(\theta_{2_t}/2)+\phi'-\theta'\}$.

Again, the solution must be of the same form as assumed, namely, $v_{t_{0_1}}=V_{t_{0_1}}\cos(\omega_1+np)t+\ldots$. Therefore, a possible solution for equation 8 can be obtained from that of periodically variable resistance oscillatory circuits provided

$$\{(\theta_{2_t}/2)+(\phi'-\theta')\}=\pi/2$$

giving

$$\begin{aligned}&(1/2)\tan^{-1}\{(V_{t_1}^2\sin 2npt+2V_{t_1}V_{t_{0_1}}\times\\ &\sin npt)/(V_{t_1}^2\cos 2npt+V_{t_{0_1}}^2+2V_{t_1}\times\\ &V_{t_{0_1}}\cos npt)\}=-\tan^{-1}[2(2d+d^2)/\times\\ &\{(4\sqrt{a_t})/(\omega_1+np)+h_{2_t}G_t/\times\\ &(\omega_1+np)C\}]+\tan^{-1}\{(-\sqrt{a_t})/\times\\ &(\omega_1+np)\} \qquad (9)\end{aligned}$$

where

$$\begin{aligned}\sqrt{a_t}=&\{(\omega_1+np)/4\}[\{h_{2_t}G_t/(\omega_1+np)C\}^2-\\ &\{2(2d+d^2)\}^2]^{1/2}\end{aligned}$$

As the amount of nonlinearity is assumed small, $\sqrt{a_t}/(\omega_1+np)$ will be very small and can be neglected in equation 9; also the amount of detune d is very small. Therefore, to a satisfactory degree of approximation, $\sqrt{a_t}\approx h_{2_t}G_t/4C$ and equation 9 becomes

$$\begin{aligned}-(2d+d^2)&=1-\{\omega_{0_1}^2/(\omega_1+np)^2\}\\ &=\{3\gamma'(\mu M/L-1)^3/4(\omega_1+np)C\}\times\\ &\{V_{t_1}^2+V_{t_{0_1}}^2+2V_{t_1}V_{t_{0_1}}\cos npt\}\times\\ &(1/2)\{(V_{t_1}^2\sin 2npt+2V_{t_1}V_{t_{0_1}}\sin npt)/\times\\ &(V_{t_1}^2\cos 2npt+V_{t_{0_1}}^2+2V_{t_1}V_{t_{0_1}}\times\\ &\cos npt)\} \qquad (10)\end{aligned}$$

where

$$\omega_{0_1}^2\approx\omega_0^2\{1-(E/V_{t_{0_1}})\cos(\phi_t-npt)\}$$

and

$$(1+d)=\omega_{0_1}/(\omega_1+np)$$

The voltage v_{0_1} can be given satisfactorily by

$$v_{0_1}=V_s\epsilon^{\int X_1 dt}\{\cos(\omega_1+np)t+\ldots\} \qquad (11)$$

giving the steady-state solution, there is no transient, where

$$\begin{aligned}X_1\approx&(1/2C)\{\alpha'-G+(\omega_0^2C/(\omega_1+np))\times\\ &(E/V_{t_{0_1}})\sin(\phi_t-npt)-(3\gamma'/4)\times\\ &(\mu M/L-1)^3(V_{t_1}^2+V_{t_{0_1}}^2)-\\ &(3\gamma'/2)(\mu M/L-1)N^2-(3\gamma'/2)\times\\ &(\mu M/L-1)N^2\cos 2pt-(3\gamma'/2)\times\\ &(\mu M/L-1)^3V_{t_1}V_{t_{0_1}}\cos npt\} \qquad (12)\end{aligned}$$

V_s in equation 11 is the amplitude of oscillation at the instant at which X_1 just starts to be positive.

From relations 10 and 12, $\cos(\phi_t-npt)$ and hence $\sin(\phi_t-npt)$ can be obtained.

It is shown from the solution of v_{0_1} that its envelope is modified; it is modulated with fundamental frequency $np/2\pi$. This is besides the modulation appearing in the case where synchronization is at the signal frequency $\omega_1/2\pi$. The amplitude of such modulation depends on V_{t_1} which

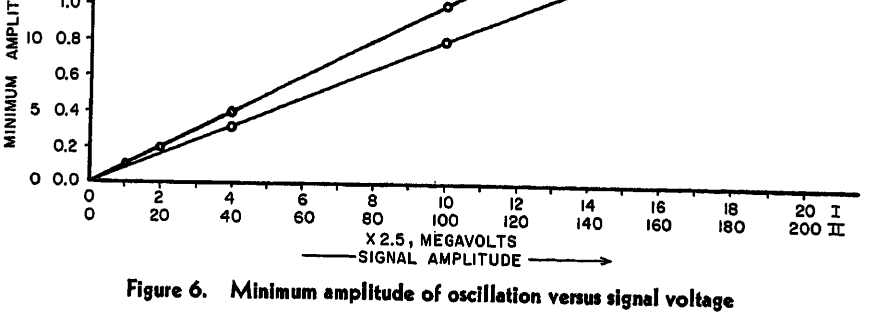

Figure 6. Minimum amplitude of oscillation versus signal voltage

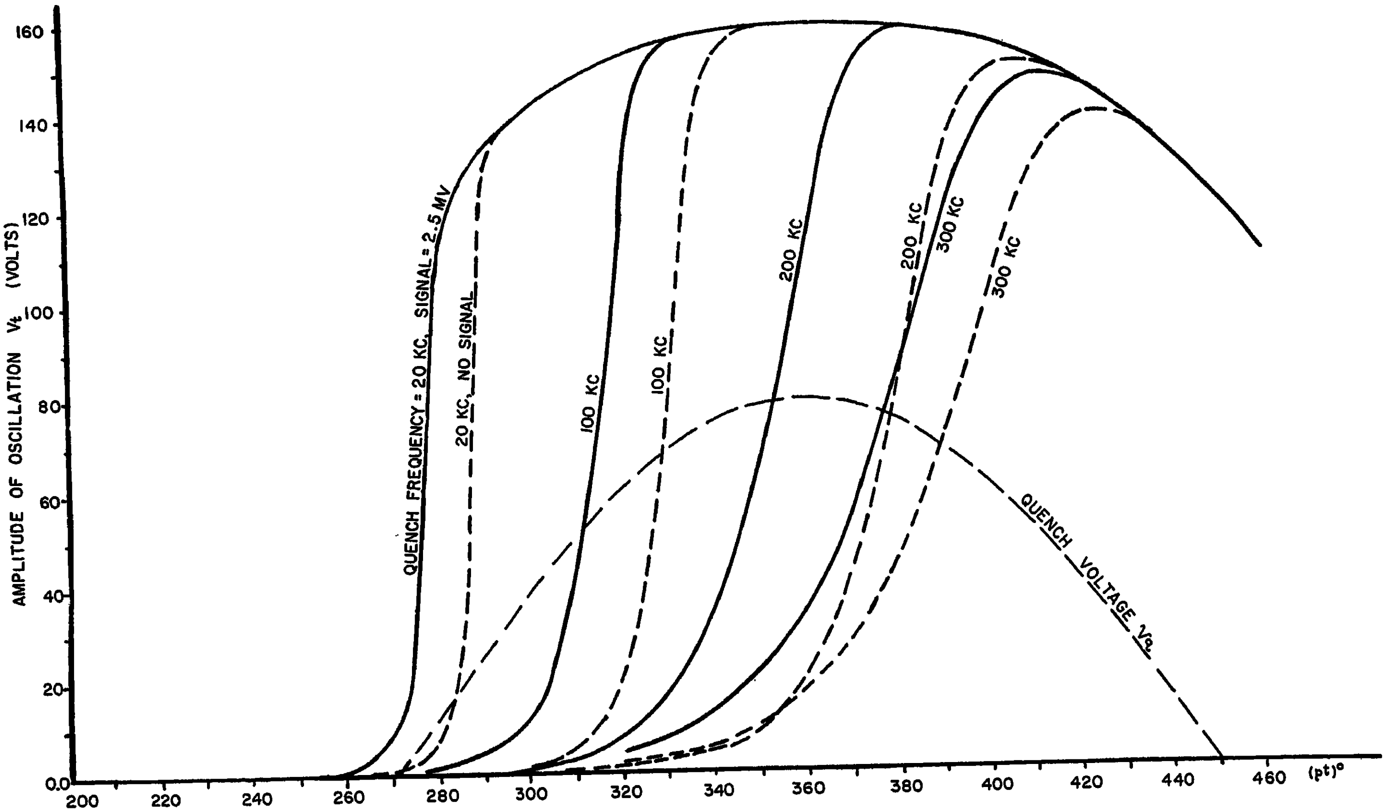

Figure 7. Building up curves for different quench frequencies at no-signal and at a signal of 2.5 millivolts

latter depends on the amount of detune between ω_1 and ω_0. As n increases, V_{t_1} is reduced and hence the amplitude of such modulation is reduced.

The oscillation v_1 is represented by the second differential equation of 7. As far as v_1 is concerned, the tube works as a detuned amplifier. This detuned amplification is also affected by the "semi-synchronized oscillation" v_{0_1} as seen from the differential equation. The amplitude of v_1 depends on the amount of detune between $\omega_1/2\pi$ and $\omega_0/2\pi$. As n increases, the amount of detune increases and hence V_{t_1} is reduced.

STABILITY OF A SUPERREGENERATIVE DETECTOR WHEN SIGNAL VOLTAGE IS PRESENT

Besides the condition of stability when the signal voltage is absent, which has been treated in the first paper,[1] there is another stability condition when the signal voltage is present. This condition is that the system should be stably synchronized during the whole quench cycle whether the synchronization is between the free oscillation and the signal voltage or between the free oscillation and one of the equivalent side bands. If this condition is not satisfied, the system will break out of synchronism at some parts of the quench cycle and both the signal frequency and the free oscillation frequency will be present, the initial conditions at the start of the oscillations will be irregular and the characteristic noise will exist.

Following the same lines as in the case when the signal voltage is absent, and which was treated in the first paper,[1] the condition of stability of a synchronized superregenerative detector can be obtained. The two cases will be treated separately.

Synchronization at Signal Frequency

The condition for stability is $(dX/dV_m)_{V_t=V_m}<0$. Using equation 4(A) we get

$$(d/dV_m)\{\alpha'-G+\omega_1 Ck_{t_m}\sin\phi_{t_m}-(3\gamma'/4)(\mu M/L-1)^3V_m^2-(3\gamma'/2)\times(\mu M/L-1)N^2\}<-(d/dV_m)\times\{2\beta(\mu M/L-1)N\cos pt_m-(3\gamma'/2)\times(\mu M/L-1)N^2\cos 2pt_m\}$$

where ϕ_{t_m} is the phase angle at $V_t=V_m=$ maximum amplitude, $k_{t_m}=E/V_m$, and t_m is the time at $V_t=V_m$.

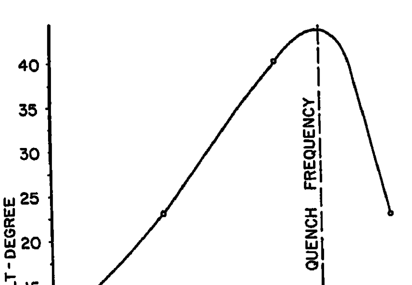

Figure 8. Increase in envelope area for a constant signal (= 2.5 millivolts) versus quench frequency

If the quench source were absent, the system would act as a simple synchronized oscillator and if its stationary amplitude $=V_m$, then its condition of stability would be

$$(d/dV_m)\{\alpha'-G+\omega_1 C(E/V_m)\sin\phi_{t_m}-(3\gamma'/4)(\mu M/L-1)^3V_m^2\}<0$$

Therefore, a stable synchronized system in the superregenerative state may be unstable in the simple synchronized state for the same maximum amplitude of oscillation.

Synchronization at an Equivalent Side-Band Frequency

The condition for stability is $(dX_1/dV_{0_{1m}})<0$; using equation 12 we get

$$(d/dV_{0_{1m}})\{\alpha'-G+(\omega_0^2C/(\omega_1+np))k_{t_m}\times\sin(\phi_{t_m}-npt_m)-(3\gamma'/4)(\mu M/L-1)^3(V_{t_{01m}}{}^2+V_{t_{1m}}{}^2)-(3\gamma'/2)\times(\mu M/L-1)N^2\}<(d/dV_{0_{1m}})\times\{(3\gamma'/2)(\mu M/L-1)^3V_{t_{01m}}V_{t_{1m}}\times\cos npt_m+(3\gamma'/2)(\mu M/L-1)N^2\times\cos 2pt_m\}$$

where $V_{t_{1m}}$ is the amplitude of V_{t_1} when

$V_{t_{01}}$ is maximum (that is, $dV_{t_{01}}/dt=0$) of amplitude $V_{t_{01m}}$, $k_{tm}=E/V_{t_{01m}}$, and t_m is the time at which $V_{t_{01}}$ is maximum.

This shows that the condition of stable synchronization at an equivalent sideband frequency depends on n, that is on the order of the side band, as well as on the amplitude $V_{t_{1m}}$. The latter depends also on the amount of detune between $\omega_0/2\pi$ and $\omega_1/2\pi$, that is, on the order of the side band. Therefore, there is a maximum value for n at which stable synchronization ceases.

Numerical Examples

From the foregoing theoretical analysis, most of the phenomenon of superregenerative receiving circuits can be obtained. The sensitivity, the automatic volume control action, the optimum quench frequency, and the different operating states during a quench cycle can be clarified by the following numerical examples. To simplify matters, the examples will be taken for the case when the signal frequency $=\omega_0/2\pi$, stably synchronized oscillation being assumed.

Let the signal frequency $=\omega_1/2\pi=75$ megacycles per second

$$\epsilon=(\alpha'-G)/\omega C=0.01$$

$$V_0=100 \text{ volts}$$

$$\{(3\gamma'/2)(\mu M/L-1)/(\alpha'-G)\}N^2=0.5$$

$$Z=0$$

and

$$\{2\beta(\mu M/L-1)/(\alpha'-G)\}N=2.5$$

Substitution in equation 6 gives

$$dV_t/dpt=\{3.75\times10^6/(p/2\pi)\}\times \{0.5(1+5\cos pt-\cos 2pt)+ 100(E/V_t)-(V_t^2/100^2)\}V_t \quad (13)$$

The amplitude V_t can be obtained graphically using equation 13 for any suitable values of E and $p/2\pi$. The graphical integration is carried out by the step-by-step method. For a quench frequency of 100 kilocycles per second, the envelopes of oscillation at no-signal and at signals equal to 2.5, 5.0, 10.0, 25.0, and 50.0 millivolts are shown in Figure 2. The regions in which the system operates as a regenerative amplifier and a synchronized oscillator are clearly shown. It is clear from Figure 2 that the maximum amplitude of oscillation can be considered independent of the signal. However, if the signal voltage is higher than 100 millivolts, the maximum amplitude of the output voltage will depend upon the signal, Figure 3. Figure 4 shows the increase in envelope area with signal indicating the limiting action of superregenerative detectors, quench frequency being 100 kilocycles per second. Figure 5 gives the rate of variation dV_t/dpt, the exponent X, the amplitude of oscillation V_t, and the quench voltage v_q, signal amplitude $=50$ millivolts, and quench frequency $=100$ kilocycles per second; the position of the minimum value of V_t is clearly shown. It should be noted that V_t is minimum at $X=0$. At the minimum value of V_t along a quench cycle, the system works as a linear amplifier; Figure 6 shows clearly the linear relationship between the minimum value of V_t and the signal amplitude, quench frequency being 100 kilocycles per second.

To show that there is an optimum quench frequency at which the sensitivity is maximum, several envelopes are calculated under no-signal and under signal conditions for quench frequencies of 20, 100, 200, and 300 kilocycles per second, see figure 7. It is clear that at the quench frequencies 200 and 300 kilocycles per second, the detector operates in the linear mode. At 20 and 100 kilocycles per second, it operates in the logarithmic mode. Figure 8 shows the increase in envelope area for a constant signal (being proportional to the sensitivity) against quench frequency, the existence of an optimum quench frequency is clearly indicated.

A New Method for Treating Electron Tubes When Used as Superregenerative Detectors

Part III. Experimental Investigation of Superregenerative Circuits

ABD EL-SAMIE MOSTAFA
NONMEMBER AIEE

M. EL-SHISHINI
NONMEMBER AIEE

Synopsis: This is the third of a series of papers dealing with a comprehensive study of superregenerative detection. In the first paper[1] the analysis under no-signal condition was given. In the second paper[2] the analysis under signal condition was presented. In the present paper, an experimental investigation on superregenerative receiving circuits is carried out to clarify most of the phenomenon involved in these circuits, among which are: the selectivity, the sensitivity, the optimum quench frequency, and the most important phenomena, namely, the synchronization with the signal voltage at the signal frequency $\omega_1/2\pi$ and the semisynchronization or the synchronization with one of the equivalent side bands (that is, the synchronization at a frequency equal to $(\omega_1 \pm np)/2\pi$, $p/2\pi =$ quench frequency). In this way, the operating mechanism of superregenerative detectors is clearly explained. For proper reception, free oscillations are generally suppressed. The experimental results are in good agreement with the theoretical predictions given in the preceding papers.[1,2]

Owing to apparatus limitations, it was considered more appropriate to limit the work to low-frequency operation, the quench frequency being suitably chosen so that a proper relation between operating and quench frequencies is always maintained. Two different operating frequencies were chosen, one being in the neighbourhood of 100 kilocycles per second, the other being around 1,000 kilocycles per second. The first frequency is used to demonstrate a certain set of characteristics of superregenerative detectors, while the second frequency is used to demonstrate a different set of characteristics.

Paper 53-155, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted March 10, 1952; made available for printing December 4, 1952.

Abd El-Samie Mostafa is with the Alexandria University, Alexandria, Egypt. M. El-Shishini is a member of the Egyptian Senate, Cairo, Egypt.

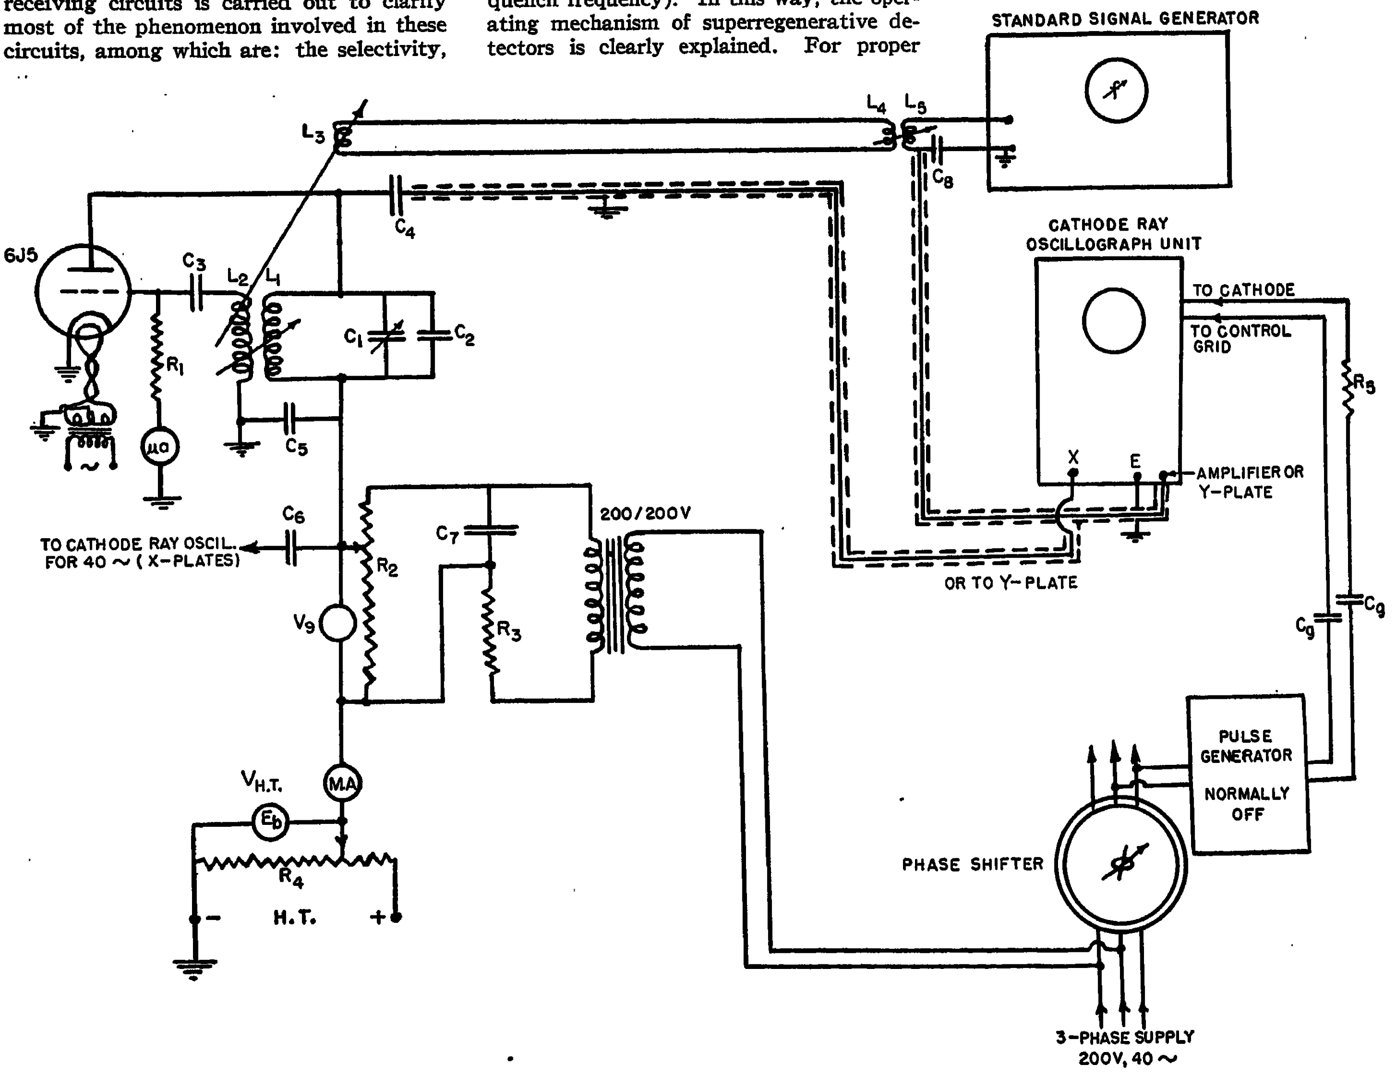

Figure 1. Connection diagram, operating frequency = 100 kilocycles per second. $L_1=1{,}560$, $L_2=1{,}560$, $L_3=160$, $L_4=1{,}045$, $L_5=1{,}560$, $C_1=1{,}200$, $C_2=1{,}500$, $C_3=500$, $C_4=100$, $C_5=10{,}000$, $C_6=0.25$ microfarad, $C_7=40$ microfarads, $C_8=2{,}500$, $C_9=0.01$ microfarad (2,500-V), $R_1=50{,}000$, $R_2=690$, $R_3=355$, $R_4=5{,}500$, $R_5=200{,}000$; inductances are in microhenrys, capacitances in micromicrofarads (except when stated), and resistances in ohms

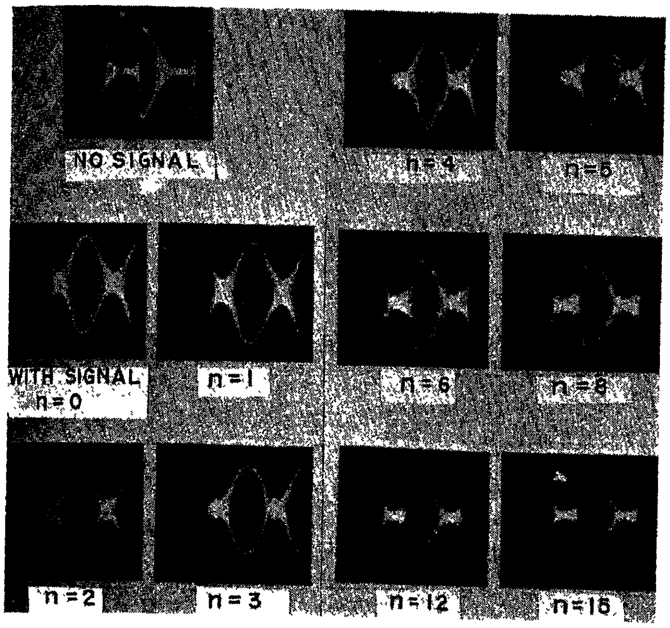

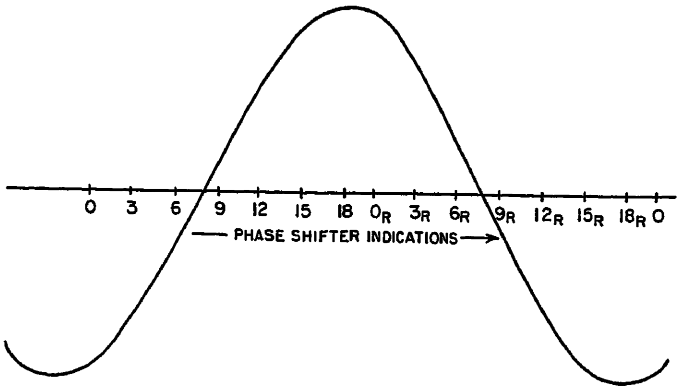

Figure 2 (left). Several oscillograms at a constant high signal and for several values of n, where $f_1 \cong f_0 - np/2\pi$, f_1 = signal frequency, f_0 = free oscillation frequency, and $p/2\pi$ = quench frequency

Figure 4 (above). Calibrated quench cycle, giving indications of phase shifter against the instant at which the electron beam of the cathode-ray oscillograph appears on the screen. The index R indicates that the connection to the phase shifter is reversed

Experimental Characteristics of Superregenerative Detectors when Signal Frequency Is About 100 Kilocycles per Second

Figure 1 represents a complete connection diagram; the values of the different elements are indicated. The d-c plate voltage is taken 120 volts, while the quench voltage is 40 volts (rms). The coupling between plate and grid coils is so adjusted that free oscillation just starts in the absence of the quench source.

The output voltage is connected, through a 100-micromicrofarad coupling capacitor to the Y-plates of a cathode-ray oscillograph; the time base frequency is synchronized to the quench frequency. With no signal applied, the oscillations are not absolutely steady; the envelope during the building up of the oscillation

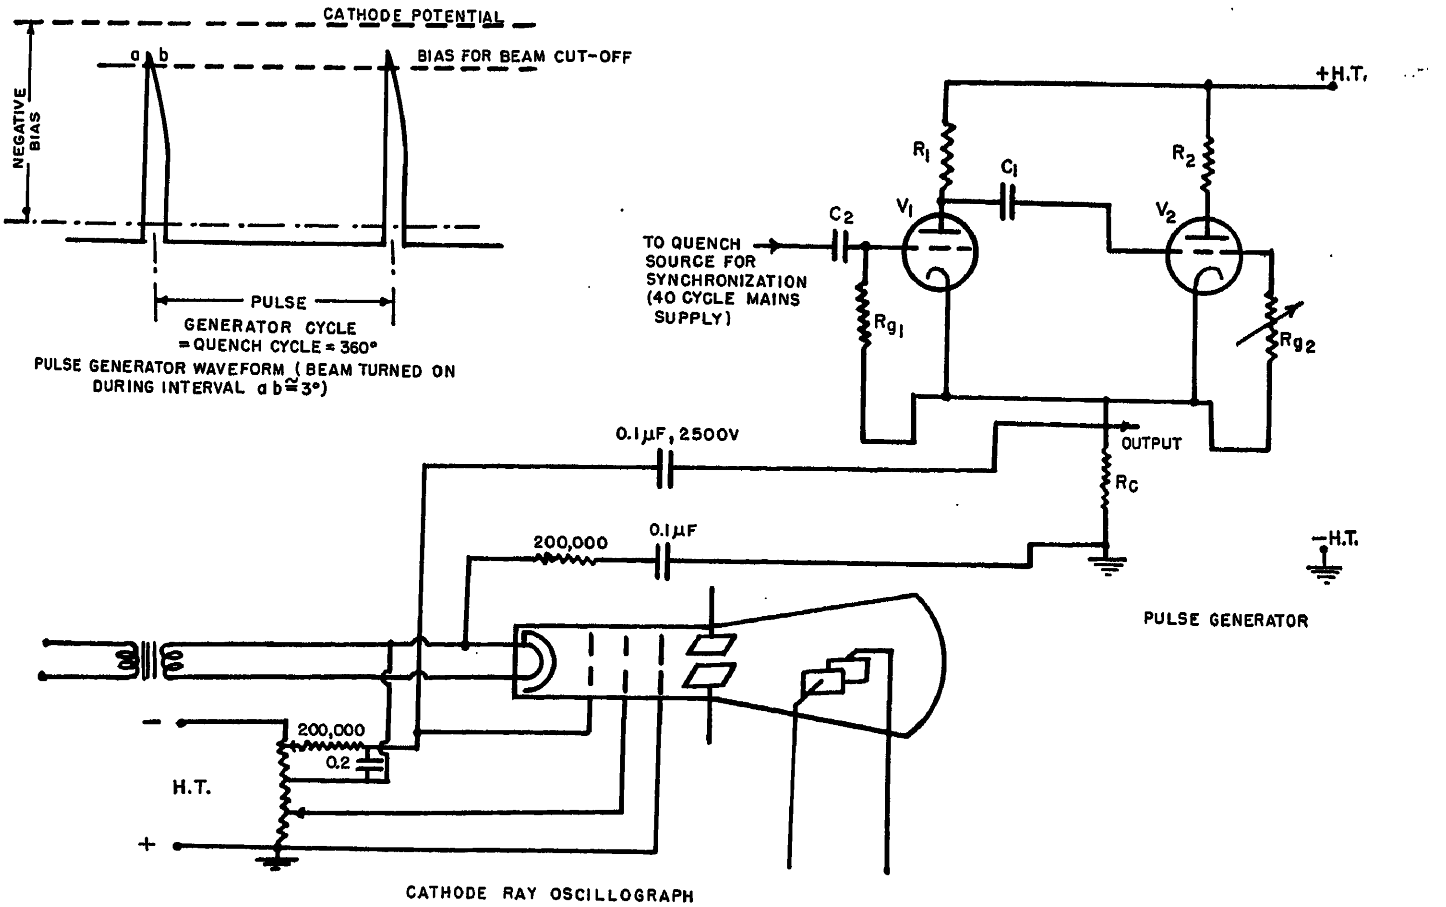

Figure 3. Connection diagram for the pulse generator when connected to the cathode-ray oscillograph, the output wave form of the generator is also shown. $R_1 = 100{,}000$ ohms, $R_2 = 100{,}000$ ohms, $R_c = 2{,}500$ ohms, $R_{g1} = 1.0$ mega-ohm, $R_{g2} = 0.5$ mega-ohm (for varying pulse width), $C_1 = 0.05$ microfarad, $C_2 = 0.01$ microfarad

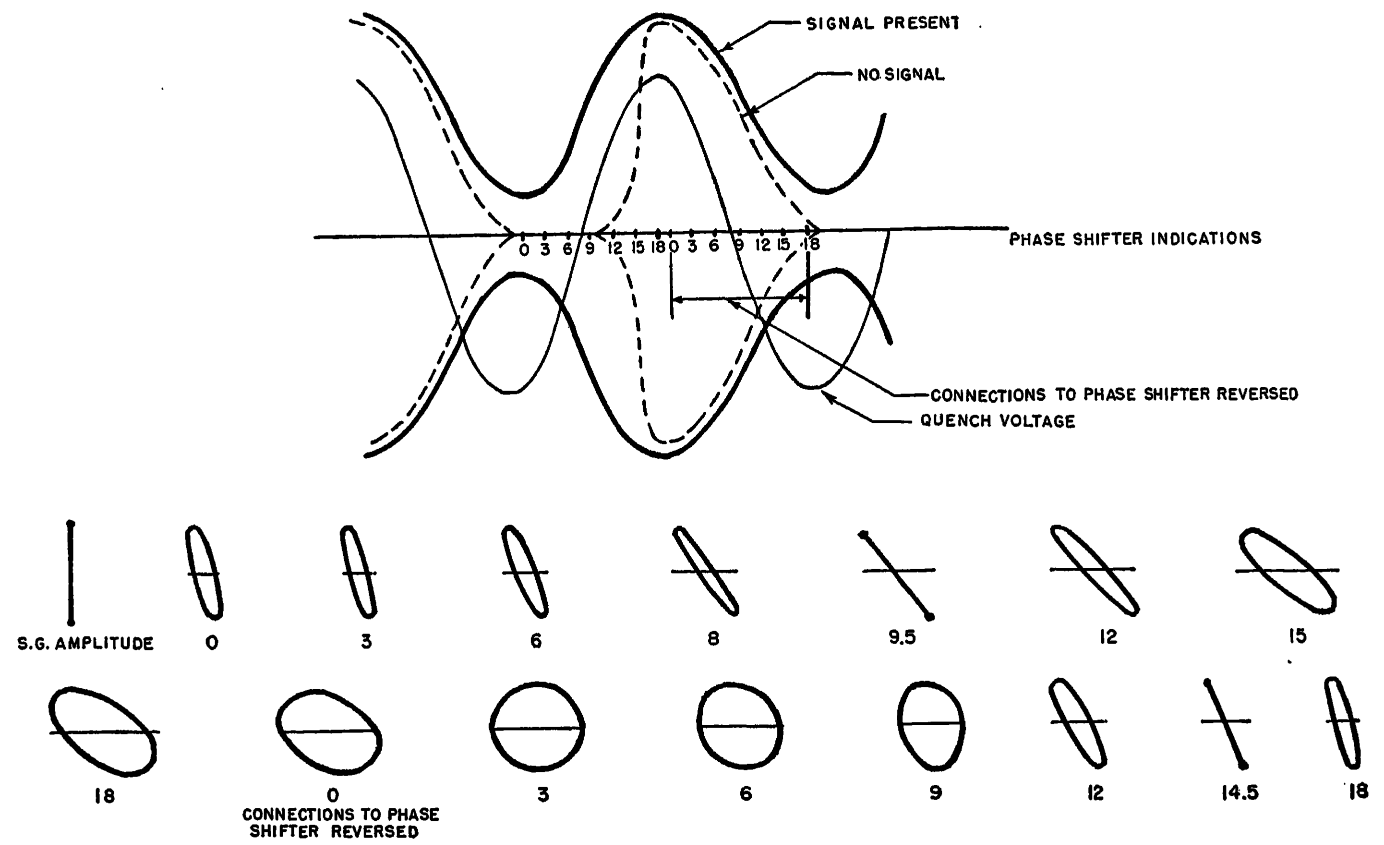

Figure 5. Synchronization at signal frequency. Lissajous figures for samples of oscillation at various points along the envelope, high signal being applied. The numbers on the oscillograms give phase shifter indications. The amplitude of oscillation is indicated by a horizontal line. Signal frequency $f_1 \cong$ free oscillation frequency f_0. Enlarged oscillograms of the envelope of oscillation without signal and with signal are also shown

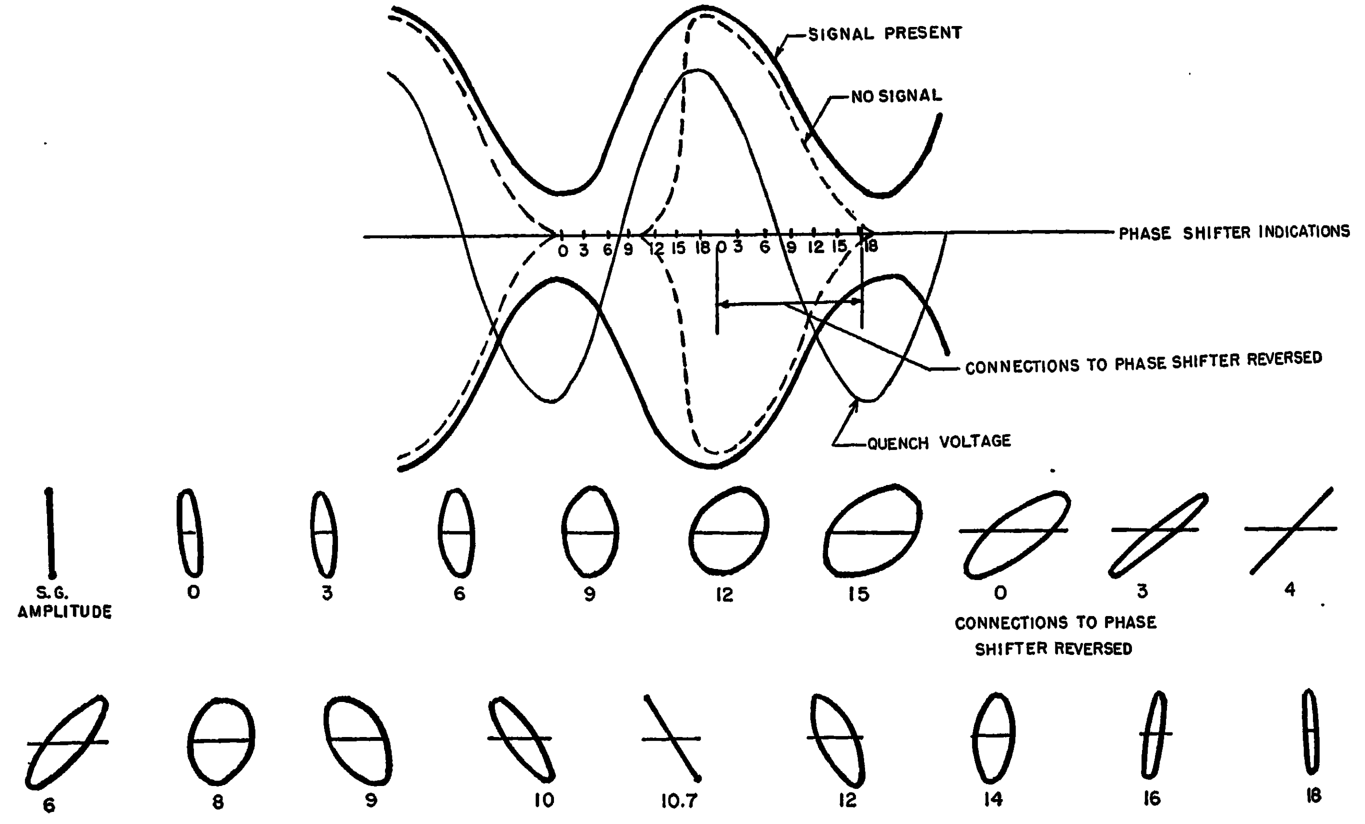

Figure 6. Synchronization at the first side band. Lissajous figures as in Figure 5, but in this case signal frequency $f_1 \cong$ free oscillation frequency $f_0 =$ quench frequency $p/2\pi$

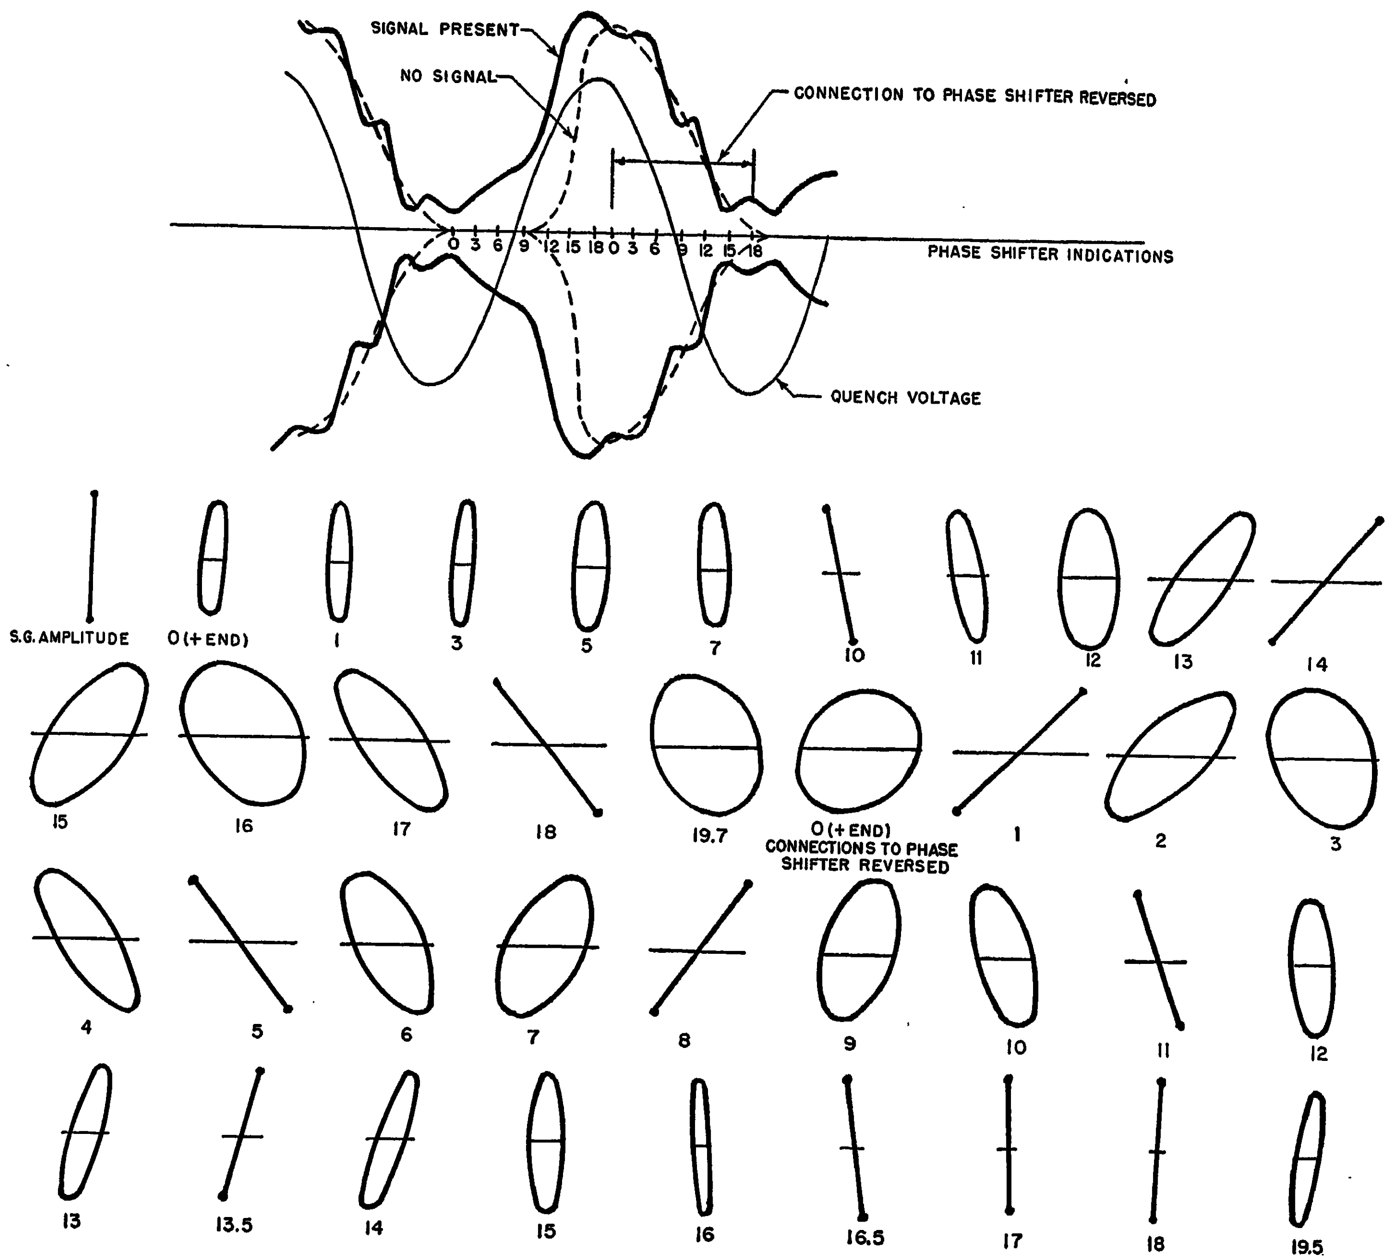

Figure 7. Synchronization at the fifth side band. Lissajous figures as in Figure 5, but $f_1 \cong f_0 - 5p/2\pi$

shows some irregularities. With a reasonable signal amplitude, the irregularities disappear and the envelopes were very steady. When the signal departs from the free oscillation frequency by approximately an integer number n of the quench frequency, the envelope of oscillation is modulated by the same number. The number n, for which the envelopes remain very steady, depends on the amplitude of the signal; as the signal increases, n increases. For higher values of n, the oscillations are no longer steady. The steadiness of the envelopes shows that the oscillations are synchronized during the whole quench cycle. Synchronization is either at the signal frequency f_1 in which case $n=0$, or at an equivalent side-band frequency $(f_1+np/2\pi)$. There is still a further test for such synchronization. Figure 2 shows several oscillograms at no signal and at comparatively high signal which is intentionally taken high in order to show the envelope modulation clearly. The signal frequency f_1 being near f_0 and $(f_0-np/2\pi)$, where f_0=free oscillation frequency, $p/2\pi$=quench frequency=40 cycles per second, and $n=0$, 1, 2, 3, 4, 5, 6, 8, 12, and 15. Steady envelopes can be obtained for as high n as 15, after which synchronization ceases.

LISSAJOUS FIGURES FOR SAMPLES OF OSCILLATION AT VARIOUS INSTANTS IN QUENCH PERIOD, SYNCHRONIZATION AT SIGNAL FREQUENCY AND EQUIVALENT SIDE BANDS

To show the Lissajous figures corresponding to the oscillation at a certain instant during the quench period, apply the output of the detector to the X-plates and the signal generator output to an amplifier, then to the Y-plates of the cathode-ray oscillograph. A pulse generator is switched on in order that the electron beam appears only for a very short interval of time during the quench period corresponding to approximately 3 degrees of the quench cycle. Figure 3 shows a connection diagram for the pulse generator and its connection to the grid of the cathode-ray tube, as well as its output wave form. Figure 4 shows a calibrated quench cycle, showing clearly the indication of the phase shifter and the instant in the quench cycle which appears on the screen of the oscillograph.

Figure 5 shows several oscillograms at

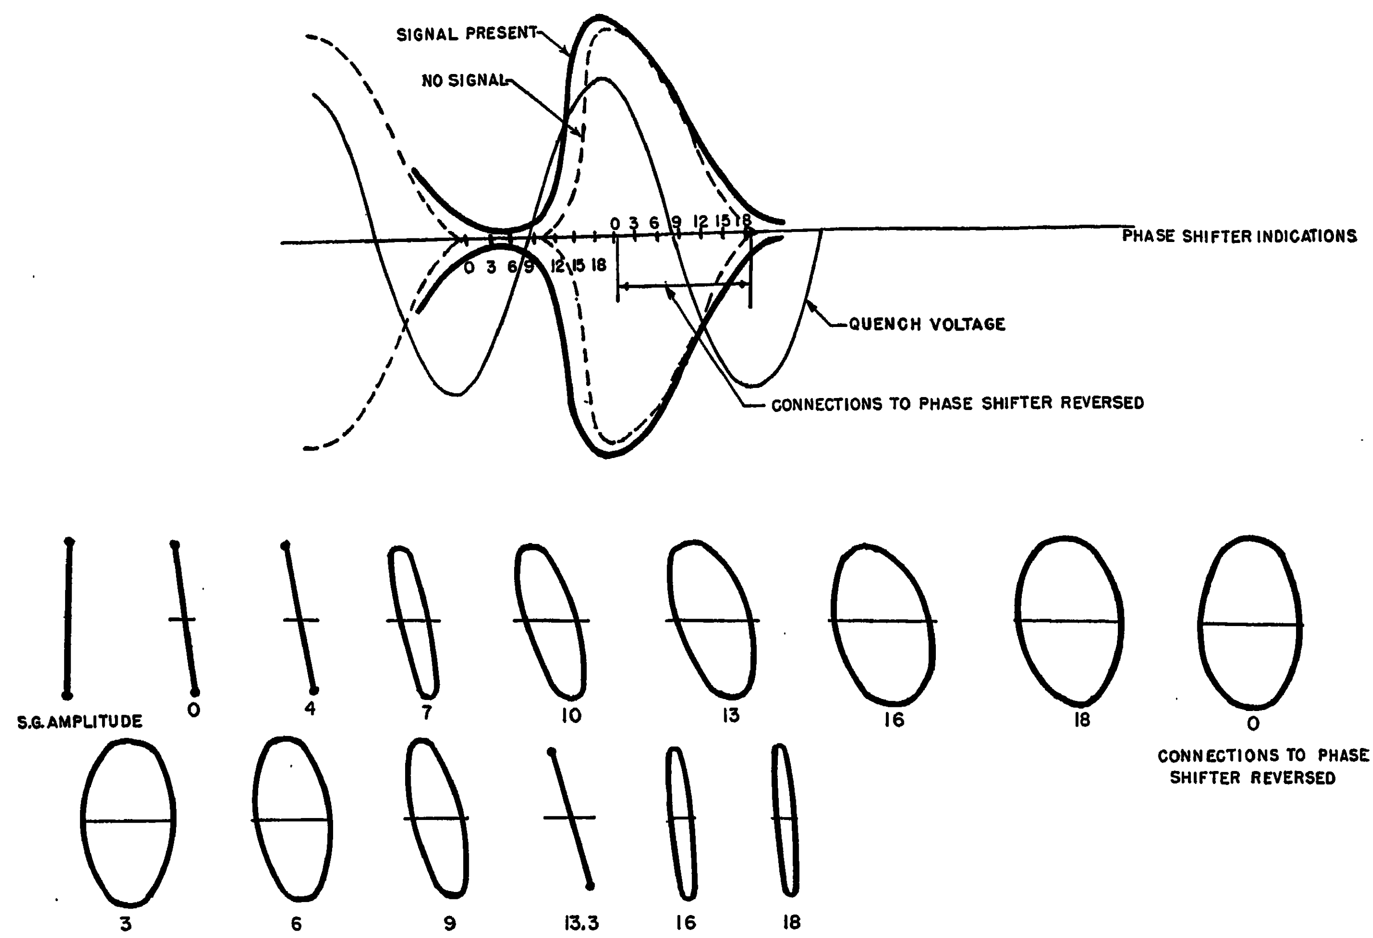

Figure 8. Synchronization at signal frequency. Lissajous figures as in Figure 5, but with a low applied signal

the high signal corresponding to Figure 2, the signal frequency being near f_0; the ellipses, taken at several phase shifter indications along the quench cycle, indicate that the phase angle between the signal and the output voltage lies between 0 and $\pi/2$, the oscillation frequency being that of the signal and there being synchronization at signal frequency. The corresponding amplitudes of oscillation are also shown.

Figure 6 shows several oscillograms at the same signal amplitude, but the signal frequency is near $(f_0-p/2\pi)$; the ellipses, taken at several phase shifter indications along the quench cycle, show that the phase angle between the signal and output voltage varies from 0 to $(\pi/2)+2\pi$, that is, repeats itself indicating that the frequency of oscillation $=f_1+p/2\pi$ and that there is synchronization at the side band number 1 which is termed semi-synchronization.

Figure 7 shows similar oscillograms at the same signal amplitude, but the signal frequency is near $(f_0-5p/2\pi)$. The oscillograms indicate that the frequency of oscillation is $(f_1+5p/2\pi)$ and there is synchronization at the side band number 5.

Figures 8 and 9 show oscillograms similar to the former figures but with a low signal, the signal frequency being near f_0 and $(f_0-5p/2\pi)$ respectively.

Automatic Volume Control Action

This is actually a limiting action. Such action can be understood from Figure 10 which represents several time variations of the envelopes at signals proportional to 0.0, 2.0, 5, 10, 20, 50, and 100, signal frequency being very near f_0. Figure 11 shows the increase of grid current and the decrease of plate current for increasing signal amplitude, signal frequency being very near f_0. It is clear from Figure 11 that the limiting action is a characteristic of a super-regenerative detector under logarithmic mode of operation.

High Frequency Detector Operating Frequency Around 1,000 Kilocycles per Second

Figure 12 represents a complete connection diagram, the values of the different elements are indicated. The d-c plate voltage is taken 100 volts. The coupling between plate and grid coils is so adjusted that the free oscillation just starts in the absence of the quench source.

Dependence of Sensitivity on Quench Frequency

A constant low signal of 50 microvolts is applied from the standard signal generator, signal frequency being near f_0 which is 1,100 kilocycles per second. A compensation for the grid current at no signal is effected by a 2-V battery and a 17,500-ohm resistance as shown.

Figure 13 shows the increase of grid current and the decrease of plate current with the variation of the quench frequency from 100 to 2,000 cycles per second, indicating clearly that there is an optimum quench frequency. The latter depends on the amplitude of the quench voltage V_q. For $V_q=60$ volts, $(p/2\pi)$ optimum$\cong$800 cycles per second, and for $V_q=50$ volts, $(p/2\pi)$ optimum$\cong$470 cycles per second.

Figure 14 shows several oscillograms representing the cartesian (time) envelopes at quench frequencies of 200, 500, 1,500, and 2,000 cycles per second, $V_q=60$ volts, no signal being applied. Figure 15 is as Figure 14 but with a constant applied signal. It is clear from

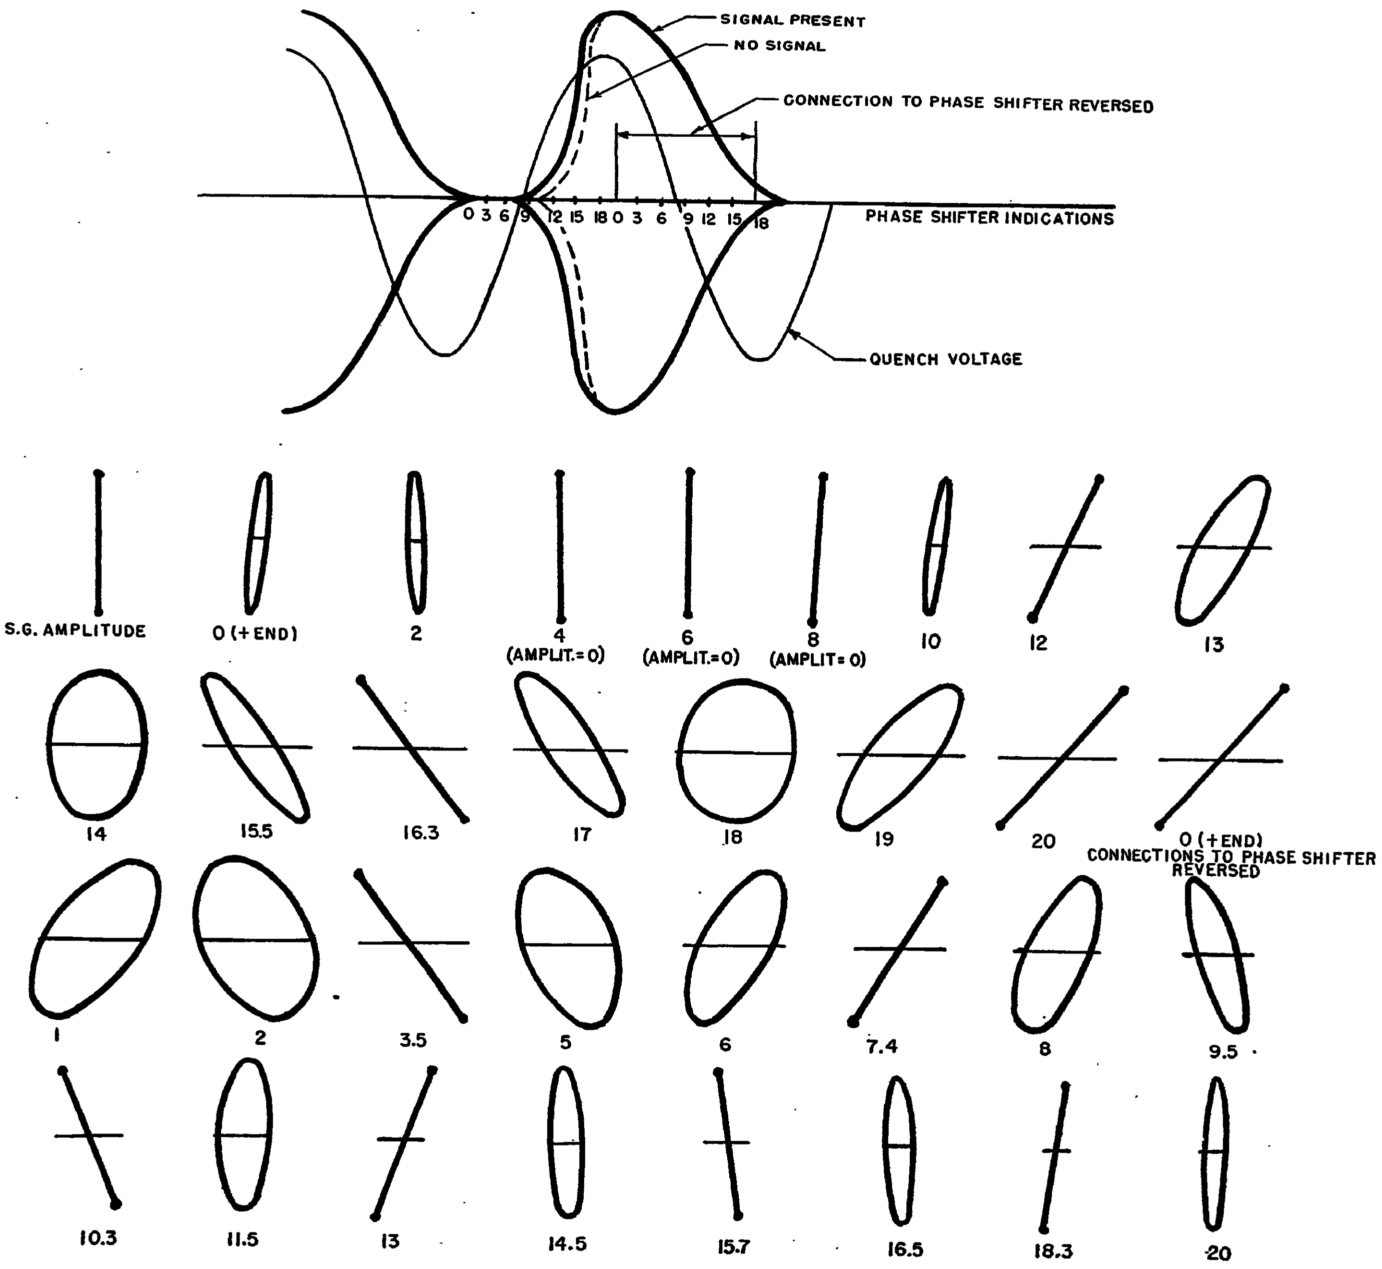

Figure 9. Synchronization at the fifth side band, Lissajous figures as in Figure 7, but with a low applied signal

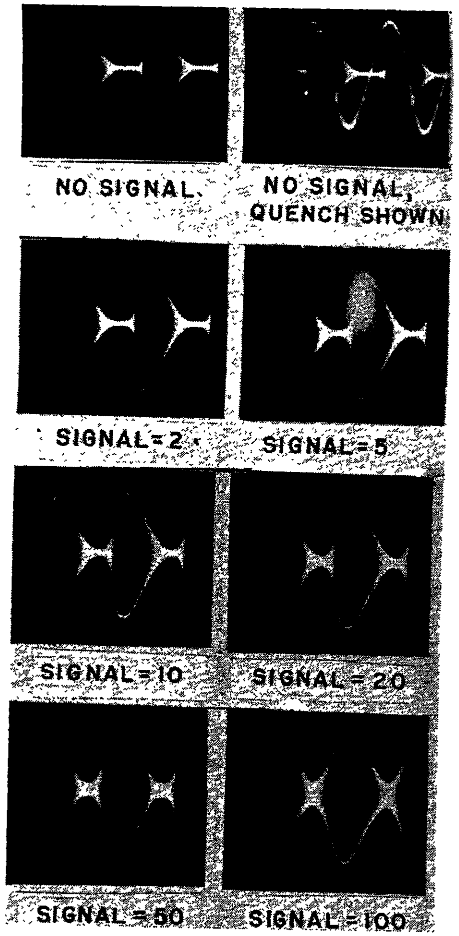

Figure 10. Oscillograms giving envelopes at no signal and at signals proportional to 2.0, 5.0, 10, 20, 50, and 100. Signal frequency $f_1 \cong$ free oscillation frequency f_0

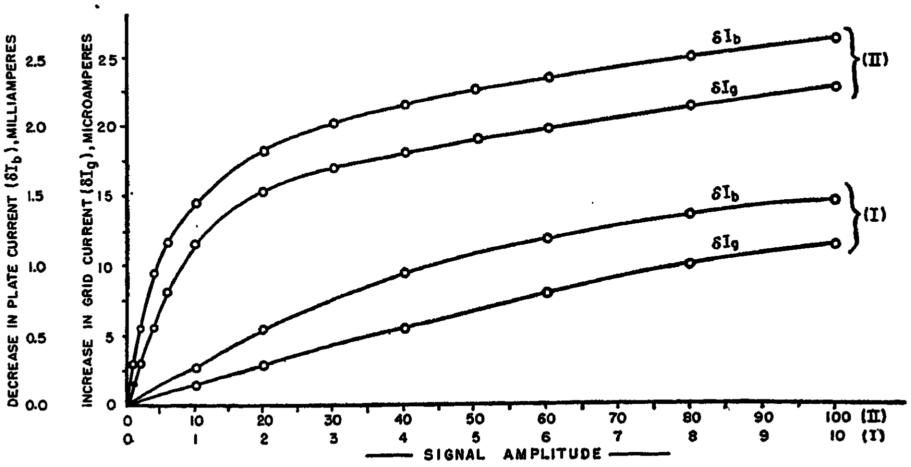

Figure 11. Automatic volume control action (limiting action) at no signal, $I_b=11$ milliamperes, $I_g=30$ microamperes, $V_{HT}=120$ volts, $V_q=40$ volts (rms), and $f_1=96$ kilocycles per second

Figures 14 and 15 that there is an optimum quench frequency at which the increase of envelope area and hence the sensitivity is maximum.

SELECTIVITY CHARACTERISTICS OF SUPERREGENERATIVE DETECTORS

A static point-by-point selectivity measurement takes rather a long time and small drifts in the oscillation frequency occur. For this reason a dynamic characteristic is preferred. The signal is applied from a frequency modulated signal generator; the output voltage across the grid leak resistance is filtered in a 2-section low-pass filter and is applied to the vertical amplifier of the C.R.O. whose time base sweep drives the reactance valve of the frequency modulated signal generator as shown in Figure 12.

Figure 16 shows oscillograms of selectivity characteristics at signals proportional to 0.5, 1.0, 2.0, 4.0, 10.0, and 100. The mean frequency = 1,050 kilocycles per second. The oscillograms show clearly the synchronization at the signal and side-band frequencies. The synchronization curve at any side-band frequency is clearly indicated. At the high signal levels (10 and 100), the synchronizing curves of most of the frequency bands overlap and a smooth curve only is indicated. The oscillograms show a slight deformation near the ends; this is due to the transients of the oscillograph amplifier at the low sweep frequencies used. The synchronization curves at the frequency bands near the ends of the selectivity characteristics are not stable; after such ends, certain movable irregularities appear indicating noise characteristics.

(Figures 13 through 16 appear on the following page.)

Wire and Cable in the Telegraph Industry

W. F. MARKLEY
NONMEMBER AIEE

THE TECHNOLOGICAL advances in the art of telegraphy, starting with the original simple Morse key, sounder, and relay, and progressing to the semiautomatic, and then the fully automatic selective-switching system in a modern telegraph office of today, have justified the modernization of the wire and cable network, insuring efficiency of operation and dependability of the complex electronic equipment, which is in continuous operation over a wide range of frequencies and operating conditions. An extremely essential component of this network is the wire plant concentrated in each of the mechanized communication centers where the proper functioning of the automatic equipment is dependent upon the performance of some 3,000 miles of high-grade wire conductors and more than 1,000,000 intricate wire connections.

General

Almost from the inception of the telegraph over a century ago, rubber compounds, enamel with textile overserves, and dry paper have comprised the insulating materials employed for inside and outside wires and cables. Deep-sea submarine cable has always relied upon gutta-percha as the medium of conductor insulation. Although all these materials have served the industry well, and even today are being employed to a considerable extent in the communication field, they possess certain objectionable characteristics.

Rubber compounds lack heat stability and resistance to deterioration in outdoor exposure, possess high electrical losses in high-frequency operation, and adversely affect weights and diameters. The combination of enamel coatings and textile servings is not adequate electrically under warm moist room conditions and involves high installation and terminating costs. Dry paper for cable conductors always necessitates the use of the traditional lead sheath or other impervious jacket to exclude moisture and is expensive to terminate and splice. Gutta-percha for deep-sea submarine cable has given an excellent account of itself, except that its uniformity of composition, heat stability prior to final installation, and electrical efficiency have not always been fully adequate.

In recent years, with the development of high-speed transmitting and recording apparatus and all forms of electronic equipment, the old standards of conductor insulation have had to give way to newer and more efficient materials in order to meet the demands for:

1. Increased sensitivity of the circuits;
2. Reduced transmission losses;
3. Improved electrical efficiency under adverse conditions of temperature and humidity;
4. Greater heat and light stability;
5. Reduced weights and diameters;
6. Decreased installation costs

These increased demands for more effective primary insulating materials have had a marked influence on the rapidity of development of synthetic-resin compounds, which began to appear about 15 years ago. From the very beginning, many of these so-called plastics found a ready market because of the many advantages they offered with respect to physical and electrical stability, chemical inertness, heat and light aging, moisture resistance, weight, cost, and so forth.

The plastic compounds employed for extruded primary insulation include vinyl compounds, polyethylene compounds, and fluorocarbon resins. The jacketing materials include extruded vinyl compounds, extruded polyethylene compounds, and extruded and woven nylons.

VINYL COMPOUNDS

The vinyl insulating and jacketing compounds consist of synthetic base resins, such as polyvinyl chloride or copolymers of polyvinyl chloride and polyvinyl acetate, to which are added plasticizers which serve to convert the rigid resins to flexible, rubberlike materials. These plasticized resins are further compounded with small percentages of certain base salts, such as lead salts, which serve as stabilizers to insure heat and light resistance. Other ingredients include lubricants to improve and increase gloss, fillers to provide opacity and decrease cost, and colorants to effect a limitless variety of shades.

These elastomeric compositions are mechanically strong and tough, having tensile values of 1,500 to 3,000 pounds per square inch; are nonflammable, resistant to heat and light and unaffected by exposure to water, oils, and most chemicals; exhibit high surface resistivity and good electrical properties, as indicated by a dielectric constant of 4.5 to 8, insulation resistance constant K per 1,000 feet of wire, at room temperature, of 500 to 10,000 and power factor of 0.070 to 0.160. In addition, they are suitable for operation over a wide temperature range (−50 degrees centigrade to 105 degrees centigrade), have an extremely low rate of water-vapor transmission, possess a high degree of abrasion resistance, are nonoxidizing, and can be produced in a wide variety of colors. By means of suitable formulation, it is possible to accent any specific property or group of properties.

POLYETHYLENE

Polyethylene, originally developed in England, is a pure hydrocarbon resin derived from the polymerization of ethylene gas. The principal advantages in the use of this material over vinyl compounds are its exceptionally low dielectric losses (dielectric constant 2.3 and power factor 0.0004) at all frequencies, its inherent extreme resistance to moisture, and its low temperature (−45 degrees centigrade flexibility). Polyethylene is reasonably tough and flexible as indicated by its tensile strength of 1,400 to 3,000 pounds per square inch and elongation of not less than 400 per cent at ordinary room temperature. It is extremely light in weight (specific gravity 0.92) and contains no plasticizers. Additives in small quantities (less than 2 per cent total, except as will be noted in reference to ocean cable insulation) comprise antioxidants to insure retention of electrical properties under thermal abuse, pigments to produce colored compounds, and carbon black to impart resistance to aging in outdoor exposure. The principal limitations to the use of polyethylene

in wire and cable insulations and jackets are thermal in nature; that is, temperatures above 100 degrees centigrade appreciably soften the material and, in the presence of an open flame, polyethylene will burn freely.

FLUOROTHENE

In addition to the vinyl and polyethylene compounds limited use is made of extruded fluorothene synthetic resin as a primary insulation. Chemically, this resin is a polymer of chlorotrifluoroethylene. In its natural state this material is colorless, although it can be blended with solid fillers and coloring agents if desired. Fluorothene was selected as the insulating medium for the conductors used for wiring submarine cable repeaters, primarily because of its extreme toughness and abrasion resistance, and its resistance to the oil in which this equipment is immersed, as will be referred to later. It is likely that other fluorocarbon resins, such as teflon, would be equally satisfactory for this application. All these resins are characterized by extreme inertness to chemicals, unusual heat resistance, toughness over a wide range of operating temperatures, and good electrical properties. Manufacturing costs of the base resins and processing costs of the wire and cable coverings are relatively high, as compared with similar costs for vinyl and polyethylene compounds.

NYLON

Nylon, because of its abrasion resistance and extreme toughness and thermal stability over a wide temperature range, is employed primarily for jacketing purposes, although it was tried as a primary insulation in the extruded form, in connection with the development of office cable. E. I. du Pont de Nemours and Company describes nylon as a generic name applied to all materials defined scientifically as synthetic fiber-forming polymeric amides having protein-like chemical structure, derivable from coal, air, and water, or other substances. Nylon is supplied in various grades, the electrical grade being the one specified in the following as the protective covering for insulated wire. It is employed both in the extruded form as a continuous covering and in the form of a braid woven from nylon yarn.

Instrument Wires

NUMBER 22 AMERICAN WIRE GAUGE

The first major application of plastic-insulated wire in the telegraph industry occurred in 1940 when the supply of rubber was critical. Because millions of feet of number 22 American Wire Gauge (AWG) solid instrument wire are consumed annually as an all-purpose wire for general use in wiring equipment and apparatus, it seemed appropriate, to facilitate delivery of this badly needed material, to replace the rubber insulation with vinyl compound.

Prior to 1940, this instrument wire comprised a tinned-copper conductor insulated with a 15-mil wall of rubber in-

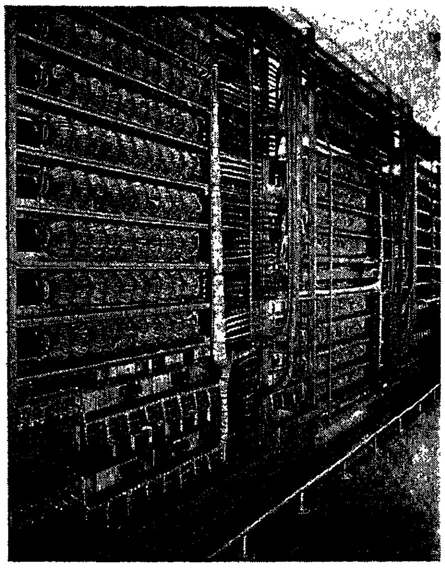

Figure 3. Rotary switch rack

sulation and an outer treated rayon braid, providing an over-all diameter of 90 mils, see Figure 1(A). After intensive study, the rubber and rayon covering was replaced with a 15-mil radial thickness of vinyl insulation, without any external jacket of any kind, and suitable for operating temperatures up to 60 degrees centigrade, Figure 1 (B). The over-all diameter of this wire was only 60 mils. This reduction of one-third in the diameter of the finished wire was a decided advantage in that it permitted a greater number of wires to be pulled into ducts, and effected decreased diameters of hand-made multiple conductor cable forms.

Instrument wire must normally withstand considerable abuse in handling and installation. It is bent around steel supporting strips and angles in cabinets and on frames, is held in multiple conductor forms by wrappings of twine, tape, and so forth is pulled across and is looped up against other wires causing considerable pressure at the contact surfaces. All these represent areas of potential weakness in the insulation due to thinning out of the compound due to cold flow, thereby resulting in excessive current leakage, or by completely cutting through to the conductor. Such wire failures and consequent outages of equipment became so numerous that for a time it looked as though plastic insulated wire could not be depended upon to give adequate service in automatic equipment in continuous operation.

At this point it became obvious that some form of mechanical reinforcement for the insulation must be resorted to if plastic compounds were to be continued for equipment wiring and, accordingly, in 1946 a lacquered-cotton serving was adopted as a jacket for this wire using number 100s single-ply cotton yarn. Because of the mechanical reinforcement by the cotton serving, the thickness of the vinyl insulation was safely reduced from the 15 mils specified to a maximum of 10 mils, Figure 1 (C).

This wire, with its lacquered-cotton serving, was generally satisfactory but still lacked the desired degree of thermal stability and abrasion resistance, showed objectionable wicking action in the presence of moisture, and possessed surface resistivity values under abnormal conditions of humidity that varied over a wide range after a period of service (primarily because of the tendency for dirt and foreign matter to collect in the interstices of the lightly-lacquered cotton serving).

In order to overcome these weaknesses the lacquered-cotton serving was replaced by an extruded electrical-grade nylon jacket in a 3-mil wall, and vinyl insulation heretofore suitable for 60-degree-centigrade operating temperature was changed to one suitable for 80 degree-centigrade operation. These revisions were adopted in 1951 and this wire is the present standard, Figure 1(D).

The outstanding advantages offered by the nylon jacket include the following:

1. Improved toughness (minimum 7,000 pounds per square inch) and abrasion resistance;

2. Resistance to wetting, thereby effecting vastly improved surface resistivity;
3. Freedom from oxidation at temperatures close to 100 degrees centigrade;
4. Greater resistance to fungus;
5. Improved soldering and terminating characteristics;
6. Superior thermal stability;
7. Reduced loss of plasticizer from the primary insulation

This number 22 AWG solid vinyl-insulated nylon-jacketed wire, having an over-all diameter of 51 mils (0.051 inch), provided such outstanding performance as a trouble-free wiring medium that it has now been adopted for general use in making cross connections on main distributing frames, and for making connections on carrier racks and switchboards where heretofore 25-mil vinyl-insulated 22-gauge wire without a jacket (over-all diameter 75 mils) was employed, this heavy wall of insulation having been specified originally because of the cold-flow characteristics of the vinyl. This change effected a one-third reduction in over-all diameter. A companion wire consists of number 22 AWG flexible (stranded) instrument wire, employed for wiring printers and other apparatus having moving parts, as illustrated in Figure 2. The development of this 22-gauge instrument wire with its extruded thin walls of plastic insulation and jacket, required to meet severe electrical requirements, represents a novel design in the wire and cable industry.

Number 24 American Wire Gauge

Even more spectacular was the development of a number 24 AWG instrument wire, required primarily for wiring rotary switches. Figure 3 shows a multiplicity of these switches, assembled on a rotary switch rack. It is the author's opinion that the design of this wire represents one of the first major advances in the art of ultra-thin-wall extruded-vinyl insulation having superior electrical properties.

From the outset, this wire was required to meet unusual conditions with respect to over-all diameter, electrical performance, and ease of stripping of the insulation. The compact rotary switches on which this wire is employed are equipped with several hundred soldering lugs mounted in rows in close proximity. In connecting a number of these switches in series, this 24-gauge wire is required to pass between the lugs, a condition which accounts for the limitation on the over-all diameter of the finished wire. In addition, this wire must be capable of being stripped at intermediate points along the wire, when making attachment to corresponding lugs on successive switches.

It was indicated that the thickness of primary insulation would have to be held to a maximum of 6 mils because of the space limitation. To provide this extremely thin wall of insulation, pressure-sensitive self-sealing insulating plastic tapes, which appeared to be the only practical method available, were tried but found inadequate.

An attempt was then made to extrude a good electrical vinyl compound on the conductor in a nominal thickness of 5 mils.

This request presented a real problem to the manufacturer for the following reasons:

1. Difficulty of obtaining tinned-copper wire having adequate smoothness;
2. Extent of delicate handling required during extrusion process to prevent frequent conductor breakage;
3. Adequate centering of conductor in the thin wall of compound;
4. The question of insulating and processing technique that would insure a minimum insulation resistance of 200 megohms per 1,000 feet, at 15.5 degrees centigrade, for full spools of finished wire after a water immersion period of 6 hours.

After a number of trials, a 5-mil vinyl insulated 24-gauge wire was economically produced that conformed to all of the foregoing requirements.

To provide mechanical protection for the primary insulation, a lacquered-cotton serving was specified, similar to that already described for 22-gauge instrument wire, experience with nylon having been extremely limited at that time. The nominal over-all diameter of this finished wire was only 36 mils (0.036 inch).

This wire gave an excellent account of itself in service, except that complaints were received that the lint or fluff from the cotton serving was being carried off by air currents in air-conditioned operating rooms and lodging in the moving arms of the rotary switches with adverse operating effects. In order to obviate this trouble, and in view of the increased knowledge of nylon subsequently acquired, the lacquered-cotton serving on this wire was replaced with an extruded nylon jacket having a nominal wall thickness of 2½ mils. At the same time the thickness of the primary insulation was increased to 7 mils (from 5 mils) to comply with the request of several manufacturers to effect easier processing. With this change the insulation resistance was increased to 500 megohms (instead of 200 megohms) per 1,000 feet when immersed in water at 15.5 degrees centigrade for 6 hours. The nominal over-all diameter of this finished wire, the present standard, measures about 40 mils (0.040 inch).

NUMBER 28 AMERICAN WIRE GAUGE

Even though tremendous advances have been made in the development of electronic devices, the relay continues to play an important role in the operation of modern telegraph systems. In fact, the relay can perform many functions better and more economically than the electron tube. In certain polar relays the lead wires for the cores are subjected to abnormal temperatures and severe mechanical abuse in installation and service.

For this application, number 28 AWG flexible copper wire, insulated with a 10-mil wall of fluorothene, was originally specified in order to provide adequate thermal stability to withstand the high ambient temperature of about 100 degrees centigrade (prevailing during continuous operation) and to insure adequate mechanical stability, in view of the bending encountered near terminating points. Subsequently, at a greatly reduced cost for the wire, the fluorothene insulation was replaced with vinyl compound, suitable for 105-degree-centigrade operation, over which was applied a 3-mil wall of extruded nylon. There would have been some apprehension about the use of the vinyl-insulated conductor for this service, but the reinforcement, from both a thermal and a mechanical stand-

point, by the nylon jacket has provided a finished wire having adequate serviceability. Cable forms, comprising 70 of these wires, have been satisfactorily employed for wiring test tables.

Other Types

In addition to the various types of instrument wires referred to in the foregoing, limited use is made of other sizes of solid and stranded conductors, insulated with vinyl compounds and an outer jacket of extruded nylon, such as the station or office wire illustrated in Figure 4. The nylon jacket is always held to an extremely thin wall because of the toughness of the nylon and its adverse effect on the stripping characteristics of the covering.

Experience has indicated that polyethylene insulation, in the extremely thin walls that are specified for instrument wire, is much more fragile and susceptible to mechanical injury during processing than vinyl compounds. Consequently, polyethylene is used for instrument wire only in exceptional cases where uniformly low capacitance is required over a wide range of frequencies and under extreme variations in temperature and humidity.

All colors for coding purposes consist of solid colors embodied in the primary insulation using light and dark tints of various shades to effect multiplicity of colors desired. All of these colors are sharp and readily distinguishable from one another through the clear nylon jacket. Consideration has been given to employing colored stripes on the primary insulation for coding purposes, but experience has indicated that with the various inks used for this purpose there is a serious adverse effect of the ink solvent on the insulation resistance of the primary insulation. One manufacturer has been reasonably successful in applying colored stripes to the nylon jacket but this method of coding has not been satisfactory for the extremely small over-all diameters of the finished instrument wires generally employed in the telegraph plant.

Shielded Twisted Pair Wire

Considerable time was devoted to the development of a number 22 AWG twisted pair wire, having an over-all woven-metallic shield, required for certain circuits in electronic equipment. Initially, in the original design, shown in Figure 5(A), there was some question as to how much of the surface of the twisted pair wire should be covered by the woven metallic braid.

For test purposes to determine this feature, lengths of twisted pair wire were made up having three nominal degrees of shielding, namely 70-, 85-, and 100-per-cent coverage. The results of the electrical tests indicated that no significant difference, in crosstalk, attributable to the various degrees of shield coverage, could be detected. The major contribution of the shield appeared to be the minimizing of direct capacitance between circuits. From a mechanical standpoint, that is, flexibility and minimum damage to the shield during severe bending and abuse in installation, the shield having the least coverage was the most desirable.

While, at the low frequencies used on these pairs, it appeared that a coverage of 30 to 50 per cent would be sufficient, it was decided, in view of the fact that commercial shields usually represented about

70-per-cent coverage, to standardize on the 70-per-cent value for this wire. A subsequent improvement in this wire, shown in Figure 5(B), consisted of replacing the lacquered-cotton serving on the conductors and the treated-cotton outer braid with extruded nylon.

Switchboard Cords

Figure 6 illustrates the various stages in the development of switchboard cords. For many years these cords comprised copper tinsel conductors, each insulated with servings of cellulose-acetate yarn, treated with a moistureproof compound over which was applied a soft cotton braid. These conductors, together with suitable fillers, were laid up to form a core which was covered with several cotton braids, the outer braid consisting of hard glazed cotton, see Figure 6(B). These cords are subjected to considerable wear and abuse in service, as shown by Figure 6(A), because of the continuous flexing and abrasion of pulleys and weights

Because the hardest wear on these cords occurs in the outer braid, it was decided to substitute for the all-cotton cords, a plastic cord, shown in Figure 6(C) wherein extra-flexible stranded conductors were employed, each insulated with a thin wall of extruded vinyl compound, laid up into a core with suitable fillers, and covered with an over-all extruded-vinyl jacket. These cords, however, proved unsatisfactory, because of the difficulty of obtaining a thermoplastic jacket compound that possessed adequate flexibility and abrasion resistance without the undesirable characteristic of having the plasticizer ooze out from the compound during warm weather, a condition which made the cords sticky and extremely difficult to handle.

In order to overcome the undesirable features of the vinyl-covered cords, the plastic jacket was replaced by a woven nylon braid, see Figure 6(D), at which time a bronze tinsel conductor was adopted to provide superior strength and flexibility characteristics. Indications are that the service life of these cords will be several times that of the ordinary glazed cotton braided cords.

Ticker Cable

Practically all of the cables required for inside use have been redesigned to provide for plastic primary insulation and jacketing compounds. Figure 7 is a typical example showing the old, intermediate, and present styles of 2- and 4-conductor ticker cables. The final designs provide exceptional ease of installations and excellent performance in service, particularly in warm moist climates.

Office Cable

Perhaps the most important development in inside cable is concerned with the redesign of the enamel and textile-insulated multipair cable, employed in large quantities for wiring offices. This cable is supplied in sizes varying from 3 pair to 50 pair. For a great many years the standard for this type of cable consisted of 22 AWG solid-copper conductors, each enamel-insulated and covered with servings of silk and cotton yarn, which were laid up in pairs, with a concentric lay, into a core that was thoroughly saturated with a natural or mineral beeswax, and paraffin mixture. Over this core were applied several spiral wrappings of heavy paper tape to serve primarily as a barrier for the flameproofing paint that was heavily applied to the over-all woven cotton braid which served as the jacket. This old design is shown in Figure 8(A).

This cable is subjected to considerable abrasion and abuse during installation in that it is pulled through conduit, run up over steel bars and angles of supporting frames, given sharp bends, is tied in place on racks in groups, and so forth. Also, much of this cable is employed in relatively short lengths, involving numerous terminations. Frequently, long lengths of the jacket and paper tape must be removed to provide sufficient length for breaking out the conductors at terminating points. The principal disadvantages in the use of this cable for many years have been the relatively high labor cost of terminating and the adverse effect of moisture on the operation of the circuits. In damp and wet locations, it was always necessary to supply this cable with a lead sheath. With increased knowledge on the performance and efficiency of plastic compounds, it became evident that a vast improvement could be made in the design of this cable.

POLYETHYLENE CABLE

About 5 years ago, four special plastic cables were made up in the 7-pair concentric-lay size, each having a different type of extruded plastic insulation with a lacquered-cotton overserve on the conductors; over the core was applied a 10-mil polyethylene tape and a cable jacket consisting of a lacquered woven cotton braid. For comparative test, a standard enamel and textile cable in 5-pair size was obtained.

Figure 9 shows the appearance of these four plastic cables, and the old Western Union standard enamel and textile-insulated cable. In the *A*, *B*, *C*, and *D* cables in this figure, the lacquered-cotton serving is all about the same general character and thickness; in the standard enamel-insulated cable, this yarn covering comprises two rayon servings and a serving of marking cotton, all of which have a certain amount of mineral beeswax impregnation.

Insulation resistance and capacitance tests were conducted on 100-foot lengths of these five cables after exposure for various periods of time to different at-

mospheric conditions varying from a temperature of 7.2 degrees centigrade (45 degrees Fahrenheit) and 35-per-cent relative humidity, to 35 degrees centigrade (95 degrees Fahrenheit) and 90-per-cent relative humidity. In addition, voltage-breakdown tests were made on conductors taken from the cable, and on short lengths of the cable that had been subjected to severe flexing and compression, to simulate conditions encountered in service. These tests definitely indicated the outstanding superiority of the polyethylene, and the poor insulating value of nylon and enamel. The 7½-mil vinyl-insulated cable was somewhat superior to the 5-mil vinyl-insulated cable.

While both the 7½-mil vinyl and the 5-mil polyethylene-insulated cables overcame the insulation weakness of the old standard enamel and textile-insulated cable, the fact that the polyethylene gave such outstanding electrical performance prompted the decision to give it a field trial. Accordingly, limited quantities in 40- and 50-pair size cables were made up, with a nominal 5-mil wall of polyethylene insulation and lacquered-cotton serving, with a vinyl tape placed longitudinally over the cable core and a vinyl jacket employed for the outer sheath, as illustrated in Figure 8 (B). These cables were installed in several reperforator offices as illustrated in Figure 10. The ease of installation and termination were favorably commented upon by the installers and the performance of these cables to date has been extremely satisfactory under all weather conditions.

VINYL CABLE

During the manufacture of these polyethylene-insulated cables, it was observed that the thin wall of insulation was extremely fragile and easily damaged during processing and cabling. Inasmuch as the superior electrical characteristics of polyethylene were not required for this service, and in view of the greater toughness of thin vinyl compounds, and furthermore since the 7½-mil vinyl-insulated cable gave adequate electrical performance in the tests on the original experimental plastic cables previously referred to, it was decided to substitute an 8- to 10-mil vinyl compound and a 3-mil nylon jacket for the polyethylene insulation, and lacquered-cotton serving respectively. In other words, the standard 22-gauge instrument wire, previously referred to, was adopted for these cable conductors, an arrangement which simplified production schedules and factory inspection. This design, illustrated in Figure 8 (C), represents the present standard. This same cable is now employed in damp and wet locations where formerly lead-covered cable was required.

A further refinement in the design of the plastic cable consisted of providing a lay-up for the pairs that permitted the conductors to break out easily from their natural position in the cable during the terminating operation, thus reducing to a minimum the bending and twisting of the conductors at the soldered butts. Figure 11 (A) shows the positioning of the conductors in the old 40-pair enamel-insulated cable, wherein the pairs follow in numerical sequence around the cable in the order of termination. In Figure 11 (B), the pairs of the plastic cable follow in numerical sequence back and forth across the cable. From the heavy irregular outlines in the diagrams it can be observed, when mounting the cable butt on a standard terminal block, that severe distortion of the conductors takes place as successive groups of four pairs break-out in the enamel cable, whereas with the plastic cable these groups fan out in their normal position.

RELATIVE COSTS

The cost of the all-plastic cable in the smaller sizes is somewhat greater than that of the old enamel-insulated cable but in the larger sizes it is appreciably cheaper. Also, the time consumed in terminating the plastic-insulated cable, due to the ease of stripping, is only 50 to 60 per cent of that required for the enamel type, resulting in a substantial labor saving, inasmuch as a large percentage of this cable is installed in short lengths varying from 8 to 30 feet, thereby calling for the termination of from 6 to 24 butts per 100 feet of cable. In addition, with the plastic cable, all of the stripping on a number of lengths can be done at one time and all of the soldering work carried out at a later time regardless of the interval between stripping and soldering. In the enamel type of cable, it is necessary to solder almost immediately after stripping because the copper conductors, bared during the stripping operation, readily tarnish and oxidize.

ADVANTAGES OF ALL-PLASTIC CABLE

The principal advantages in the use of the all-plastic cable over the former standard, having enamel-insulated conductors, can be summarized as follows:

1. Improved moisture resistance;
2. Superior electrical and physical properties and flexibility;
3. Increased resistance to fungus;
4. Better flame resistance;
5. Sharper coding colors for the insulated conductors;
6. Greater ease of installation and terminating, effecting vastly reduced installation costs.

Outside Wires and Cables

DISTRIBUTING WIRE

Single and twisted pair insulated and weatherproof braid-covered, tinned number 16 AWG hard-drawn copper and copperweld wire, commonly referred to as outside distributing wire, is employed in city distribution work in the telegraph plant to the extent of several thousand miles per year, in providing and maintaining time, call, ticker, printer, and other services between offices and subscribers, and to provide drops from open-line wire into railroad stations, signal towers, and industrial plants. In addition, this wire is used in repair and restoration service in storm areas, in reconstruction work involving pole-line changes necessitated by reason of grade-crossing eliminations, highway improvements, and so forth.

Figure 15 (left). Deep-sea submarine cable, single conductor, type D

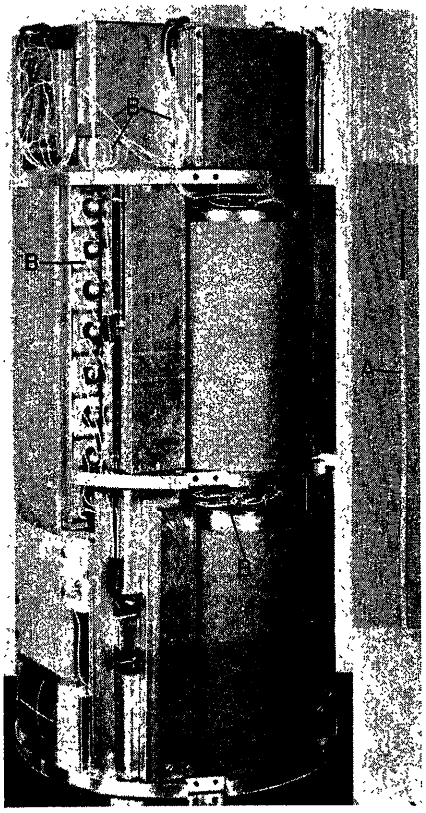

Figure 16 (right). Submerged telegraph repeater with outer steel casing removed

A shows number 18 AWG solid silver-plated copper conductor, insulated with 10 mils of fluorothene, employed for the firing at B

The first sections at which the covering of this wire begins to fail are where the wire is tied or clamped to supports, especially at points of abnormal strain, such as corners or dead ends; improper methods of attaching insulated wire at such points may reduce its useful life by 50 per cent or more. More severe abuse to the wire occurs in reconstruction work and in the restoration of service in storm areas when this wire is pulled over fences and cross-arms and under rails, tied to poles, trees, and so forth, and allowed to remain in water and ice for long periods.

Although the original rubber insulation on this wire gave a reasonably good account of itself in this service for many years, it possessed several weaknesses which not only shortened the life of the wire, but resulted in its inadequacy for certain types of service. In 1942, Western Union pioneered in the development of the first self-supporting thermoplastic-insulated wire, designed for this type of outdoor service in the communications field. In the early consideration of plastic insulation for this application, there was considerable apprehension about the suitability of this type of material, in view of the rough handling during installation and service, and the fact that the finished wire is subjected to an extremely wide range of weather conditions throughout the United States.

After considerable laboratory work, a vinyl compound was selected for this service. As an external covering, the application of a weatherproof braid appeared to be the most advantageous type of mechanical protection, from the standpoint of both economy and performance, that could be satisfactorily adapted for use over the insulated conductor. In the first complete wires that were prepared, it was found that the saturating and finishing compounds employed for weatherproofing the braid adversely affected the vinyl compound. The volatile component of the hot saturating compounds degraded the electrical characteristics of the vinyl insulation, and the heat of application of these compounds softened the insulation to the extent that the conductor would float in the insulation during processing of the braid. To overcome these weaknesses a thin Kraft paper tape was applied longitudinally over the insulation and simultaneously with the braid. Figure 12 shows the design of two types of this wire. The estimated life is in excess of 25 years and the mechanical and electrical stability are superior to the previous rubber-insulated types.

For this service, consideration is being given to conductors insulated with an extruded 1/32-inch wall of so-called high-molecular-weight "rigid"-vinyl compound, modified slightly to improve flexibility. Rigid resins have sufficient plasticity to enable them to be extruded, worked, and processed without the addition of plasticizers. These resins have the outstanding electrical, physical, and chemical properties of the pure unmodified vinyl-base resins previously referred to. No outer jacket of any kind is applied to this wire, as the rigid vinyl appears to have adequate hardness and abrasion resistance over a wide temperature range. While the proper balance between hardness, flexibility, and impact resistance for this compound has not been worked out definitely, indications are, from tests conducted so far, that an adequate simple insulated wire of this type for outside service will be available in the near future.

LINE CABLE

For cable in city distribution service and pole-line runs, where the length is not too great, it is customary to employ lead-covered cable, comprising paired number 19 AWG dry-paper-insulated annealed-copper conductors laid up with a concentric lay. This cable, commonly referred to as *CNB* cable, is supplied in sizes varying from 6 pairs to 455 pairs, and is employed in quantity, both aerially and underground. It is relatively heavy and expensive, involves high installation and terminating costs, and in many congested localities necessitates high maintenance cost in aerial installations.

It is believed that the objectionable features of this cable can be overcome by the use of plastic-insulated and jacketed cable employing polyethylene insulation for the conductors, to provide the uniformly low capacitance required. In a nominal wall thickness of about 20 mils, polyethylene gives approximately the same range of mutual-capacitance values between the conductors of a pair as that obtained in the case of the standard paper-insulated cable. Indications are that this 20-mil wall of polyethylene will provide excellent transmission characteristics for circuits up to 50 kc.

Figure 13 shows the general design of a cable of this type that is being considered, in a 26-pair size, for an aerial installation on Long Island. This cable weighs only about half as much as an equivalent lead covered cable.

CARRIER CABLE

The demand arose for an inexpensive 2-conductor twisted pair, or simple cable, which would be suitable for short-haul (up to 100 miles) carrier communication at frequencies up to 30 kc per second and which would be self-supporting, to enable it to be strung on existing pole lines without the use of a messenger and, thereby, effect minimum installation costs.

At the outset, it was evident that hard-drawn copper or copper-covered steel would be required for the conductors to provide the desired mechanical efficiency, and that polyethylene would be necessary for the primary insulation to insure the low-transmission losses for this service. As the outer jacket for mechanical protection, experience has indicated that a modern weatherproof woven-cotton braid would be both adequate and economical.

Accordingly, in this initial investigation, twisted pair copper wires were considered, in both number 10 and number 13 AWG, each conductor insulated with polyethylene, and covered with an aluminum-faced paper tape and a weatherproof braid. Subsequent samples were provided with a single 4-mil metallic shield and weatherproof braid over the two insulated conductors as a unit. These designs showed prohibitive attenuation of 3 to 4 decibels per mile, necessitating the installation of repeaters every 7 or 8 miles.

Theoretical transmission studies were then made on a simplified coaxial-cable design comprising a single number 10 AWG copper-covered steel conductor insulated with a heavy wall of polyethylene, over which a second conductor comprising a soft 5-mil longitudinal copper tape (equivalent to number $11^1/_2$ AWG copper) is applied; for mechanical reasons a 3-mil spiral tape is applied over the longitudinal tape. The details of this construction are illustrated in Figure 14.

From calculations based on the dimensions in Figure 14, the ratio of inside diameter of the outer conductor to the diameter of the central conductor approximates 3.5 as compared with the ideal ratio of 3.6 to insure minimum attenuation for this design. Indications are that, with the outer conductor applied longitudinally so as to approximate a continuous solid tube, instead of a helical tape serving, a more effective design is obtained from the standpoint of electrical losses, particularly at television frequencies.

This cable design is considered mechanically and economically promising, and is believed suitable for television frequencies if required. The attenuation is estimated at 2.0 decibels per mile at 30 kc per second, which is high, but not entirely prohibitive. It is generally recognized that a gaseous dielectric would effect a marked reduction (ratio of 3 to 2) in the attenuation, but at present such a design seems economically impractical.

The experimental approach to this project, made possible by the procurement of a length of this cable for test purposes, now on order, is valuable, since the magnetic properties of the copper-covered steel core in this application are not too well known. Furthermore, the mechanical characteristics of the thin copper outer conductor employed in a self-supporting cable are also somewhat speculative. From tests that will be conducted on this experimental length, it should be possible to estimate with fair accuracy the properties of any moderate departure in the proposed design.

Submarine Cable and Equipment

Prior to 1940, gutta-percha was used almost universally as the insulating material for ocean cable conductors, rubber compounds having been found generally unsatisfactory. All gutta-percha cables had been made abroad, either in England or Germany. As World War II shut off the supply of gutta-percha even more effectively than rubber, pressure for the development of a suitable synthetic insulation for ocean cable increased.

Deproteinized rubber had been used in this country with some success and is still being employed because it offers equally good electrical properties and certain improved physical characteristics, as compared with gutta-percha. An even better solution was achieved by English scientists in adapting polyethylene (or "polythene," as it is called in England). In Europe, polyethylene compounds containing 10 to 15 per cent "Vistanex" (polyisobutylene) are also employed, because of the greater ease of processing with existing equipment, as compared with pure polyethylene. Since 1943, polyethylene-insulated ocean cable (see Figure 15) has been manufactured in the United States.

The first purchases of polyethylene cable by Western Union were made in 1944. At the present time, the Western Union Telegraph Company has in service approximately 800 miles of this type of cable, manufactured both here and abroad, and has on order about 600 additional miles.

Polyethylene compounds are more stable than gutta-percha at relatively high atmospheric temperatures, such as those encountered by a cable ship in southern waters, where the cable might be subjected to the direct rays of the sun for short periods before laying. Also, indications are that polyethylene compounds may be substantially resistant to attack by the teredo worm, whereas gutta-percha must be protected with a serving of copper or brass tape.

In Europe, polyethylene-insulated cable costs less than the gutta-percha type and, due to the present low dollar value of the pound sterling, is appreciably cheaper than any ocean cable produced in the United States. For cables manufactured in this country, the deproteinized-rubber type is cheaper than polyethylene-insulated cable.

Considerable data have been published by the Western Union Telegraph Company during the past 2 years covering the design, installation, and operation of intermediate submerged telegraph repeaters in a long transoceanic cable, which represents the first venture into a previously unexplored field and which permits tripling signaling speed in some cases.

Equipment housed in this repeater must be designed to insure reliable, unattended, long-life operation under unusual conditions. The instrument wire for this unit must be provided with an insulating compound having extreme toughness and abrasion resistance, to withstand the abuse during installation and service resulting from the sharp bending and flexing encountered, and must have superior chemical resistance against the action of the low-vapor-pressure oil in which the unit is immersed. Fluorothene insulation was specified for this application, as indicated in Figure 16 illustrating wiring technique.

Conclusions

The foregoing descriptions serve to illustrate the major uses of the newer insulating materials that have been adopted for various specific applications in the telegraph industry during the past 12 years in supplying the millions of conductor feet of insulated wire and cable installed annually. No attempt has been made to discuss all of the special services where these insulating materials have been specified with extremely satisfactory results.

In the old days, it was necessary to more or less adopt some standard wire or cable for a specific application, for which it was not always fully adequate. Today, it is possible to have the bare conductor, the insulating materials, and the finished cable tailor-made so as to insure efficient and lasting performance in service under almost any prescribed operating conditions. There still remain many applications where the suitability of the newer insulating materials is under intensive study.

New formulations and techniques, effecting reduced diameters and weights and superior physical, chemical, thermal, and electrical characteristics, are continually being developed, that forecast major advances of great significance in the art of insulated-wire and cable design and present an ever-widening future in this field, not only in the telegraph sphere, but in all American industry as well. It would be extremely conservative to predict that even greater advances in the development of more effective wire and cable insulating compounds will be brought to light during the next decade.

◆

Discussion

A. L. Duna (United States Steel Company, Worcester, Mass.): Mr. Markley's paper is an excellent portrayal of wire and cable problems which existed in the telegraph industry, and the changes in wire and cable design which eliminated many of the problems and materially reduced costs of installation. However, the new cable designs have created many problems for the cable manufacturer, and in essence it may be said that the problems of installation have been transferred to the manufacturer of the cable. This, of course, is as it should be. It is the way of progress—the responsibility of the manufacturers to make things better for the customer who is always right.

Let us consider just one of the relatively simpler problems which have confronted the cable manufacturer in the making of instrument wire and office cable. Just picture the small number 22 or 24 AWG solid copper wire, on which 8 to 10 mils of polyvinylchloride (PVC) resin must be extruded. That gives us a nominal thickness of 9 mils, with a tolerance of ± 1 mil, which must be extruded on a thread of wire traveling at high speed, and must be maintained continuously for millions of feet of production. Also, picture the 3- to 4-mil nylon jacket, which is extruded over the PVC insulation, with a tolerance of only ± 1/2 mil, also at high speeds, for continuous runs of millions of feet. The problem has now become one of precision manufacture where extreme vigilance and care in the operation is essential, for the mere dropping of an eyelid may result in the loss of thousands of feet of production, because of failure to meet the requirements of the specifications.

Pursuing the manufacturing problem further, the making of multiple-pair office cable, which is composed of instrument wires as already described, involves the handling of these relatively fragile wires in many other operations and equipments and the transportation of them on long journeys between operations. Unless extreme care is taken in handling the component parts of the cable as it progresses through to completion, damage becomes inevitable and results in test failures, short lengths, and eventual remakes of components which are beyond repair.

Notwithstanding our difficulties, we wish to commend Mr. Markley and Western Union for their foresight and courage in pioneering this radically new design of cable which, in spite of the manufacturing problems, is a forward step in the progress of wire and cable manufacture.

W. F. Markley: The author is grateful to A. L. Duna for his excellent presentation of the manufacturer's problems that develop when attempting to fabricate insulated wire and cable according to Western Union specifications.

It is quite true, as Mr. Duna points out, in referring to inside multipair cables, that the "relatively fragile wires" must withstand the handling encountered in many operations, involving long journeys between fabricating points, and that considerable care must be exercised in processing the insulated conductors to insure freedom from undue degradation of the physical and electrical characteristics of the insulated conductors. However, it has been the author's experience that after a manufacturer has developed the technique and systematized the production of these wire and cable products with the desired precision, extremely little trouble is experienced.

These insulated wires and cables are employed for wiring complex electronic equipment concentrated in highly mechanized communication centers throughout the United States, and operating continuously 24 hours a day over a wide range of frequencies and operating conditions. This fact makes it essential that extreme vigilance and care be taken in processing the products to provide the desired quality to insure adequate functioning of this automatic equipment. Years of experience of Western Union engineers have definitely indicated that installation practices and performance requirements justify the quality levels that have been standardized.

Effects of Harmonics on the Frequency of Oscillation as Well as on the Asymmetry of the Resonance Curves

ABD EL-SAMIE MOSTAFA
NONMEMBER AIEE

Synopsis: Transforming the nonlinear equations representing the free and synchronized oscillations to linear ones with periodically varying coefficients, the complete solutions of oscillator equations to the first power of the tube parameters are obtained. The relation between frequency variation and harmonic contents is given. The effect of the harmonics on the asymmetry of the resonance curves of a synchronized oscillator is obtained for the first time. Experimental verification has been carried out, and the results agree well with the theoretical predictions.

THE DEPENDENCE of the frequency of oscillation of an electron tube oscillator on the nonlinear properties of the maintaining circuit has been the subject of several investigations, theoretical and practical.[1,2] The effects of the harmonics on the asymmetry of the resonance curves of synchronized oscillators cannot be regarded as absolutely final and complete.[3] As far as the author knows, no previous investigator has obtained a clear relationship between the harmonic contents and the asymmetry of these resonance characteristics.

Expressing the nonlinear relationship of the electron tube by a power series of infinite number of terms, the complete solution of oscillator equations has been obtained. The harmonic contents for the free and synchronized oscillations are given. The effect of harmonic contents on the asymmetry of the resonance characteristics is rigidly obtained.

Theoretical Analysis

Free Oscillations

The differential equation for the output voltage v of the oscillator in Figure 1 is given by

$$d^2v/dt^2+(1/C)(G+di_p/dv)dv/dt+\omega_0^2v=0 \quad (1)$$

where i_p is the a-c component of the plate current and $\omega_0^2=1/LC$. The losses in the circuit are represented by a shunt conductance G in order to simplify the analysis, and the results obtained can apply satisfactorily as well to the more usual case where the losses are associated with the inductance, especially when the circuit losses are relatively low. Such procedure of assuming a constant conductance G is deduced from the fact that the impedance of the parallel C-L-G circuit, for the fundamental as well as for the harmonic voltages, is very nearly the same as the more usual circuit. Strictly speaking, G cannot be considered as absolutely constant, and the analysis of the more usual case where the losses are associated with the inductance will be given by the author in another paper.

i_p can be represented as a power series of v, thus

$$i_p=\sum_{n=1} a_nv^n$$

giving

$$di_p/dv=\sum_{n=1} na_nv^{n-1}$$

The upper limit of the summation depends on the number of terms required in the expansion for satisfactory representation, but generally it is infinity.

For an oscillatory solution, v can be assumed to be of the form

$$V_t\cos\omega t+\sum_{m=2}^{\infty} V_{t_m}\cos(m\omega t+\theta_m)$$

where V_t, being a very slow function of time compared with the frequency of oscillation, is the fundamental amplitude at any instant t; V_{t_m} and θ_m are also slow functions of time and represent the amplitudes and phases of the harmonics respectively, and $\omega/2\pi$ is the frequency of oscillation (fundamental). For the solution of equation 1 to the first power (degree) of the tube parameters a_n, it is sufficient to substitute $V_t\cos\omega t$ for v in di_p/dv. Substitution gives

$$d^2v/dt^2+(G_t/C)\left(1+\sum_{r=1}^{n-1}h_r\cos r\omega t\right)\times dv/dt+\omega_0^2v=0 \quad (2)$$

where

$$G_t=G+h_0 \quad (3)$$

$$h_0=\sum_{n=1}[na_n/2^{n-1}\{(n-1)/2\}!]\times \{(n-1)(n-2)(n-3)\ldots \text{ up to } (n-1)/2 \text{ factors}\}V_t^{n-1} \quad (4)$$

$$(n \text{ being odd})$$

$$G_th_r=\sum_{\substack{p=(r+1),\\(r+3),(r+5)\ldots}}[pa_p/2^{p-2}\{(p-r-1)/2\}!]\times \{(p-1)(p-2)(p-3)\ldots \text{ up to } (p-r-1)/2 \text{ factors}\}V_t^{p-1} \quad (5)$$

In this way, the nonlinear differential equation 1 has been transformed to a linear one with periodically varying coefficients.

For the solution of equation 2 to the first power of a_n and hence to the first power of h_0 and G_th_r, the methods of superposition and successive approximation are adopted and given in Appendix I. The output voltage v will be given by

$$v=A_s\epsilon^{(1/2C)\int G_t\{(h_2/2)-1\}dt}\times \left[\cos\omega t-(1/2\omega C)\sum_{r=2}\{G_t/(r^2-1)\}\times (h_{r-1}-h_{r+1})\sin r\omega t\right] \quad (6)$$

where A_s is a constant depending on initial conditions and G_th_r is to be obtained from equation 5 and $\omega\simeq\omega_0$.

It is clear from equation 6 that the instantaneous amplitude V_t builds up from the small starting value A_s to the stationary value V according to the relation

$$V_t=A_s\epsilon^{(1/2C)\int G_t\{(h_2/2)-1\}dt}$$

Stationary state is attained when $h_2=2$. Substitutions from equations 3, 4, and 5 give

$$\alpha_1-G=\sum_{p=3}[pa_p/2^{p-1}\{(p-1)/2\}!]\times \{(p-1)(p-2)(p-3)\ldots \text{ up to } (p-3)/2 \text{ factors}\}V^{p-1} \quad (7)$$

$$(p \text{ being odd})$$

$$=(3/4)a_3V^2+(5/8)a_3V^4+(35/64)a_7V^6+(63/128)a_9V^8+(231/512)a_{11}V^{10}+\ldots \quad (7A)$$

where $\alpha_1=-a_1=(\mu M/L-1)(1/\rho)$; ρ and μ are the plate resistance and the amplification factor of the tube respectively. Equation 7 gives the stationary possible fundamental amplitudes V of the output voltage.

Paper 53-159, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 19–23, 1953. Manuscript submitted September 10, 1951; made available for printing December 3, 1952.

Abd El-Samie Mostafa is with the Alexandria University, Alexandria, Egypt.

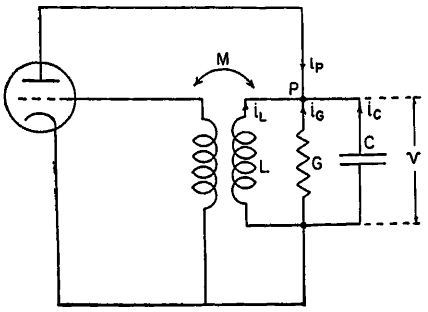

Figure 1. Tuned plate oscillator, polarized potentials omitted

At the stationary state, equation 6 reduces to

$$v = V\left[\cos\omega t - (1/2\omega C)\sum_{r=2}\{G_1/(r^2-1)\}\times (h_{r-1}-h_{r+1})\sin r\omega t\right] \quad (8)$$

$$= V\cos\omega t - \sum_{r=2} V_r \sin r\omega t \quad (8A)$$

where

V_r = amplitude of the rth harmonic

$$= (V/2\omega C)\{G_1/(r^2-1)\}(h_{r-1}-h_{r+1}) \quad (9)$$

G_1h_r is the value of G_th_r obtained from equation 5 after substituting V for V_t. Therefore

$$V_r = (1/2\omega C)\{1/(r^2-1)\}\times \left[(ra_r/2^{r-2})V^r + \sum_{\substack{p=(r+2),(r+4),\\(r+6)\ldots}} \times [rpa_p/2^{p-2}\{(p-r)/2\}!]\{(p-1)(p-2)\ldots \text{ up to } (p-r-2)/2 \text{ factors}\}V^p\right] \quad (9A)$$

Putting $r=2, 3, 4\ldots$ the different harmonics can be obtained, see Appendix II.

It is clear from the previous analysis that to the first power of the tube parameters a_n, the frequency of oscillation $\omega/2\pi$ should equal to $\omega_0/2\pi$. If there is any deviation from $\omega_0/2\pi$, it must be of the second power of a_n. Approximations up to the second power can be obtained by substituting $\left(V_t\cos\omega t - \sum_{m=2} V_{tm}\times \sin m\omega t\right)$ for v in di_p/dv of equation 1 and following the same analysis but using closer approximations. However, the frequency deviation can be obtained adopting the following conception.

Due to the presence of the harmonics, intermodulation with each other and with the fundamental give additional terms in the fundamental plate current i_p which are not in phase with the output voltage v. A deviation of frequency from $\omega_0/2\pi$ is therefore necessary to restore the correct phase relation between current and voltage.

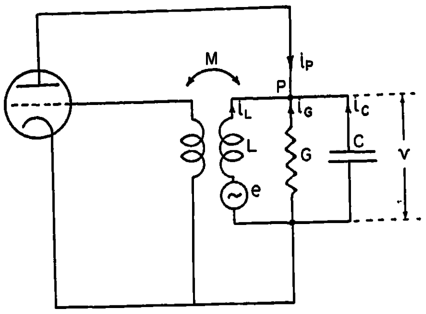

Figure 2. Simple synchronized oscillator, polarized potentials omitted

Substituting $\left(V\cos\omega t - \sum_{r=2} V_r\sin r\omega t\right)$ for v in i_p gives

$$i_p = \sum_{n=1} a_nv^n = \sum_{n=1} a_n\left(V\cos\omega t - \sum_{r=2} V_r\sin r\omega t\right)^n \quad (10)$$

Analyzing equation 10 to the first power of V_r and using equations 5 and 7 we get

$$i_p = -GV\cos\omega t - (1/2)\sum_{r=2} G_1(h_{r-1}-h_{r+1})\times V_r\sin\omega t + \text{components of frequencies other than } \omega/2\pi \quad (11)$$

Substituting equation 9 in equation 11 gives

Fundamental component of (i_p)

$$= i_{p\,\mathrm{Fund.}} = -GV\cos\omega t - \omega C\times \sum_{r=2}(r^2-1)(V_r^2/V^2)\sin\omega t = I_{p\,\mathrm{Fund.}}\cos(\omega t+\theta)$$

where

$$\tan\theta = (\omega C/-G)\sum_{r=2}(r^2-1)(V_r^2/V^2)$$

But, from C-L-G parallel circuit, Figure 1

$$\tan\theta = (\omega C/G)\{1-\omega_0^2/\omega^2\}$$

Therefore

$$(\omega_0^2/\omega^2) - 1 = \sum_{r=2}(r^2-1)(V_r^2/V^2) \quad (12)$$

This is the Groszkowski[1] relation.

Equation 12 indicates that the frequency of oscillation is reduced due to the presence of the harmonics. Therefore, solution of equation 1 to a better order of approximation, concerning the frequency of oscillation, will be as follows

$$v = A_s\,.\,\epsilon^{(1/2C)\int G_t\{(h_2/2)-1\}dt}\times \left[\cos\left(\int\omega_t dt\right) - (1/2\omega C)\sum_{r=2}\times \{G_t/(r^2-1)\}(h_{r-1}-h_{r+1})\times \sin\left(\int r\omega_t dt\right)\right] \quad (6A)$$

where the instantaneous frequency of oscillation $\omega_t/2\pi$ is given by

$$\omega_t^2/\omega^2 = 1 + \sum_{r=2}(r^2-1)(V_{t_r}^2/V_t^2) \quad (12A)$$

V_t and V_{t_r} are the instantaneous amplitudes of the fundamental and rth harmonic respectively. It is clear from equation 6(A) and 12(A) that as the amplitude of oscillation builds up, the frequency of oscillation decreases till the stationary state is reached and V_t and ω_t attain the stationary values V and ω given by equations 7 and 12 respectively.

FORCED OSCILLATIONS

The differential equation for the output voltage v of the synchronized oscillator of Figure 2 is given by

$$d^2v/dt^2 + (1/C)\{G + di_p/dv\}dv/dt + \omega_0^2(v-\epsilon) = 0 \quad (13)$$

where ϵ is an external source of amplitude E and frequency $\omega/2\pi$; G, i_p, v, and ω_0 have the same indications as before.

In this case, i_p can also be represented as a power series of v, thus

$$i_p = \sum_{n=1} a_nv^n, \text{ and } di_p/dv = \sum_{n=1} na_nv^{n-1}$$

If synchronized oscillation only is present, whether the system is in the stationary or the transient state, the output voltage v will generally be of the form

$$v = b_t\cos\omega t + \sum_{m=2} b_{tm}\cos(m\omega t+\theta_m)$$

and the synchronizing voltage of the form, $\epsilon = E\cos(\omega t+\phi_t)$, where b_t, b_{tm}, θ_m, and the instantaneous phase angle ϕ_t are slowly varying functions of time compared with the frequency of oscillation. b_t is the fundamental amplitude and b_{tm} and θ_m are the instantaneous amplitudes and phases of the harmonics of the output voltage respectively.

For the solution of equation 13 to the first power of the tube parameters a_n, it is sufficient to substitute $b_t\cos\omega t$ for v in di_p/dt and to substitute $k_t\{v\cos\phi_t + (1/\omega)\sin\phi_t\,dv/dt\}$ for ϵ, where $k_t = E/b_t$. Substitution gives

$$d^2v/dt^2 + (G_t/C)\left(1+\sum_{r=1}^{n-1} h_r\cos r\omega t\right)\times dv/dt + \omega_{0t}^2v = 0 \quad (14)$$

where

$$\omega_{0t}^2 = \omega_0^2(1-k_t\cos\phi_t) \quad (15)$$

$$G_t = G + h_0 \quad (3A)$$

$$h_0 = -\omega_0k_t\sin\phi_t + \sum_{n=1}[na_n/\{2^{n-1}((n-1)/2)!\}]\{(n-1)(n-2)(n-3)\ldots \text{ up to } (n-1)/2 \text{ factors}\}\times b_t^{n-1} \quad (4A)$$

(n being odd)

$$G_t h_r = \sum_{\substack{p=(r+1),\,(r+3),\\ (r+5)\ldots}} [pa_p/2^{p-2}\{(p-r-1)/2\}!]\{(p-1)(p-2)(p-3)\ldots \text{ up to } (p-r-1)/2 \text{ factors}\}b_t^{p-1} \quad \text{(5A)}$$

Equation 14 is of the same form as equation 2 or equation 23 and therefore its solution, being of the form $b_t \cos \omega_t + \ldots$ as assumed, can be directly obtained from equation 6(A) and is given by

$$v = A_s e^{(1/2C)\int G_t\{(h_2/2)-1\}dt} \times \left\{\cos \omega t - (1/2\omega C)\sum_{r=2} \{G_t/(r^2-1)\} \times (h_{r-1}-h_{r+1}) \sin r\omega t\right\} \quad (16)$$

where A_s is a constant depending on initial conditions and $G_t h_r$ is to be obtained from equation 5(A), and $(\omega_{0t}^2/\omega^2) = 1 + \sum_{r=2} (r^2-1)b_{t_r}^2/b_t^2$; using equation 15 we get

$$-k_t \cos \phi_t = \{2(\omega-\omega_0)/\omega_0\} + \sum_{r=2}(r^2-1)b_{t_r}^2/b_t^2 \quad (17)$$

It is clear from equation 16 that the instantaneous amplitude b_t of the synchronized oscillation builds up from the small starting value A_s according to the following relation

$$b_t = A_s e^{(1/2C)\int G_t\{(h_2/2)-1\}dt}$$

Stationary state is attained when $h_2 = 2$, in which case $b_t = b$, $b_{t_r} = b_r$ and $\phi_t = \phi$; substituting from equation 3(A), 4(A), and 5(A), and using equation 7 we get

$$\omega_0(E/b)\sin\phi = -(\alpha_1 - G)\times \left[1 - \frac{\sum_{p=3,5,7\ldots} [pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots \text{ up to } (p-3)/2 \text{ factors}\}b^{p-1}}{\sum_{p=3,5,7\ldots} [pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots \text{ up to } (p-3)/2 \text{ factors}\}b_0^{p-1}}\right] \quad (18)$$

where b_0 is the amplitude of the free oscillation, and $\alpha_1 = -a_1$.

Also, at the steady state equation 17 becomes

$$-\omega_0(E/b)\cos\phi = z + \omega_0 \sum_{r=2} (r^2-1)b_r^2/b^2 \quad \text{(17A)}$$

where

$$z = 2(\omega - \omega_0)$$

Elimination of ϕ between equations 18 and 17(A) gives the frequency/amplitude equation, namely

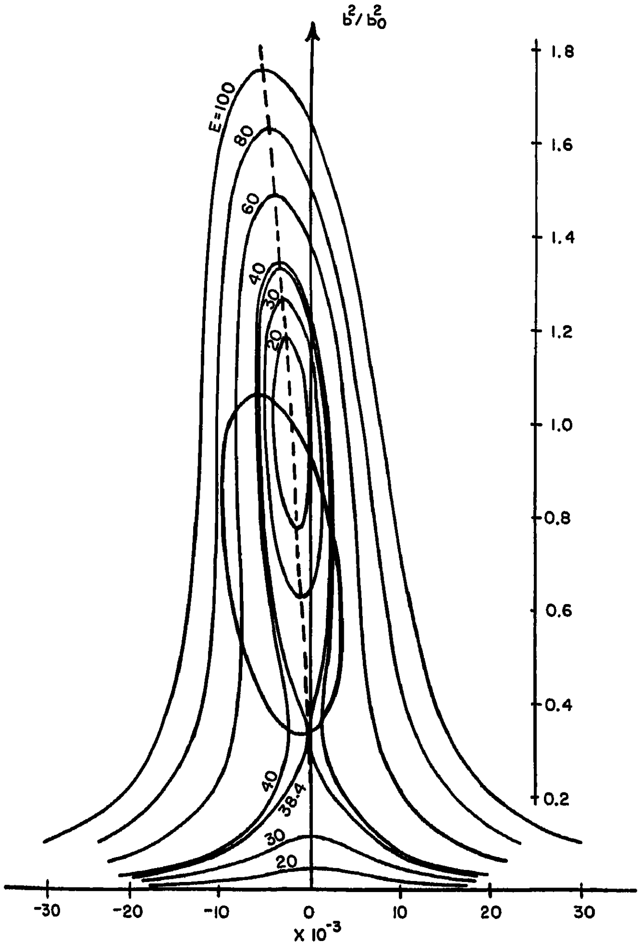

Figure 3 (left). Resonance curves and the threshold of stability, calculated from equations 19(A) and 22(A)

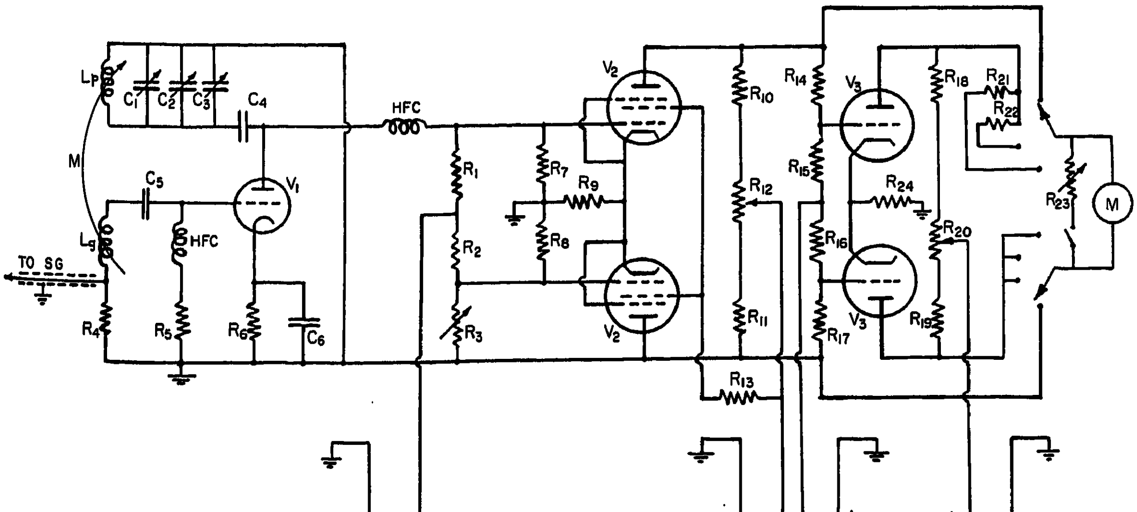

Figure 4. Connection diagram for the experimental determination of the resonance characteristics. Values of components are: C_1=1,000, C_2=10, C_3=5, C_4=C_6=500, C_5=100, R_1=R_3=R_{21}=47, R_2=100 (fixed)+50 (variable), R_4=R_9=1, R_5=12, R_6=5.6, R_7=R_8 = R_{22} = 470, R_{10} = R_{11} = 120, R_{12}=20, R_{13}=R_{14} = R_{15} = R_{16} = R_{17}=270, R_{18}=R_{19}=15, R_{20}=10, R_{23}=15 ohms, R_{24}=1.2; capacitances are in micromicrofarads and resistances in kilohms

$$b^2\left[\left\{z+\omega_0\sum_{r=2}(r^2-1)b_r^2/b^2\right\}^2+(\alpha_1-G)^2\times\left\{1-\frac{\displaystyle\sum_{p=3,5\ldots}[pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots\text{ up to }(p-3)/2\text{ factors}\}b^{p-1}}{\displaystyle\sum_{p=3,5\ldots}[pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots\text{ up to}(p-3)/2\text{factors}\}b_0^{p-1}}\right\}^2\right]=\omega_0^2E^2 \quad (19)$$

It is clear from equation 19 that b is maximum when

$$z+\omega_0\sum_{r=2}(r^2-1)b_r^2/b^2=0 \quad (20)$$

indicating that the resonance curve is not symmetrical. The asymmetry is due to the harmonics present. If the harmonics were neglected and if terms up to a_3 were only considered, equation 19 would be reduced to that obtained by Van der Pol.[4] Again, at the stationary state, equation 16 becomes

$$v=b\left[\cos\omega t-(1/2\omega C)\sum_{r=2}\{G_1/(r^2-1)\}\times(h_{r-1}-h_{r+1})\sin r\omega t\right]$$

$$=b\cos\omega t-\sum_{r=2}b_r\sin r\omega t \quad (16A)$$

where

b_r = amplitude of the rth harmonic
$=(b/2\omega C)\{G_1/(r^2-1)\}(h_{r-1}-h_{r+1})$

G_1h_r is the value of G_th_r obtained from equation 5(A) after substituting b for b_t. Therefore

$$b_r=(1/2\omega C)\{1/(r^2-1)\}\times\left[(ra_r/2^{r-2})b^r+\sum_{p=(r+2),(r+4)\ldots}\times[rpa_p/2^{p-2}\{(p-r)/2\}!]\{(p-1)(p-2)\ldots\text{ up to }(p-2-r)/2\text{ factors}\}b^p\right] \quad (9B)$$

Putting $r=2$, 3, 4, 5, 6, et cetera, the different harmonics can be obtained, see appendix III. The amplitude b can be obtained from equation 19 for any detune z.

Stability of the Stationary Amplitudes of Forced Oscillations

The stationary amplitudes b of the fundamental can be obtained from equation 19. Whether these amplitudes occur in practice or not depends on their stability. Now

$$b_t=A_se^{\int X dt}$$

where

$$X=(1/2C)G_t\{(h_2/2)-1\}$$

G_th_2 is to be obtained from equation 5(A) by putting $r=2$. Near the stationary state, $X\to 0$ and

$$b_t(=A_se^{\int X dt})\to b$$

At the stationary state, $X=0$ and $b_t=b$. Therefore, the condition for stability could be stated as follows: if there is a slight increase δb in the possible stationary amplitude b (given by equation 19), then the increase δX in X must be negative, that is X must be reduced from its stationary value which is zero to a negative value, otherwise $A_se^{\int X dt}$ would increase beyond b and hence the amplitude would rise indefinitely which is contrary to the fact, and vice versa. Therefore, the condition for stability is given by

$$(dX/db)<0$$

that is

$$(d/db)[(1/2C)\{G_t((h_2/2)-1)\}_{b_t=b}]<0$$

Using equations 3(A), 4(A), and 5(A), $(dX/db)<0$ becomes

$$\left[\omega_0C(E/b)\cos\phi\, d\phi/db-\omega_0C(E/b^2)\sin\phi-\sum_{p=3,5,7\ldots}(p-1)[pa_p/2^{p-1}\{(p-1)/2\}!]\{(p-1)(p-2)\ldots\text{ up to }(p-3)/2\text{ factors}\}b^{p-1}\right]<0$$

Differentiating 17(A) gives

$$\omega_0E\sin\phi\, d\phi/db=z+\omega_0(d/db)\times\left\{\sum_{r=2}(r^2-1)b_r^2/b^2\right\} \quad (21)$$

Substituting equations 17(A), 18, and 21 in the inequality gives the condition of stability at low synchronizing signals which is

$$\left[\left(z+\omega_0\sum_{r=2}(r^2-1)b_r^2/b^2\right)\left[z+\omega_0(d/db)\times\left\{\sum_{r=2}(r^2-1)b_r^2/b^2\right\}\right]+\{(\alpha_1-G)/C\}^2\times\left\{\frac{\displaystyle\sum_{p=3,5\ldots}[pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots\text{ up to}(p-3)/2\text{ factors}\}b^{p-1}}{\displaystyle\sum_{p=3,5\ldots}[pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots\text{ up to}(p-3)/2\text{ factors}\}b_0^{p-1}}-1\right\}\times\left[\frac{\displaystyle\sum_{p=3,5\ldots}[pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots\text{ up to }(p-3)/2\text{ factors}\}b^{p-1}}{\displaystyle\sum_{p=3,5\ldots}[pa_p/2^{p-1}\{(p-1)/2\}!]\times\{(p-1)(p-2)\ldots\text{ up to }(p-3)/2\text{ factors}\}b_0^{p-1}}+\{b/(\alpha'-G)\}\sum_{p=3,5\ldots}(p-1)\times[pa_p/2^{p-1}\{(p-1)/2\}!]\{(p-1)(p-2)\ldots\text{ up to}(p-3)/2\text{ factors}\}b^{p-2}]\right]\right]>0 \quad (22)$$

If the harmonics were neglected and if terms (in i_p-series) up to a_3 were only considered, equation 22 would be reduced to the corresponding condition obtained by Van der Pol.[4]

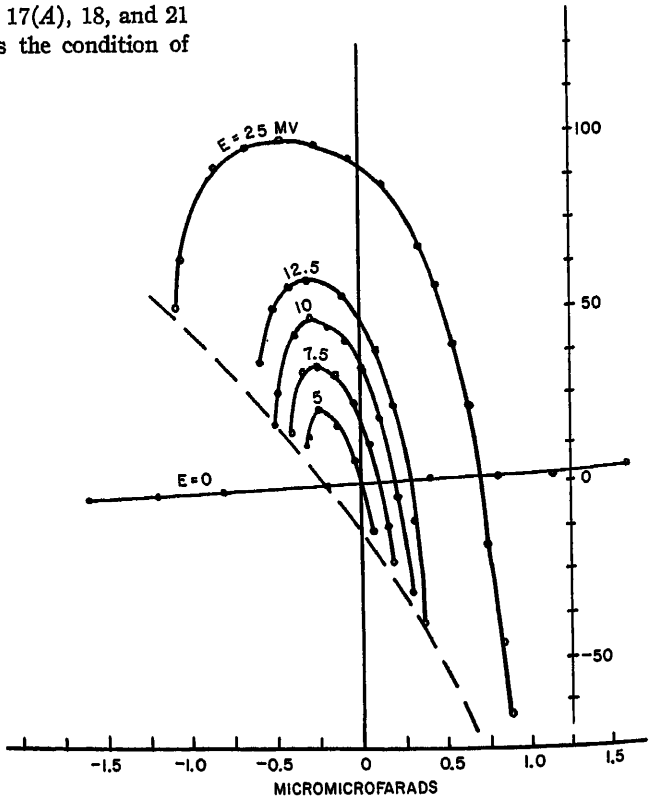

Figure 5. Experimental resonance characteristics for several low values of synchronizing voltages E

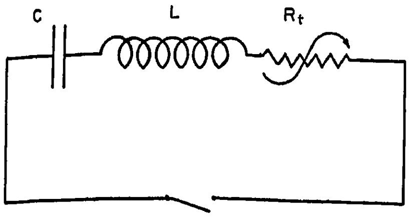

Figure 6. Series oscillatory circuit having a periodically varying resistance

If terms up to a_4 in the series of i_p are only considered, then equations 19 and 22 reduce to

$$b^2[[(z/\omega_0)+\{1/(\omega_0C)^2\}\{(1/3)a_2{}^2b^2+\{(81/1024)a_3{}^2+(2/3)a_2a_4\}b^4+(21/60)a_4{}^2b^6\}]^2+\epsilon^2\{1-b^2/b_0{}^2\}^2]=E^2 \quad (19A)$$

and

$$[[(z/\omega_0)+\{1/(\omega_0C)^2\}\{(1/3)a_2{}^2b^2+\{(81/1024)a_3{}^2+(2/3)a_2a_4\}b^4+(21/60)a_4{}^2b^6\}][(z/\omega_0)+\{1/(\omega_0C)^2\}\times\{a_2{}^2b^2+\{(45/128)a_3{}^2+(10/3)a_2a_4\}b^4+(147/60)a_4{}^2b^6\}]+\epsilon^2(1-b^2/b_0{}^2)\times(1-3b^2/b_0{}^2)]>0 \quad (22A)$$

where

$$\epsilon=(\alpha_1-G)/\omega_0C$$

Taking $\epsilon=0.01$, $\omega_0/2\pi=500$ kilocycles per second, $C=500$ micromicrofarads, $b_0=10$ volts, $a_2=90\times10^{-7}$, $a_3\cong2\times10^{-7}$ and $a_4=0.3\times10^{-7}$, the resonance curves as well as the threshold of stability (obtained by equating equation 22(A) with zero) are calculated from equations 19(A) and 22(A) respectively. Figure 3 shows the resonance curves for synchronizing voltages E equal to 100, 80, 60, 40, 38.4, 30, and 20 millivolts. The maximum points of the resonance characteristics lie on the dashed curve given by equation 20 which, for the present particulars, is

$$(z/\omega_0)\times10^3+(1/225)\{2.7b^2+1.8285\times10^{-2}b^4+0.326\times10^{-4}b^6+0.01823\times10^{-8}b^8\}=0$$

The threshold of stability is also shown in Figure 3. Substituting the given particulars in equation 9(B), we get (at $b=10$ volts): second harmonic per cent=2.55 per cent, third harmonic per cent=0.12 per cent, fourth harmonic per cent=0.0663 per cent.

Experimental Verification

In order to test the validity of the foregoing theoretical relations regarding the asymmetry of the resonance characteristics of synchronized oscillators, the following experimental work was carried out.

The oscillator used is of the ordinary tuned plate type, see Figure 4. The tuned circuit comprises a coil L_p, a main tuning capacitor C_1, a trimmer capacitor C_2, and a calibrated trimmer one C_3. The signal used to synchronize the oscillator, obtained from the "Marconi Echo" standard signal generator (S.G.), is injected in the grid circuit across the resistance R_4. As the variation of the output voltage of a synchronized oscillator in the whole synchronizing range is small, especially for the small input signals used in the experiments, a need is felt for a method to measure only these small variations. The change in the d-c plate current is a measure of the output voltage variation. A bridge system is used in order to balance the no-signal plate current. The arms forming the bridge are R_1, R_2, a variable resistance R_3, and the plate resistance ρ of the tube. Balance is obtained by adjusting R_3. The variation of ρ during the synchronizing range is very small and can be neglected. The direct voltage across R_1 and R_2 is applied to a balanced d-c amplifier having negative feedback by means of cathode resistances R_9 and R_{24} to increase the immunity of the amplifier from drift troubles, see Figure 4. A well regulated high tension source is used to supply the direct voltages to the plates of the oscillator and the amplifier.

Figure 5 shows the change in the d-c plate current as read on a central-zero 100-0-100 micro ammeter (M) of the d-c amplifier against the variation of the calibrated trimmer condenser C_3 for several small synchronizing voltages E. The curve for $E=0$ (free oscillation) is also shown. The free oscillation frequency is about 500 kilocycles per second. Before applying the signal, C_3 is always kept at its zero-position while the trimmer condenser C_2 is adjusted till the free oscillation frequency is exactly equal to the signal frequency.

It is clear from Figure 5 that the resonance characteristics are not symmetrical; the dashed curve connecting their ends is evidently a part of the closed curve of Figure 4 representing the threshold of stability at low signals.

Appendix I

Consider the series circuit, Figure 6, where R_t is a periodically varying resistance and given by

$$R_t=R_0\left(1+\sum_{r=1}^{\infty}h_r\cos r\omega t\right)$$

while the inductance L and the capacitance C are constants. The differential equation for the charge Q across the capacitor is given by

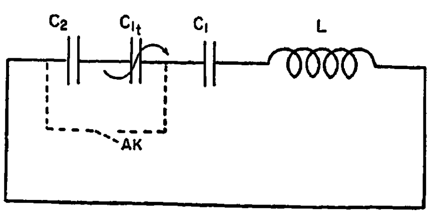

Figure 7. Connection diagram for equation 24

$$d^2Q/dt^2+(R_0/L)\left(1+\sum_{r=1}^{\infty}h_r\cos r\omega t\right)\times dQ/dt+\omega_0{}^2Q=0 \quad (23)$$

Substituting the transformation $Q=q\epsilon^F$ and choosing the function of time F such that dq/dt vanishes, and also neglecting terms containing high powers of $R_0/\omega L$ and $R_0h_r/\omega L$, equation 23 is reduced to

$$di_q/dt+\omega_0{}^2\left\{1+(R_0/2\omega L)(\omega/\omega_0)\sum_{r=1}^{\infty}\times rh_r\sin r\omega t\right\}\int i_q dt=0 \quad (24)$$

where

$$i_q=dq/dt$$

The function of time F is given by

$$F=-(R_0/2L)\left\{t+\sum_{r=1}^{\infty}(h_r/r\omega)\sin r\omega t\right\}$$

Let $\omega_0=\omega(1+d)$ and d=amount of detune, and it is assumed to be very small compared with unity.

The connection diagram giving the current iq of equation 24 will be as shown, Figure 7, where

$$1/C_1=\omega^2L,\ \ 1/C_2=(2d+d^2)/C_1,$$

$$1/C_{1t}=(1/C_1)(R_0/2\omega L)\sum_{r=1}^{\infty}rh_r\sin r\omega t$$

According to the well-known "compensation theorem," if short-circuiting C_2 and C_{1t} by closing the artificial key (a.k.) and replacing instead a generator of zero internal impedance and having an electromotive force equals $-\{(1/C_2)+(1/C_{1t})\}\int iq\,dt$, the actual current iq flowing in the circuit would be unchanged; but iq is unknown, therefore, successive approximations will be adopted as follows. Closing the a.k., the first approximation of iq would be given by $i_1=A\sin(\omega t+\phi)$, where A and ϕ are constants to be determined from initial conditions. For a second approximation, C_2 and C_{1t} are replaced by a generator of zero internal impedance and having an electromotive force $=v_1=-\{(1/C_2)+(1/C_{1t})\}\int i_1dt$. Closing the a.k. of Figure 7 and applying the component of v_1 of frequency $\omega/2\pi$, the current will be given by

$$i_2\cong A[\{(2d+d^2)/2\}\omega t\cos(\omega t+\phi)+(R_0/\omega L)(h_2\omega/4)t\sin(\omega t-\phi)]$$

(i_1+i_2) gives the fundamental component of *iq* to a second degree of approximation.

Following the same lines, other approximations can be obtained. Therefore, to the first power of R_0, R_0h_r, and $(2d+d^2)$, the fundamental of the current *iq* is given by

$$i_{q_{\text{Fund.}}}=B_1\epsilon^{\sqrt{a}t}\sin(\omega t+\phi')+ B_2\epsilon^{-\sqrt{a}t}\sin(\omega t+\phi'') \qquad (25)$$

where

$$\sqrt{a}=(\omega/)4\sqrt{(h_2R_0/\omega L)^2-\{2(2d+d^2)\}^2},$$

$$\tan\phi'=2(2d+d^2)/\{(4\sqrt{\bar{a}}/\omega)+h_2R_0/\omega L\},$$

$$\tan\phi''=-2(2d+d^2)/\{(4\sqrt{\bar{a}}/\omega)-h_2R_0/\omega L\}$$

B_1 and B_2 could be considered as constants depending on initial conditions. The term containing $e^{\sqrt{a}t}$ in equation 25 will be neglected as it is a highly damped one. The harmonics other than the fundamental are obtained as follows: replace C_2 and C_{1t} by a generator of zero internal impedance and having an electromotive force

$$\begin{aligned}v_h&=-\{(1/C_2)+(1/C_{1t})\}\int i_{q\text{Fund.}}dt\\ &=-B_1\{R_0/4\sqrt{1+a/\omega^2}\}\epsilon^{\sqrt{a}t}\times\\ &[h_1\cos(\phi'-\theta')+4(\omega L/R_0)(2d+d^2)\times\\ &\sin(\omega t+\phi'-\theta')+\sum_{r=2}^{\infty}-(r-2)h_{r-2}\times\\ &\cos\{(r-1)\omega t+\phi'-\theta'\}+rh_r\times\\ &\qquad\cos\{(r-1)\omega t-(\phi'-\theta')\}]\end{aligned}$$

where

$$\tan\theta'=\omega/\sqrt{\bar{a}}$$

The effect of the component of v_h of frequency $\omega/2\pi$ is included in the predetermined fundamental, while the effects of the other components give the harmonic currents including the zero-frequency one.

Therefore, the current *iq* approximated to the first power of R_0, R_0h_r, and $(2d+d^2)$ will be given by

$$\begin{aligned}i_q=B_1\epsilon^{\sqrt{at}}\Big[&\sin(\omega t+\phi')-(R_0/4\omega L)h_1\times\\ &(\sqrt{a}/\omega)\cos(\phi'-\theta')+(R_0/4\omega L)\times\\ &\sum_{r=3}^{\infty}\{(r-1)/((r-1)^2-1)\}\times\\ &[(r-2)h_{r-2}\sin\{(r-1)\omega t+\phi'-\theta'\}-\\ &\qquad rh_r\sin\{(r-1)\omega t-(\phi'-\theta')\}]\Big]\end{aligned}$$

The charge

$$\begin{aligned}Q=q\epsilon^F=\epsilon^F\int iq\,dt\\ \cong(B_1/\omega)\epsilon^{(\sqrt{\bar{a}}-R_0/2L)t}\Big[&\sin(\omega t+\phi'-\theta')-\\ &(1/2)(R_0/2\omega L)h_1\cos(\phi'-\theta')-\\ &(1/2)(R_0/2\omega L)\sum_{r=3}^{\infty}\{1/((r-1)^2-\\ &1)\}[(r-2)h_{r-2}\cos\{(r-1)\omega t+\phi'-\\ &\theta'\}-rh_r\cos\{(r-1)\omega t-(\phi'-\theta')\}]-\\ &(1/2)(R_0/2\omega L)\sum_{r=1}^{\infty}(h_r/r)\times\\ &[\cos\{(r-1)\omega t-(\phi'-\theta')\}-\\ &\qquad\cos\{(r+1)\omega t+\phi'-\theta'\}]\Big] \qquad (26)\end{aligned}$$

If R_0, h_r, and the amount of detune d are not constants but slowly varying functions of time, equation 26 becomes

$$\begin{aligned}Q\cong(B_1/\omega)\epsilon^{\int(\sqrt{\bar{a}}-R_0/2L)dt}\Big[&\sin(\textstyle\int\omega dt+\phi'-\\ &\theta')-(1/2)(R_0/2\omega L)h_1\cos(\phi'-\theta')-\\ &(1/2)(R_0/2\omega L)\sum_{r=3}^{\infty}\{1/((r-1)^2-\\ &1)\}[(r-2)h_{r-2}\cos\{\textstyle\int(r-1)\omega dt+\\ &\phi'-\theta'\}-rh_r\cos\{\textstyle\int(r-1)\omega dt-\\ &(\phi'-\theta')\}]-(1/2)(R_0/2\omega L)\sum_{r=1}^{\infty}\\ &(h_r/r)[\cos\{\textstyle\int(r-1)\omega dt-(\phi'-\theta')\}-\\ &\cos\{\textstyle\int(r+1)\omega dt+\phi'-\theta'\}]\Big] \qquad (26A)\end{aligned}$$

It should be noted that the component of Q of frequency $\omega/2\pi$ is very approximately equal to

$$(B_1/\omega)\epsilon^{\int[\sqrt{\bar{a}}-(R_0/2L)]dt}\sin(\textstyle\int\omega dt+\phi'-\theta')$$

Equation 23 is similar to equation 2 with the substitution of Q, R_0, L, and C for v, G_t, C, and L respectively. However, the fundamental of the output voltage v must be of the same form as assumed and which is $v=V_t\cos\omega t$, therefore, a possible solution for equation 2 can be obtained from equation 26(A) provided $\phi'-\theta'=\pi/2$, giving $d\cong-(1/8)(G_t/\omega C)^2h_2^2\cong0$ (high powers of G_th_r being neglected), and $\omega\cong\omega_0$, therefore

$$\begin{aligned}v=A_s\epsilon^{(1/2C)\int G_t\{(h_2/2)-1\}dt}\times\\ \Big[\cos\omega t-(1/2\omega C)\sum_{r=2}\{G_t/(r^2-1)\}\times\\ (h_{r-1}-h_{r+1})\sin r\omega t\Big]\end{aligned}$$

as given in the text.

Appendix II

Putting $r=2, 3, 4, 5, 6$, and so forth in equation 9(A) we get

$$V_2=(1/6\omega C)\{2a_2V^2+2a_4V^4+(15/8)a_6V^6+(7/4)a_8V^8+\ldots\}$$

$$V_3=(1/16\omega C)\{(3/2)a_3V^3+(15/8)a_5V^5+(63/32)a_7V^7+\ldots\}$$

$$V_4=(1/30\omega C)\{a_4V^4+(3/2)a_6V^6+(7/4)a_8V^8+\ldots\}$$

$$V_5=(1/48\omega C)\{(5/8)a_5V^5+(35/32)a_7V^7+(45/32)a_9V^9+\ldots\}$$

$$V_6=(1/70\omega C)\{(3/8)a_6V^6+(3/4)a_8V^8+\ldots\}$$

Appendix III

Putting $r=2, 3, 4, 5, 6$, and so forth in equation 9(B) we get

$$b_2=(1/6\omega C)\{2a_2b^2+2a_4b^4+(15/8)a_6b^6+(7/4)a_8b^8+\ldots\}$$

$$b_3=(1/16\omega C)\{(3/2)a_3b^3+(15/8)a_5b^5+(63/32)a_7b^7+\ldots\}$$

$$b_4=(1/30\omega C)\{a_4b^4+(3/2)a_6b^6+(7/4)a_8b^8+\ldots\}$$

$$b_5=(1/48\omega C)\{(5/8)a_5b^5+(35/32)a_7b^7+(45/32)a_9b^9+\ldots\}$$

$$b^6=(1/70\omega C)\{(3/8)a_6b^6+(3/4)a_8b^8+\ldots\}$$

Communications for Civil Defense

C. A. ARMSTRONG
MEMBER AIEE

HERE IN America, we have never been subjected to the kind of devastating all-out home-front attack that was launched against so many cities and towns of Europe, Asia, and Africa during World War II. There are those who may ask, what is civil defense and why does it need communications? Let us consider first, what civil defense is. Briefly, civil defense may be described as the protection of the home front by civilians, acting under civil authority, to minimize casualties and war damage and to preserve the maximum civilian support of the war effort. When a country is under threatened or actual attack, civil defense becomes a full partner of the military in the defense of that country. In recent years civil defense has grown in importance because the progress of air warfare has increased the possibilities of attacks on the civil populace. Industries, vital facilities, and population centers are all likely targets for hostile attack.

Now, why does civil defense need communications? There are two principal reasons. First, because civil defense is responsible for giving the people advance warning of impending attacks. This responsibility is shared jointly with the air-defense command of the United States Air Force in a manner which will be described in the following. The high speeds of modern aircraft require that the communications for alerting be speedy and efficient if the public is to receive adequate advance warning. This is a most important phase of civil-defense communications because, based on experience in Europe and Japan, it has been estimated that the casualties are reduced 50 per cent or more, simply by the giving of adequate advance warning of an air attack.

Secondly, communications are needed because civil defense has responsibilities in connection with fire fighting, rescue, medical, debris clearance, emergency repair or restoration of vital facilities, monitoring for specific hazards or special weapons, and so forth. For all these missions, communications are required to determine the situation at any moment, to dispatch forces, and to direct and coordinate activities toward the relief of that situation. Communications are needed between fixed points, also between fixed points and mobile units. Communications are needed within cities, between cities in the same state, and on a nation-wide basis. In a real sense, communications are the nerves of the civil-defense effort.

Engineering Requirements

The engineering of communications for civil defense must be based on the following factors

1. Coverage—able to interconnect all points between which communications are required and able to be expanded readily.
2. Expense—a minimum consistent with other requirements
3. Reliability—dependable under disaster conditions
4. Security—not susceptible to interception or unauthorized transmissions
5. Simplicity—easily operated by volunteers

Does civil defense need to build an extensive communications network for its own exclusive use in carrying out its mission? This question will be answered for many detailed instances in the following; however, at the outset, it is well to recognize a few salient factors. The communications requirements for civil defense might well be compared with the road and highway requirements for civil defense. Obviously, it would be impracticable to build a network of highways for use only by civil-defense forces and to be used only in time of disaster. Likewise, it would be impracticable to build a network of communications facilities for use exclusively by civil-defense forces in times of disaster. Like our road system, both our local and long-distance networks of communications facilities for normal peacetime usage are vast, diversified, and extensive. In the interest of providing the necessary coverage with adequate reliability and at reasonable costs, communications planning for civil defense needs to be based on the maximum utilization of existing facilities.

Attack Warning

Few people realize the extensive communications which lie behind the wailing of the air-raid warning siren. It is not simply the result of an observer somewhere seeing a flight of hostile aircraft and phoning someone to set off the sirens. If it were this simple, there probably would be many false alerts. But when the sirens sound an alert, it is the functioning of a carefully planned nation-wide system. This system involves several echelons whereby aircraft movements are reported, plotted, filtered, and analyzed by an Air Force general, or his deputy, who is stationed at an air-defense control center (ADCC). This general officer is responsible for the initiation of air-raid warnings throughout an entire air division, encompassing an area which includes several states.

AIRCRAFT DETECTION

Before attack warnings are disseminated, hostile aircraft must be detected and identified. To begin with there is the ground observer, who is located at observation posts spaced about 8 miles apart. In the ultimate plan, these posts will be uniformly spaced throughout the entire country. Using his ears and eyes, he scans the skies and reports to his filter center all the aircraft movements which he observes.

In general, regular telephone lines are used in transmitting the ground observers' reports to the filter center. However, these calls are accorded special handling. A distinctive phrase is used in placing these aircraft flash calls and this phrase immediately identifies these calls to the telephone operators, who handle them on a priority basis. Of course, aircraft flash calls are accepted only from officially authorized telephones. The traffic routing instructions are such that these calls are completed, not only to the correct filter center, but also to the correct position around the plotting table, where the call will be answered by a volunteer who is responsible for plotting reports from the particular observation post which is calling.

The ground observer reports the number of planes and type, their altitude, direction of travel, and other pertinent details. At the filter center the reports are plotted on a grid map and followed up as more reports come in. This information is put together and the course and position of the enemy aircraft are determined. In this way the enemy aircraft

is continuously kept track of and the probable targets are determined. Meanwhile, by means of private-line telephone circuits, the filter center relays this filtered track information to the appropriate radar plotting station. This track information is again plotted at the radar. station, together with reports from adjacent filter centers. At the same time, strategically located radar sets are scanning the skies, locating and tracking any enemy aircraft within the range of their radar beams, and sending appropriate information, again by means of private-line telephone circuits, to the radar plotting station.

Thus, information about hostile planes flows into the radar station through two channels: 1. From the observation post, via the filter centers and 2. From the radar sets. The ground observer system is a vital part of the detection system and is needed to supplement the radar network because of the inherent limitations of radar. On the basis of all this information the radar plotting station will call the appropriate fighter-intercepter air craft bases into action; they send up their fighter planes to attack the enemy. These fighter planes are directed by the radar plotting station, which follows both our own and the enemy aircraft by radar and directs our fighter planes into the best positions for attack on the enemy aircraft.

By means of a private-line telephone circuit, the situation, with regard to hostile aircraft and any countermeasures taken by our aircraft, is continually being reported by all the radar stations within each division to the ADCC, which is the headquarters for the air division. At the ADCC, all of the information is continually plotted, and is analyzed by the commanding general, who is reponsible for the entire air division. This general is responsible for determining when and what type of alerts shall be disseminated throughout his division. When he determines that an alert should be transmitted, he passes this information to the civil air-raid controller at the center, who immediately disseminates the alert through the civil-defense attack-warning system.

Attack-Warning System

Alerts are disseminated from an ADCC to civil key-point warning stations by means of a special 4-wire private-line telephone circuit, which includes several unusual features. This civil air-defense warning (CADW) private-line circuit is illustrated by Fig. 1. A typical circuit would be 500 to 1,000 miles in total length and would connect an ADCC to about 25 key-point cities. Several such circuits may radiate from one ADCC. To send an alert, the controller at the ADCC operates a key which causes a bell to ring instantaneously and simultaneously in all of the key-point warning stations connected to this network. He then announces the alert, and this announcement is heard over loudspeakers, simultaneously at all the key points. The controller then calls the roll of key points for acknowledgments. The key-point attendant acknowledges using the push-to-talk hand set provided. The raising of the hand set (switchhook) cuts off the loudspeaker and permits conversation between the key point and the ADCC.

Several of the special features of this circuit are designed to prevent the origination of false alerts from any key point. Only one-way signaling is provided; only the ADCC can ring on this circuit. If a key-point operator wants to call the ADCC, he can speak into the hand set and his voice call will be heard over the loudspeaker at the ADCC, but no key

point can ring on the circuit. Furthermore, the two directions of transmission are completely separated so that the key points can not talk to each other; that is, the key points can hear only the ADCC while the ADCC can hear all the key points.

With this system, the alert reaches all the key-point personnel simultaneously so that the first step of CADW dissemination is completed in only about 10 seconds—the time it takes to ring the bells and announce: "Air-Defense Warning—Red, (Repeat) Air-Defense Warning—Red." The roll-call acknowledgement of the fact that the alert has been received and the degree of alert understood is completed in about 3 minutes, the exact time depending on the number of key points connected to a given network and the speed of response of the key-point personnel. A voice recorder is connected to this circuit at the ADCC so that a permanent record is available of this acceptance of responsibility by the key-point operator for the further dissemination of the alert.

Should the ADCC controller fail for any reason to receive an acknowledgment to the roll call from any key point, he will immediately place a long-distance telephone call to that point. For this purpose the ADCC has a specially provided toll-terminal telephone line. This is a direct telephone line to the nearest toll switchboard. A similar toll-terminal line is provided from each key point to the serving toll switchboard. In placing these calls, the controller uses a distinctive phrase which will, in an emergency, insure that the call receives the highest priority. With this arrangement, the entire network of toll message facilities (with many alternate routing possibilities) serves as a backup for the special CADW private line.

Key-point cities are chosen with consideration both to critical target areas and to geographical relationships. Some states have only one; others may have more than a dozen key points. Within the cities, the key-point warning station location is chosen as one which has reliable 24-hour coverage; for example, a police headquarters. From here the alert is disseminated to other points in the same city and to the adjacent cities and towns. For each target area it is desirable that an alternate location be designated for the key-point warning station. This alternate key-point location should be about 5 miles or more from the key point. It should be provided with a toll-terminal telephone line, which is served from a toll office other than the one serving the key point. The alternate key point receives alerts directly from the ADCC only if the regular key point is not operative, in which case the alternate will take over the functions of the key point.

The method used to disseminate alerts from key points varies, depending upon the following:

1. Existence of suitable private-line circuits which can be used
2. The number of points to be notified
3. The urgency, or speed requirements

This latter point may require some clarification, since one might argue that the dissemination of alerts is equally urgent to all points. However, as a practical matter speed is much more compelling in the alerting of points within or near target areas. There is an element of logic in the somewhat exaggerated idea that the weekly newspaper is a sufficiently good way to alert some of the remote rural areas in the interior of the country.

The need for an acknowledgment from the points being warned must be considered carefully. With many types of facilities, the cost is materially reduced if acknowledgments are not essential. In the first step of passing the warning (from the ADCC to key points) the cost of providing for acknowledgments is undoubtedly justified because of the importance of the key-point city and large numbers of people within each key-point area. In succeeding steps, as the number of people dependent upon the warned point becomes smaller, the number of points becomes very much larger and the possible over-all damage caused by a human or circuit failure becomes less. Since the cost of providing for acknowledgments increases very rapidly as the number of warning points expands, the acknowledgment feature usually cannot be justified in the lower steps of the warning chain.

To meet the requirements of alerting a large number of points quickly, simultaneously, and at a minimum cost, the Bell Telephone System has developed the "bell-and-lights" civil air-raid warning system. The use of this system is illustrated in Fig. 2. The system consists of a bell-and-lights indicator set installed at each location that is to receive the alerts; the set is so arranged that a different code ring and different light signal is received for each degree of alert. These indicator sets are all controlled by a special dial which is installed at the control point from which the alert is to be sent, normally a key point.

With the bell-and-lights system, a special sunflower-type dial is arranged with the different degrees of alert (rather than the usual letters and digits) shown

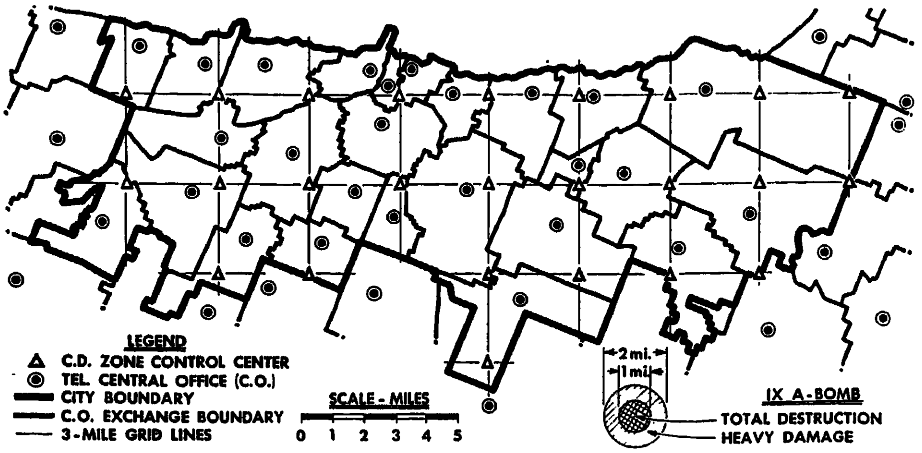

Fig. 5. Typical large city showing relationship of telephone central offices and zone control centers

by name and color on the petals outside the dial wheel. To send the yellow alert, for example, dialing the yellow color is all that is required. As soon as the dial action is completed, an audible code ring is received and a yellow light appears at those bell-and-lights stations which are authorized to receive the yellow (advance warning) alert. For the red (attack imminent) alert a red code ring and a red light appears at all bell-and-lights locations following the dialing of the red code. The white (all clear) is disseminated in the same manner by dialing the white code: a steady ring and a white light is transmitted. Provision has been made, in the design of this system, for a fourth alert—blue—which is not required at the present. By means of a simple strapping change in the central office equipment, the system may be so arranged that the yellow and/or blue can be sent either to all stations or only to a limited number of stations which have been previously designated. Any alerts sent from the master-dial location will continue until the control point operator dials "stop."

A larger number of warning points may be connected to a given bell-and-lights network. Alternate-control points may be provided, and generally should be at the same locations as the alternate key points. The principal circuits of the system are under continual automatic test so that trouble conditions will immediately register a major alarm in the telephone central office but will not cause the transmission of a false alert. This system employs dial-pulse signals between the control point and each central office. Between each warning station and its serving central office, the fundamentals of 4-party selective ringing are employed. The station indicator sets utilize a high-impedance ringer and cold-cathode neon lamps. One advantage of this system, as well as of the CADW private-line system, is that it is not dependent upon local power supply for operation; only telephone central office power is required. (As will be discussed later, these telephone offices are equipped with storage batteries and other emergency-power arrangements.)

The bell-and-lights system can be arranged to control the operation of public warning devices such as sirens, horns, whistles, and so forth. Public sirens which are connected to a bell-and-lights network will be sounded on the red and on the "public white" alerts simultaneously with the transmittal of the alert to bell-and-lights stations. The circuit is fully automatic and includes a memory feature which prevents the sounding of the sirens on confidential alerts—the yellow, the blue and the "confidential white" (a white which follows either a yellow or blue.)

In a number of cities and states the alerts are disseminated from key points to subkey points by means of an existing police-teletype network, which is normally used for other purposes. This is speedy and provides simultaneous alerting to a large number of locations. Existing police-radio systems are also used for this purpose. However, with both teletype and radio networks, the operation of the system is dependent upon the reliability of the local power at all the warning stations. Should the regular power fail for any reason, the system would not work unless emergency arrangements have been provided.

With both the ADCC-to-key-point special private-line circuit and the key-point-to-public bell-and-lights system, the transmission of alerts is practically instantaneous. With this combination, the only time delay between the decision at the ADCC to transmit a red alert, and the sounding of sirens in cities throughout the air division, some hundreds of miles away from the ADCC, is the time required for two simple operations: 1. The voice announcement of the alert at the ADCC and 2. The operation of the dial by the key-point operator. Assuming the controller and key-point operators are at their posts and act promptly, both these operations (not including the acknowledgment to ADCC) could easily be completed in less than 30 seconds. Allowing some time for slow answers and so forth, less than 2 minutes might be a good estimate of the time required.

If it were necessary to alert the entire country in less than 2 minutes, this could be done if all locations were provided with the private-line arrangements outlined in the foregoing. However, the costs could not be justified to provide facilities

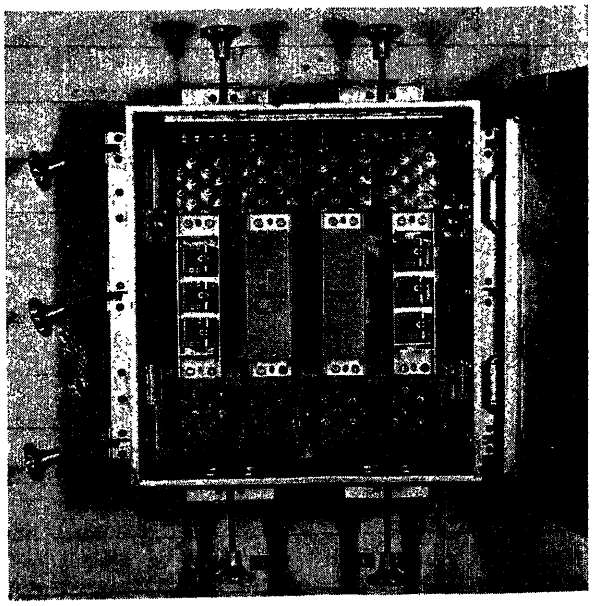

Fig. 6. Typical underground transfer relay installation. Steel door with moisture-proof seal has been opened and relay covers removed to show two banks of U-type relays

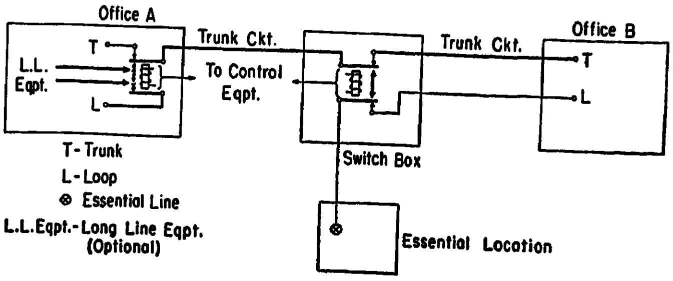

Fig. 7. **Diversity protection obtained by means of transfer relay. Emergency operation of relay by remote-control transfers service from office B to office A**

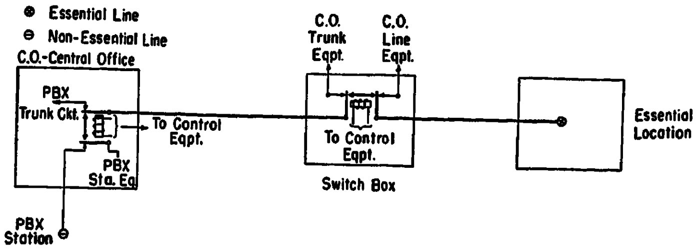

Fig. 8. **Diversity protection obtained by use of PBX. Transfer relay in underground switch box may be remotely controlled to transfer important lines from normal telephone office to PBX terminations**

so that the whole country, including every town and hamlet, can be alerted in 2 minutes. To alert those points, not in target areas, where the expense of a private-line system can not be justified, "chain" telephone calling is the most practicable method.

In planning to disseminate alerts by telephone calling, the chain must be carefully studied with due consideration to the number of telephone operators that may be on duty during periods of minimum traffic (such as midnight to morning) the number of telephone trunk circuits, and so forth. In some situations where it is important that the alert be received quickly at one or at a few points but where there are not enough such important points to justify the installation of a bell-and-lights system, it is practicable to install a special telephone which is used for no other purpose than receiving alerts. This is to avoid the possibility of an alert being delayed by a "busy" condition. The dissemination of alerts to the smaller cities and towns by means of chain calling can further be speeded if the calling is originated, not from a single point, but rather from a number of points all of which are served by a bell-and-lights network. In this way, the calling chain is built upon the fast fan-out of the bell-and-lights system.

Thus, the responsibilities for air-raid warning are shared. Civil-defense volunteers operate the observation posts and filter centers. However, the tactical control of the entire air-detection system, including observation posts and filter centers, and the manning of the radar stations and ADCC is the responsibility of the air-defense command of the United States Air Force. From this point on, civil defense is responsible for the dissemination of the alerts to key points, and from these to other cities, and so forth, and for the sounding of public sirens. The present aircraft-detection and attack-warning system which has been described is an outgrowth of World War II arrangements, and the experiences of Britain as well as of Germany and Japan. It is a tried and proven system. The principal change from World War II arrangements has been to increase the speed capabilities of the system, principally by the use of private-line circuits. This change has been necessitated by the higher speeds of the newer aircraft.

Conelrad

Although not in itself an alert warning, Conelrad deserves a bried mention here because of its association with, and relation to, alerts. Very briefly, Conelrad, as its name implies—CONtrol of ELectromagnetic RADiations—provides a means of operating standard amplitude-modulation broadcast stations so as to deny usable navagational aid to an enemy. Other types of radio transmitters which might serve as navagational aids will either go off the air or will utilize special operational procedures during the period of the "Conelrad alert."

Many of the country's stations will receive their Conelrad alert by monitoring other key stations. Because of the small number of broadcast stations which operate on a 24-hour 7-day-a-week basis, and because of propagation problems, several hundred key stations must receive their alert notification from the ADCC by wire lines, in a manner somewhat similar to the arrangements previously described. The Conelrad alert may, or may not coincide either with the civil defense yellow or red alerts.

Disaster Control

Distinguished from attack warning, communications are required following an attack, for disaster control. Communications are used first in forwarding damage and casuality reports, so that authorities can obtain an over-all appraisal of the damage situation. Secondly, these communications are required to request, dispatch, and direct forces who will combat the spread of fires, rescue trapped people, control traffic, begin the restoration of essential vital facilities, and so forth. These communications connect together the various echelons of the civil-defense organization.

Within a given city, centralized over-all direction is required to control and combat the disaster situation; otherwise, resources might be wasted on hopeless or useless ventures. This over-all direction is the function of the main control center. An alternate main control center, located a considerable distance from the main control center, serves in the event of the destruction of the main control center.

Subordinate to the main control center, depending upon the size of the city, there may be several zone control centers. A zone control center serves its particular zone, generally including about 100,000 to 200,000 people, and about 10 square miles of area.

Within each zone there are usually five to ten report centers which receive damage reports from block wardens and other field workers and forward these reports to the zone control center. Any one (or several) of these report centers may serve as a command post for a damage control team, that is, it may serve as the field headquarters for a portion of the fire department, police department, the public-works department, and other civil-defense personnel.

There are a number of other locations where civil-defense forces will operate and will require communications. These include mobilization points, rendezvous areas where outside help assembles (mutual-aid and mobile-support teams), hospitals, radio broadcasting stations, and so forth.

Main Control Center

Main control centers are selected in secure locations, generally the basement of a steel frame or reinforced-concrete building, and away from the most likely targets. For similar reasons main control centers need secure and reliable communications with other civil-defense forces. A main control center contains two princi-

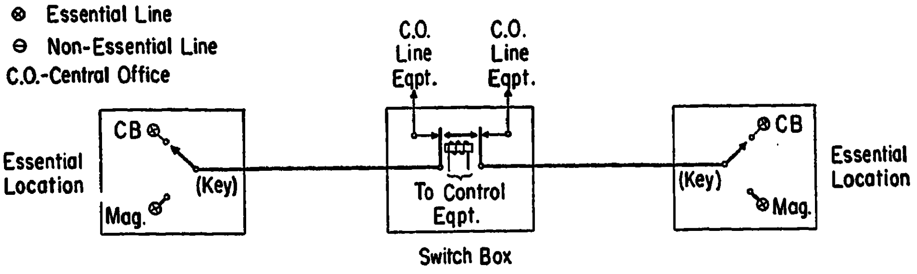

Fig. 9. Remotely controlled transfer relay in underground switch box used to connect essential locations

pal rooms which are important from a communications standpoint: an operations room and a message room.

In the operations room, which is illustrated in Fig. 3, a telephone is provided for the director of civil defense and for the head of each of the services such as police, fire, public works, transportation, and so forth. In addition to his regular local telephone, the director should also have a toll-terminal line. This will give him direct access to the long-distance switchboard. This will serve both to speed service for intercity and interstate communications and also to add an element of insurance of the continuity of communications.

A typical message room within a main control center is illustrated in Fig. 4. It is equipped with two groups of telephones. One group is used to receive incoming calls, and the other is used for the dispatching of outgoing messages. In the permanently setup control centers, where a refined arrangement is desired, the telephones may be of the operator-headset type. This frees both hands of the telephonist for writing and handling papers. With this arrangement, answering or placing a call (switchhook supervision) is accomplished by inserting the headset plug into a jack mounted on the table. To disconnect, the plug is removed. In dial-service areas, a permanently connected dial is mounted on the table. A separate bell or call indicator lamp (or both) is usually provided for each line.

The telephones in the message room are manned by volunteer telephonists who, in the case of incoming calls, record each message on a multicopy form. One copy is for each agency that may be concerned with any particular report. The telephones for incoming calls should be in a consecutive-number series, and appear in a "terminal hunting group"at the telephone office. This means that all of the phones in the incoming group will be assigned consecutive numbers. However, only one number, the number of the first line, need be used by those who call the control center. The first incoming call will then go to the first line, the next call will automatically switch to the second line if the first is busy, or to the third if both the first and second lines are busy, and so on to the end. The numbers assigned to the telephone lines serving a permanently setup control center should not be published and should be given only to those who may have a legitimate need to call the control center.

In addition to the foregoing, in the larger cities there might be provided in the message room a Teletypewriter Exchange (TWX) machine, for printed communication with state headquarters and the higher echelons of civil defense. This would be used primarily for forwarding summaries and situation reports and for requesting outside aid, material, and supplies. The larger cities might also make arrangements to have a teleprinter available for connection to a previously installed direct line to the Western Union switching center.

In order to insure the continuity of communications with the main control center, there should be telephone service from at least two central offices which are separated from each other by several miles. Under these conditions, a single bomb probably would not knock out both telephone offices and would not, therefore, sever the communications of the main control center. Any bombing that did knock out both of these telephone offices would probably also knock out the control center itself. Transfer relays (which are described later) may be used in lieu of having the control center permanently served from two or more telephone offices; these can provide essentially the same degree of reliability as full-time dual-office service.

The control center will usually be connected to the telephone offices by means of completely underground cable routes. Underground cables are little affected by an air-burst atom-bombing. These cables are already in their own "bombproof shelters." Whereas high-explosive bombs may sever any underground cables which they hit, this type of damage is of a localized nature and so, if adequate alternate routes are planned beforehand, it will not cut all communication paths with the control center. In the surburban areas, away from likely targets, the preference for underground rather than aerial cable is of less importance.

The foregoing arrangements (underground cable with multiroute and multioffice service) provide good insurance of the continuity of communications with the main control centers. These may be supplemented by a pool of the existing mobile radio services. Since this pool serves many other points besides the main control center, it will be described later in a separate section.

Zone Control Center

Whereas some cities have selected the zone control centers in municipally owned or rented space and equipped them on a full-time standby basis, this is a somewhat expensive plan. Therefore, many cities prefer simply to designate suitable loca-

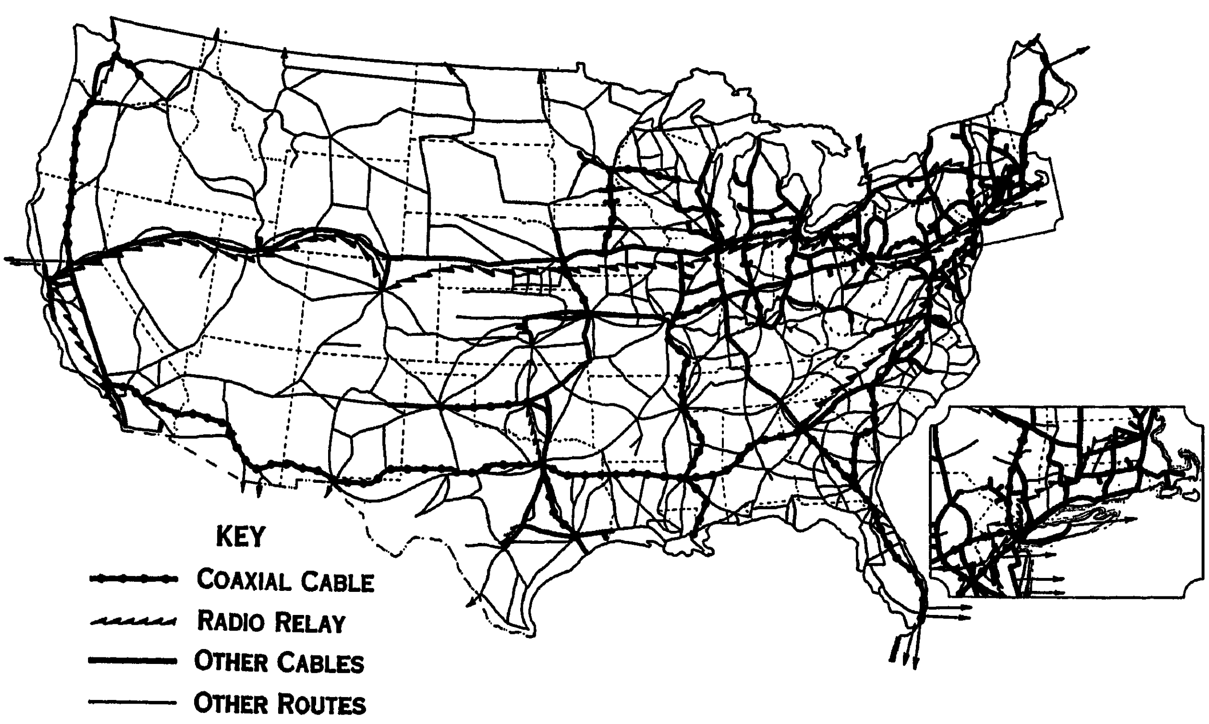

Fig. 11. Principal toll routes of the Bell System and connecting companies

tions and facilities, which have normal peace-time functions and can serve in an emergency as a zone control center. The establishments selected to serve as zone control centers are those whose normal activities may be suspended or curtailed in the event of an emergency. The selection is based on the availability of existing communications and the desirability of obtaining a secure, well-protected location. A department store basement, or a protected location in a hotel are examples of such locations.

A compromise plan would include a few fully equipped zone control centers, which are used for no other purpose and which are employed for drills and training, together with a number of other zone control centers which have been designated in locations having other normal peace-time functions.

Similar to a main control center, but smaller, the zone control center also has an operations room and a message room. In the operations room, there should be a sufficient number of telephones, usually about 10, for the zone controller and for each of the civil-defense services represented. The message-room telephones are divided into incoming and outgoing groups just as in the main control center. Generally, about six phones are required for the incoming group and from two to four telephones for the outgoing-message group. While it is desirable to have the incoming phones connected in a terminal hunting group, this is not essential; any industrial or business establishment which has the required number of telephones may serve as a zone control center.

To understand the problem of reliability of communications for a zone control center, and to decide upon the extent of communications insurance needed, let us refer to a typical city. Fig. 5 illustrates the situation in a typical American city; the number of, and location of, the telephone central-office buildings as shown are identical with an actual city of the size indicated. (In New York City there are 60 separate telephone central-office buildings which are similarly dispersed.) Assume the worst type of attack such as an atom-bomb or a hydrogen-bomb attack; anything less would simplify the problem.

Referring to Fig. 5, suppose that an atom-bomb explodes, causing the destruction represented by the circle. In most of the locations that the circle can be placed, it will cover at least one zone control center and a telephone central office.

In certain places the circle may be placed to indicate the destruction of a zone control center but not its associated Central office, and vice versa. But there will always be an adjacent zone control center which is served from a working telephone central office; this adjacent zone control center can function as an alternate for a zone control center which either has been destroyed, or has lost its telephone service.

Therefore, it is generally not necessary to resort to any special measures to insure communications to a zone control center, as is done with the main control center. There may be a few exceptions which justify the use of transfer relays as discussed in a later section. Such an exception might be a city where there are a few, but an insufficient number of locations suitable to serve as zone control centers.

Report Centers

The report center is a very small communications center which serves as an intermediate level between field operations and the zone control center. From 30 to 50 warden posts may report to a single report center. In selecting existing establishments to serve as report centers, consideration is given to easy access, safety of construction, and availability of existing communications. Ideally, there would be three or four telephones arranged in an incoming-service group, plus one or two lines for outgoing service in forwarding evaluated reports to the zone control center. While it would be desirable to have the incoming lines in sequence, any establishment having a sufficient number of telephones may be utilized.

Report centers are generally located on a grid basis, roughly one report center at each intersection of 1-mile grid lines. Within each grid, three establishments should be selected which meet as nearly as possible the telephone requirements of a report center, with first, second, and third choices being designated. As a further aid to securing an organized group, the personnel of the establishments selected are often enrolled to serve as report-center personnel.

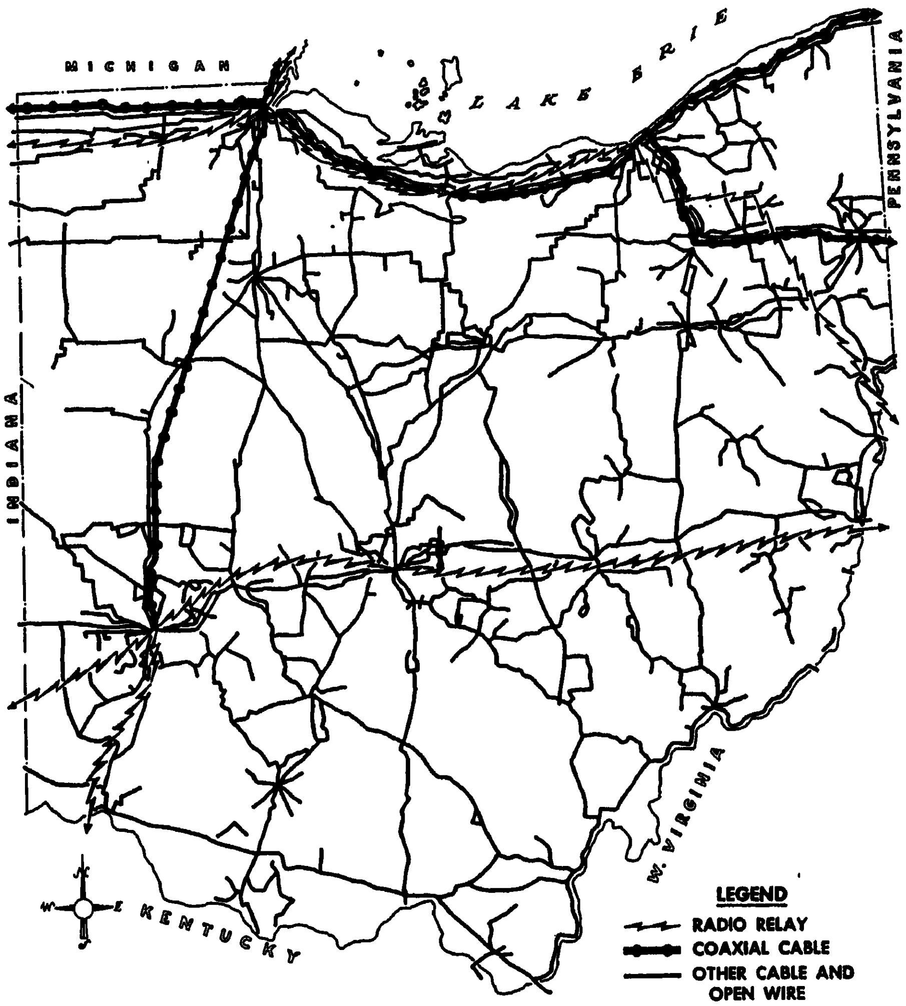

Fig. 12. Telephone toll routes in the state of Ohio

Miscellaneous Communication Points

In addition to the control and report centers, which are uniquely civil defense, there are many miscellaneous fixed locations to which civil defense will require a small number of communications channels. Such locations are the police and fire departments, most of the city departments, hospitals, each of the public utilities, transportation companies, radio broadcasting stations, assembly points, rendezvous areas, triangulation observation posts, and so forth. Generally, the existing telephone facilities to these places will provide adequate communications.

Where there are interruptions to the regular telephone service to any point, use may be made of mobile radiotelephones. This is a regular service provided by the telephone companies in 150 service areas, including nearly all of the cities classed as critical target areas by the Federal Civil Defense Administration. This service is provided on frequencies in the 152–162 megacycle range and in the 30–44 megacycle range. From a mobile radiotelephone, one may talk to any telephone in the city, or for that matter, any of the 45-million telephones in the country.

In addition to using the telephone company's mobile radiotelephone service, communications to any of these miscellaneous points may be supplemented by means of walkie-talkies or quickly run "field wire" and telephones. The hand-carried 2-way radio units are particularly useful where the points requiring communications are not fixed. They are somewhat less suitable for prolonged use between fixed points because of their battery-life limitations.

Field wire can be run within a reasonably short time interval to provide telephone service to fixed points. It may be carried by a man on foot or it may be unreeled directly from a moving vehicle. The term field wire as used here includes many types of wire which are not—strictly speaking—field wire, but which are similar and may be used for the same purposes. For example, "drop wire" which is normally used between a cable terminal box and a subscriber's residence, "bridle wire," "twist," and other types which are normally carried both in telephone company supplies and on telephone company trucks; all may be used as field wire.

Field wire may be used either for direct point-to-point circuits or to connect a fixed point with the general telephone system, thus making it possible for that point to communicate with any other telephone. One typical point-to-point application would be the establishment of a circuit between the relay pumpers used for fire fighting. When it is necessary for the fire department to pump water from some distance away to the scene of the fire, emergency pipe is quickly laid along the street and relay pumpers are used to maintain the pressure. More quickly than the pipe can be laid and the relay pumpers connected, field wire may be run paralleling the pipe from end to end and magneto field telephones connected on to the circuit at each pumper to be used for co-ordinating this tandem operation.

Pool of Existing Mobile Radio

In addition to the telephone company mobile radiotelephones, there are a large number of other existing 2-way mobile radio systems in everyday use. The police department, the fire department, and the taxicab 2-way mobile radio system are outstanding examples. In addition, there are ambulances, transit companies, the press, various industrial, and other mobile radio users. Further, there are a large number of amateurs whose help has always been valuable in emergencies.

Obviously, the fire and police radio systems will be utilized for the fire and police functions of civil defense. Rather than assign the other existing mobile ratio systems individually to specific uses (such as to assign the taxicab radio specifically to the warden service), it is generally preferable to assign to a pool all of the existing mobile radio systems which might appropriately be used by civil defense. Then in a disaster, units from this pool will be assigned to those locations where supplemental communications are needed. In this way, maximum use is made of the available mobile equipment.

Because none of the 2-way mobile radio systems (except the telephone company's mobile radiotelephone system) connect with the general telephone system, some additional arrangements must be made in order to get messages from the control centers to the various mobile units, for example, to the taxicabs. This may be accomplished by any of several means, such as the following:

1. The control center may simply telephone messages to the regular taxicab base station, at which point they will be relayed to the mobile units. This is the simplest and least expensive method.

2. By means of a remote control channel, between the control center and the regular base station, the control center may talk directly to the mobile units.

3. An alternate base station on the taxicab channel may be installed at the control center. This will permit direct conversation between the control center and the mobile units. This involves a relatively expensive alternate base station installation; sometimes the control-center location is a poor site for an antenna, which may result in poor transmission; in addition, arrangements must be made for emergency power.

4. As a variation of the foregoing alternate base station setup, prior arrangements may be made for one of the existing mobile units to serve as an alternate base station. This unit, equipped with two crystals and a channel-changeover switch, if necessary, may then be driven to the control center and used there as an alternate base station. Reasonably good transmission can generally be obtained if advance arrangements have been made for connecting the mobile unit to a previously erected antenna which is suitably located. This method avoids the installation of a separate base station and will be useful in the event that either the normal telephone service with the regular base station is interrupted or the regular base station is knocked out.

Telephone Line Load Control

Since reliance is to be placed on the telephone system for essential communications at the time of a major disaster, means are provided to prevent the general public from overloading the switching facilities (switchboards and dial-switching equipment) by an excessively large number of calls being originated at the same time. The public is, of course, asked not to make unnecessary calls during an emergency. But more than that, measures are needed to insure definitely that calls from essential lines will not encounter an "all paths busy" condition. Protection against such a circumstance is made by the provision of line load control arrangements which insure that outgoing service is available to the lines which are essentially under disaster conditions, whether or not it is available to the general subscribers. Incoming service to all lines is available at all times. Authorized central office supervisory people, watching the volume of traffic through an office, can quickly and continuously adjust the load so as to avoid excessive overloads on the telephone central office equipment.

Transfer Relays

Used with alternate routes, transfer relays can provide a high degree of insurance of the continuity of communications in the event of an enemy attack. Transfer relays may be installed in underground locations, manholes, or cable vaults, and operated from a distant control point. Fig. 6 shows a typical installation of transfer relays mounted in a watertight metal case. In the installation shown, there are 12 relays which are capable of transferring a total of 24 circuits by means of one or more remote control circuits. The remote control circuits are under continual automatic test. Following are a few examples of how transfer relays may be applied to insure the continuity of service to preselected essential locations.

Transfer relays can be installed in a cable vault or manhole, near or beneath the regular serving central office, and connected to the lines serving a civil-defense control center, the fire and police departments, and other essential locations. Then, in the event of damage to the telephone office which normally serves these lines, these relays would be operated by remote control, and would transfer the lines (possibly via existing trunk cable facilities) to an alternate central office which is located in another building a considerable distance from the normal serving central office. At the alternate telephone office, other transfer relays which are associated with the same control circuit would connect the proper cable facilities to appropriate terminations. This application of transfer relays is illustrated in Fig. 7.

It will be observed that the transfer-relay arrangement shown in Fig. 7 affords service protection by means of diversity and, in this respect, is approximately equivalent to the permanent provision of lines from the essential location both to office *A* and also to office *B*. Generally, depending on geographical relations and other factors, the transfer-relay arrangement is less costly than the full-time provision of service from two offices. Furthermore, it will be noted that the cable facilities between offices *A* and *B* are normally used by the telephone company as interoffice trunks. These trunk cable facilities would be used exclusively by the essential subscriber only, in an emergency, in the event of an interruption in service from the regular serving office.

In those cities which have only one telephone building, transfer relays may be employed to connect the lines of the essential subscribers to a suitably located private branch exchange (PBX). This PBX may be one which is normally used for other purposes but which can be utilized for emergency operations. This is illustrated in Fig. 8.

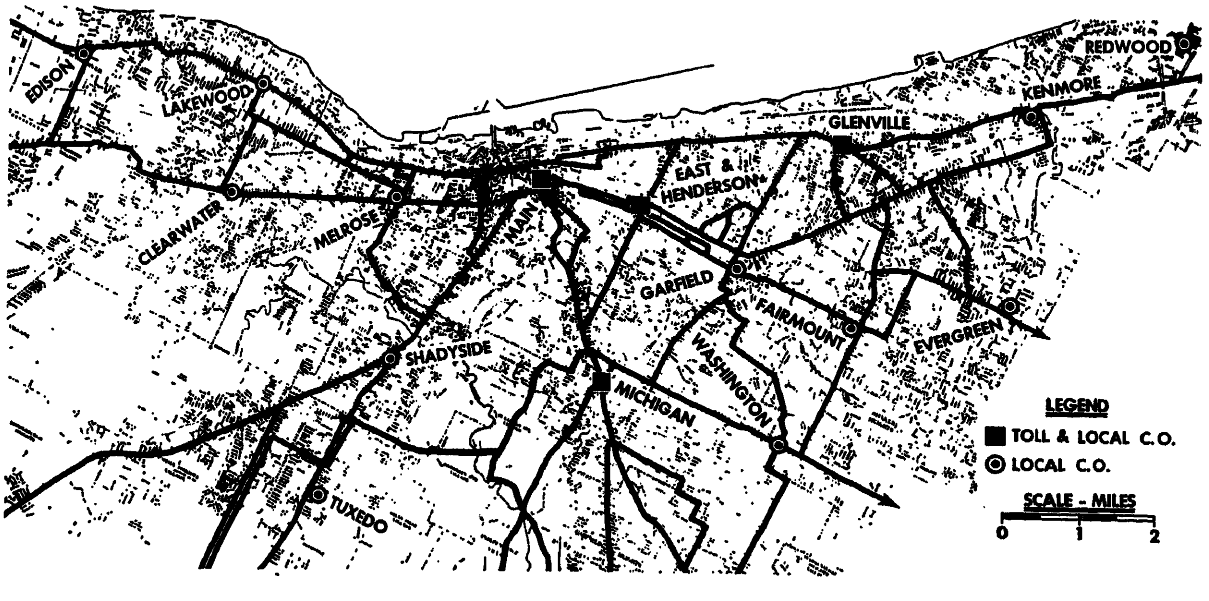

Fig. 13. Telephone central offices, toll and trunk facilities within city

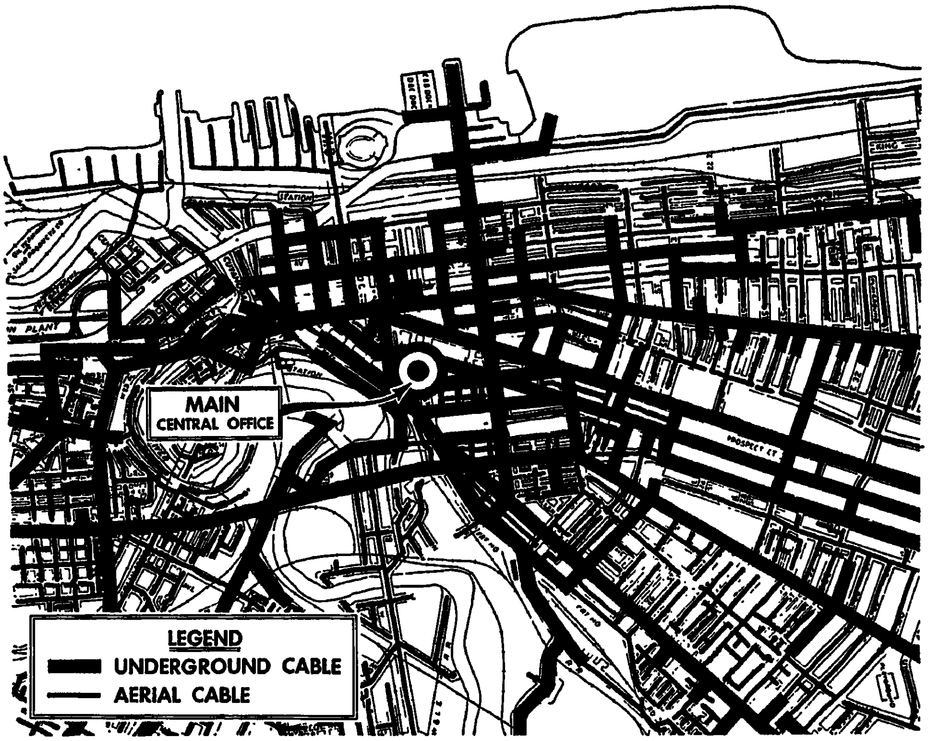

Fig. 14. Section of one central office area

If there is neither an alternate office nor a suitable PBX which can be used practicably in an emergency, then the transfer relays can be used to establish direct point to-point tie lines between the various essential locations. This is illustrated in Fig. 9. Transfer relays also may be used to facilitate the immediate restoration of service on various types of private-line circuits.

Transfer relays may also be employed to permit the immediate restoration of toll service to an alternate toll office or to emergency terminations in the event of the destruction of a toll office. This is illustrated in Fig. 10. With one of the existing installations of underground transfer relays similar to that illustrated in Fig. 10, 240 toll circuits (*K* carrier) may be transferred from one toll office to an alternate toll office, by means of remote control. Restoration plans which utilize transfer relays, in contrast to splicing operations, do not have to contend with the removal of debris, getting splicers on the job, and other time-consuming operations.

Review of Requirements

Having outlined the means of providing civil defense with the communications which it needs, let us examine whether the proposed arrangements meet the basic requirements, as set forth at the outset.

Coverage

The exact requirements for communications following an attack can not be completely foreseen. Therefore, maximum provision should be made for coverage, flexibility, and adaptability of civil-defense communications, both in respect to the points among which communications are available and also the volume of communications to be handled.

The regular telephone system inherently contains a great deal of coverage, in that some service exists in almost every building. There is complete flexibility in that any telephone or unit of the mobile telephone service can be connected to any other telephone.

For important locations, advance arrangements may be made, such as station prewiring and placing of house cables, that will permit quick expansion in the amount of telephone service. There are a large number of telephone-supply warehouses which are dispersed throughout the United States and which carry substantial stocks of various types of telephone material and equipment. These stocks, which are normally provided for growth—now at the phenomenal rate of about 2,000,000 telephones per year—can be used to establish or restore service in an emergency.

The maximum flexibility in the use of radio circuits is obtained by the use of mobile and portable types of equipment. These equipments can be moved quickly to the points where they are needed, and the specific circuits (channels) can be assigned to the most urgent use at the time. The proposed civil defense use of a pool of existing mobile-ratio units fulfills this need.

Expense

In meeting their communications requirements, civil-defense officials find themselves in competition with other needs and agencies, both for money (federal, state, county, and city appropriations) and for materials, facilities, and equipment. In engineering a communications system for civil defense, one of the most important factors is the cost of alternative arrangements needed as insurance for continuity of service. In each case, studies are necessary to take into account all of the costs involved, since the initial outlay is not the only consideration. Costs of obsolescence of equipment must be considered, since it is entirely possible that civil-defense facilities will be needed for a long time. Maintenance costs usually are an extremely important factor if special facilities are to be provided.

Because the proposed arrangements would utilize, to the maximum extent practicable, existing facilities which have normal peacetime uses and would therefore, be paid for generally by the normal user, both the over-all cost and the cost to civil defense will be kept to the minimum. The cost of the transfer-relay arrangements as outlined in the foregoing, is generally less than the cost of other arrangements or facilities which would provide comparable diversity for protecting the continuity of service.

The principal situation in which special communications facilities must be provided by civil defense is for attack warning. Due to the very nature of the function these facilities are to perform, they cannot be "mothballed." Because they must be speedy and must be ready for instantaneous use, it is generally impracticable to provide attack-warning facilities on the basis that they will be disconnected until needed. The systems outlined in the foregoing for attack warning have been designed with the objective of keeping the long-term cost at a minimum consistent with the important requirements of speed and reliability.

Reliability

To the people who will use the communications provided for civil defense, the reliability of these communications under disaster conditions is probably the most important requirement. Basically, facilities which are in normal day-today use are inherently more dependable under emergency conditions than are facilities which are provided for use only during an emergency. In keeping with this principle, the arrangements outlined in the foregoing are based on making the maximum use of all existing communications facilities, including both wire-line and radio facilities. Since communications are of paramount importance to civil defense, it is appropriate to examine carefully the factors which determine their reliability under disaster conditions.

An outstanding factor which contributes to the reliability of the regular telephone system for disaster communications is the great quantity and diversity of telephone plant. To appreciate this factor, first consider the nation-wide network; second, in effect place a magnifying glass over one portion of the nation-wide picture and see more closely the detail of the facilities within a given state; third, in effect place a higher-powered magnifying glass over an individual city within that state and study the number and locations of the individual central offices and the layout of interoffice trunks within that city; and fourth, in effect using a still more powerful magnifying glass, examine more closely the area served by an individual central office.

On a nation-wide scale, Fig. 11 shows only the principal toll routes of the telephone companies. The toll circuits connecting any two widely separated cities are normally routed, not all through the same cable and not even on the same route, but generally among several different routes. In addition to meeting the normal circuit requirements, this prevents any single incident, such as a bulldozer accidentally cutting a cable, from having any serious effect on the handling of normal day-to-day traffic. Furthermore, toll calls can be completed over alternate routes if their normal routing is cut. For example, a New York-San Francisco call which is normally completed via Chicago may be routed in an emergency via St. Louis, or via Atlanta and Dallas, or via any of several other routes. Rearrangement of the intercity circuits to meet normal daily fluctuations in demand for service, and to meet emergency conditions, is a regular day-to-day function of the telephone forces. On a nation-wide scale it is directed by traffic control bureaus located in Boston, New York, Washington, Richmond, Norfolk, Cleveland, Chicago, and San Francisco.

Not only is there diversity of routing available but also there is a diversity of the type of facilities used. There are ordinary toll cables, many employing type-*K* (12-channel) carrier systems; there are open wire lines, many employing type-*J* (12-channel) carrier systems; there are coaxial cables, all employing type-*L* (600-channel) carrier systems; and there are microwave radio-relay systems, each capable of carrying hundreds of telephone channels. Some of these cross sections are very heavy; for example, in the New York-Philadelphia cross section there are about 5,000 circuits which are divided among several different routes and different types of facilities. The Cleveland-Chicago cross section includes over 3,000 circuits, which are likewise diversified with respect to route and type of facility.

Having reviewed the nation-wide picture, let us place our magnifying glass over just one state. Fig. 12 shows the principal intercity toll routes within the state of Ohio; there are many routes shown here which could not be shown clearly on the nation-wide map. The same factors of diversity which exist on a national scale exist here on a state-wide scale. There are many other important factors, almost too numerous to mention, which have been provided to insure the continuity of communications. For example, toll cables are maintained under gas pressure (nitrogen, about 9 pounds per square inch), and are equipped with alarms at regular intervals. Any troubles which cause a break in the cable sheath will register a gas-pressure alarm in the nearest test room. By means of Wheatstone-bridge measurements on the alarm pair, the testmen can determine the approximate location of the trouble. Another example of emergency protective arrangements is the automatic line-switching circuit associated with the type-*L* carrier system; in the event of trouble on one line which causes as much as a 3-decibel change in the received level of a pilot channel, the line switching circuit will automatically transfer the service to a spare line. Similar arrangements are used on the radio-relay system to transfer service to a protective channel, in case of failure of the regular channel.

Now having seen the nation-wide and state-wide pictures, let us look at a single city within Ohio. Fig. 13 shows the locations of the telephone central offices and the interoffice trunk-cable routes within the boundaries of one city. There are 16 different central office buildings, each of these serving its own neighborhood and separated from each other so that if one of them happens to be near "ground zero" for an atom-bomb, the others are not likely to be hurt seriously. In this connection, most telephone buildings are built of heavy steel-framed or reinforced-concrete construction, to carry a floor load of 150 pounds per square foot, which means that they will generally remain standing as long or longer than most other buildings in the neighborhood.

Referring again to Fig. 13. it will be noted that four of the telephone buildings include toll-switching facilities. Thus, toll operations are dispersed. Additional toll-dispersion work is currently under way in many of the cities which are considered the most important toll-switching centers.

Let us look at one of these central office buildings. This is shown in Fig. 14, which completes our picture of the great quantity and diversity of the existing telephone system. It will be noted that cables are routed along nearly every street. The important point here is that they are nearly all underground. In a sample of cities large and small, which are rated as critical target areas, over 80 per cent of all the wires are underground. In the vital downtown areas of the larger cities, this percentage is close to 100 per cent.

Another important factor in the reliability of telephone service is that the local station equipment (the telephones themselves) do not require any local power. The power for their operation comes from the telephone central offices; these are equipped with storage batteries of sufficient capacity to carry the load for a reasonable period of time. In addition, there are standby diesel or gasoline-engine-driven generators which can charge the batteries in the event of an emergency requiring their use. For use in the smaller offices which do not justify a permanently installed standby generator, there are portable generators which can be used as required.

The telephone companies have maintained for a number of years a quantity of emergency radio facilities which can be used quickly to restore service around breaks in individual lines. These units are strategically dispersed throughout the country.

A further important factor behind the reliability of telephone service is the support organization, with standardized methods and materials, that is in being. There are nearly 700,000 trained people who are normally, in their day-to-day business, operating and maintaining the telephone facilities of the country. These people are organized into a number of individual companies, each one of which is a complete operating unit within itself. Often in past emergencies, earthquakes, floods, hurricanes, and so forth, it has been demonstrated how these trained people can be loaned from different places to a hard-hit area and how they can all work together as a team.

Security

It is important that the privacy of civil-defense communications be maintained. Possible panic-creating information must not become available to the general public. Also the enemy must be denied information that would be helpful to him. A direct private-line wire circuit provides the highest degree of privacy for communication between two points. The proposed arrangements for post-disaster communications afford the best security that could be provided without multiplying the cost manyfold.

For attack warning, security has a special significance with respect to the prevention of false alerts. It is for this reason that the special private-line arrangements which have been outlined in the foregoing need to be provided. This reason, plus speed, justify the use of the direct private-line civil air-raid warning arrangements, in lieu of relying exclusively on existing facilities for attack warning.

Simplicity

Because civil-defense communications must be used largely by volunteer workers, it is important that their operation be kept as simple as possible to avoid excessive training requirements. Most people are familiar with the use of regular telephone service in their locality. It is simple and straightforward.

With radio circuits, simplicity of operation indicates that use should be made of voice radio rather that radiotelegraph. Practically all of the existing radio systems which will be included in the "pool" are voice operated. In the civil-defense plans to operate existing radio facilities, it is preferable to utilize the personnel who operate them in normal day-to-day business. They are most familiar with the facilities and with their capabilities.

Conclusions

Civil defense can best be made effective if it is organized and operated on the principle that existing organizations and existing facilities are used wherever they exist. Wherever possible, the functions of civil defense are assigned to existing organizations whose normal peacetime operations include such functions, or are related to them. This insures the maximum efficiency and competence of both personnel and facilities.

In keeping with the foregoing principle, the police department, the fire department, the department of public works, the water supply and sanitation departments, the health department, and hospitals are all assigned the task of training themselves for their emergency role in civil defense. To them is given the task of organizing and training the auxiliaries they will need in times of disaster. Similarly, it is appropriate that public utilities, such as the power and communications companies, be brought into civil-defense planning and assigned responsibilities for enlarging or adjusting their normal functions to meet an emergency situation.

Civil defense must be accomplished by reliance on those who are doing, on an everyday basis (in local, state, and federal government, and in industry), work that is similar or comparable to that required in a civil defense emergency. The most efficient and reliable procedure is, therefore, to make maximum use of all existing communications agencies, together with their trained personnel. These are adequate, sufficient, and reliable.

No Discussion

Path Testing for Microwave-Radio Routes

R. D. CAMPBELL
MEMBER AIEE

IN PLANNING the construction of a microwave-radio relay system, it is of utmost importance that the sites for the terminal and intermediate stations be so selected that undesirable radio-propagation conditions are avoided. At the same time it is desirable, for reasons of economy to minimize the number of intermediate stations required, and to utilize the smallest towers which will give satisfactory radio transmission. In order to achieve these objectives great care must be exercised in the selection of the station sites.

In selecting sites, it is customary to determine the path profile, to establish the clearance of the center line of the path above the earth's surface. The path clearance can sometimes be determined with the aid of suitable maps and visual sighting methods, but contour maps in many cases have been found to be inaccurate; they do not indicate obstructions such as high trees and buildings, and atmospheric conditions are often not good enough for the use of visual sighting methods. Furthermore, such information needs to be supplemented with information about the nature of the surface of the earth along the path, particularly the possibilities for strong ground reflections which may adversely affect transmission. The possibility of reflections can be roughly assessed by an experienced observer after consideration of maps and inspection of the terrain. This procedure may be satisfactory in special situations where the terrain is obviously conducive to strong reflections, such as in the case on overwater paths, or in cases where the terrain is rough or covered with trees or sizable vegetation and is obviously not likely to cause strong reflections. However, in most cases it is not possible to determine by inspection whether ground reflections will prove serious, or what antenna heights should be selected for best results on a given path. For these reasons, where substantial sums are to be invested in a microwave system, such as that required for a backbone radio relay route, it is the usual practice in the Bell System to make special tests of microwave propagation on each path selected. It is the purpose of this paper to describe

the equipment and procedures used in making such tests and to outline the method of analysis of the results obtained in typical cases.

Theoretical Considerations

The tests usually made to check path-propagation conditions consist in transmitting microwave energy between antennas at the ends of the path, elevated to various heights up to 200 feet above the earth. The purpose of these tests can best be understood by considering an idealized situation such as that indicated in Fig. 1, where *ARB* represents, in greatly exaggerated form, the surface of the earth along the desired path. For this case the earth is assumed to be perfectly smooth and to have a reflection coefficient approaching unity. With the antennas at *A* and *B* located at ground level, the direct path is obstructed by the earth and the radio energy is attenuated below the value calculated for free-space transmission over the same length path.

As the antennas are raised, the attenuation caused by the earth decreases until the signal strength reaches a value equal to that corresponding to transmission in free space. Theory and tests indicate that the free-space value is reached when the antenna elevations are such that the minimum clearance of the direct path above the earth is about 0.6 of the first Fresnel zone radius, as represented by line *CD* on Fig. 1. For antenna elevations below the line-of-sight path, only the small percentage of the energy which is diffracted beyond the horizon will reach the receiver. For all antenna elevations above the path barely grazing the earth's surface, there will be a reflected ray reaching the receiver in addition to the direct ray, and under the assumption of an earth with unity reflection coefficient, the reflected ray will have a strength equal to the direct ray.

With the antennas elevated above *CD* by an amount such that the length of the path traveled by the reflected ray *ERF* is between one-sixth and five-sixth wave length longer than the direct ray, the reflected wave will tend to reinforce the direct wave, and signal strengths above calculated free space values will be observed. The maximum received signal is 6 decibels above free space, and occurs at elevations such that the clearance of the direct path over the earth is equal to the radius of the first Fresnel zone. With this clearance, the path of the reflected ray is one-half wave length longer than the path of the direct ray, and the two waves add since there is a 180-degree phase shift on reflection. As the antennas are raised still higher the reflection path length will increase so that the reflected wave will arrive in such phase as to reduce the signal received over the direct path. When the reflected path is one wave length longer than the direct path, the two signals will just cancel each other. This condition occurs when the clearance of the direct path above the earth equals the radius of the second Fresnel zone. As the antennas are raised still further the received signal strength again increases, passing through another maximum 6 decibels above free space (clearance equal to radius of third Fresnel zone) and falls again to zero (clearance equal to radius of fourth Fresnel zone). This waxing and waning of the signal strength is repeated over and over as the antennas are raised, the maximum signals corresponding to clearances above earth equal to the radii of the odd numbered Fresnel zones, and the minimum signals corresponding to clearances equal to the radii of the even numbered Fresnel zones.

The dashed lines on Fig. 2 illustrate

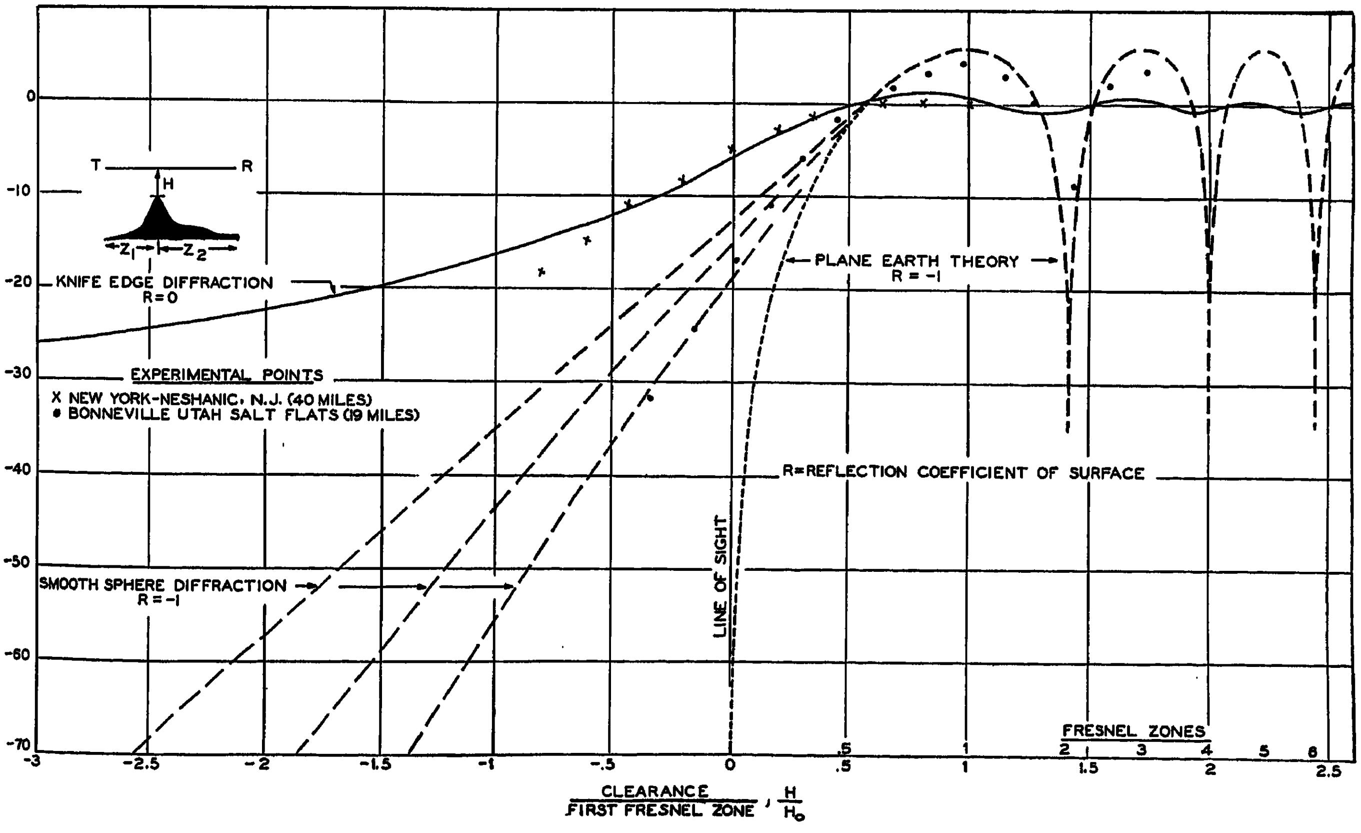

Fig. 2. Effect of clearance on radio transmission

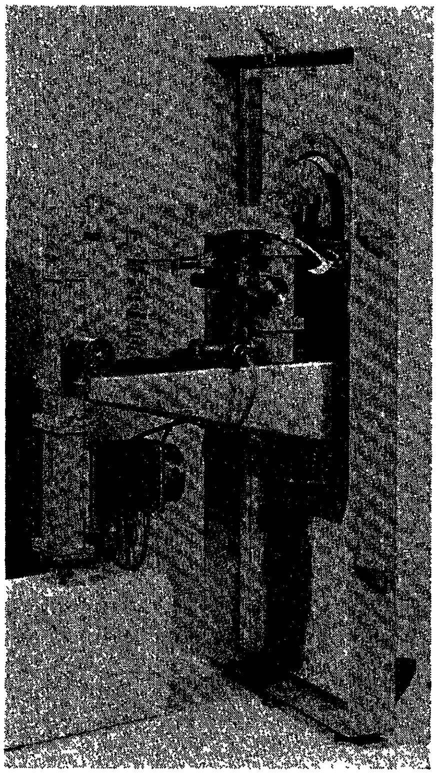

Fig. 3. Microwave transmitter for path testing

these theoretical considerations and show the calculated deviation from free-space transmission of signals received over smooth or plane earth, as a function of the path clearance. Calculations based on a path assuming a reflection coefficient of zero and a knife-edge obstruction or discontinuity on the earth's surface, such as that illustrated by the insert on Fig. 2, show that for this case the received signal remains within a decibel or two of that for free-space transmission, for clearances over the obstruction greater than about 0.3 of a Fresnel zone, see solid curve on Fig. 2.

As indicated by the points plotted on Fig. 2, actual paths having characteristics approaching the smooth-earth calculations and the calculations for knife-edge obstruction have been encountered. In general, however, actual paths can be expected to have characteristics lying somewhere between the theoretical cases assumed.

Another factor which complicates the problem of selecting suitable antenna locations is the fact that propagation conditions are affected by the dielectric constant of the atmosphere which, in turn, is a function of atmospheric pressure, temperature, and humidity. The radio energy travels along a straight line between the transmitter and receiver when the dielectric constant is the same at all elevations. When the dielectric constant increases with height, the radio waves are refracted upward and the path clearance of the energy that reaches the receiving antenna is less than the clearance for straight line transmission. Conversely, when the dielectric constant decreases with height, the radio waves are refracted downward, and the path clearance of the energy that reaches the receiving antenna is greater than that for straight-line transmission. Both conditions are encountered in practice.

For purposes of analysis it is often assumed that the radio energy travels in a straight line but that the earth radius changes to give increased or decreased clearance as conditions vary. This gives rise to the concept of "earth flattening" or "earth bulging." The degree of flattening or bulging is frequently expressed in terms of the ratio between the effective earth radius and the actual earth radius as, for instance, an earth of 4/3 or 2/3 actual radius.

It has not been possible to determine accurately what range of effective earth radii may be encountered in a given area, but estimates based on the rather meager information available indicate that the changes follow the laws of probability, varying around a mean value of about 4/3 radius with extreme conditions represented by "flat earth" (infinite radius) on the one hand, and 2/3 earth radius on the other hand, being reached only a few per cent of the time during the worst months. Accordingly it is customary to use 4/3 earth radius as the normal condition and to investigate clearances and ground reflections under the extreme conditions of flat earth and 2/3 earth.

Since the preceding changes in the transmitting medium have the effect of causing the effective clearance on any path to increase and decrease with time, its effect on transmission over the theoretical path assumed in Fig. 1 is to cause the characteristic curves of Fig. 2 to shift to the right or left along the abscissa as transmitting conditions change. Care must therefore be taken to pick antenna heights so as to avoid, in so far as possible, operation in the nulls caused by cancellation of the direct by the reflected signals, as the transmission characteristic shifts. In the majority of cases, reflections occur from several surfaces and the aim is to choose such antenna heights that the nulls from the various surfaces will not coincide as conditions change. Where strong ground reflections cannot be avoided, as sometimes happens on paths over water or over salt flats, it is considered good practice to select antenna elevations which fall, if possible on a broad hump of the characteristic between nulls. Elevations providing a minimum clearance of about 0.25 first Fresnel zone radius for the 2/3 earth radius condition to 1.7 for the flat-earth condition are considered about optimum for such paths.

It will be apparent from the foregoing discussion that path tests should, if possible, be made under normal atmospheric conditions, or transmitting conditions which are likely to prevail most of the time. Such conditions generally exist during the daylight hours when the atmosphere is most likely to be stable. In any event, it is undesirable to make tests during periods when strong fading is observed, as this in itself would be an indication of varying propagation conditions. The prevailing conditions are

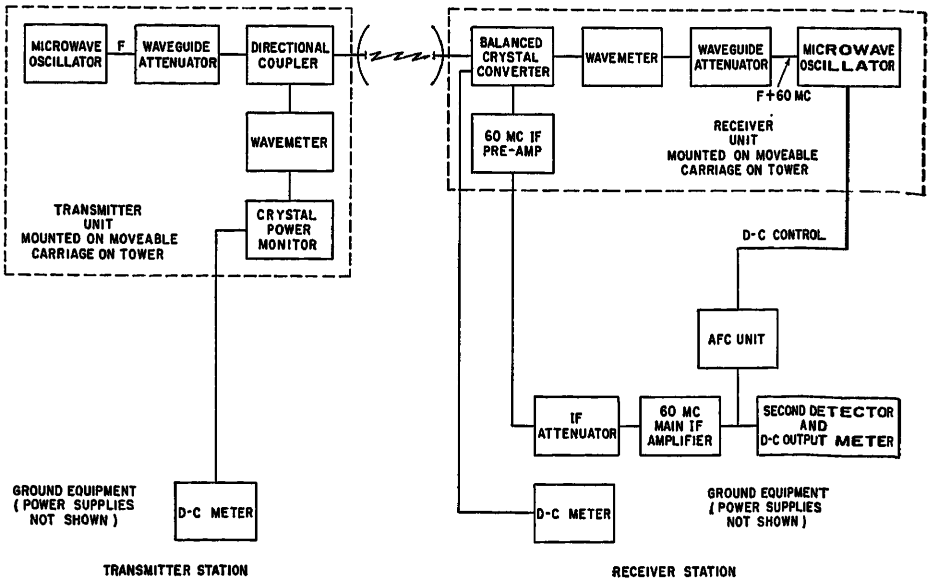

Fig. 4. Block diagram of equipment for path testing

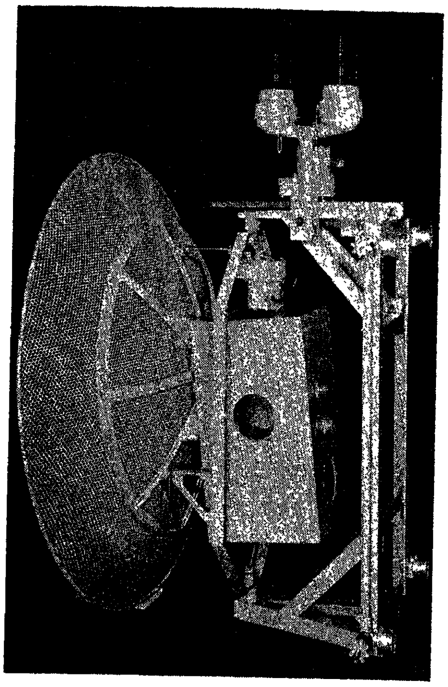

Fig. 5. Antenna carriage assembly

checked by observations on one or more obstacles in the path whose locations are definitely known.

Equipment Arrangements

The development and use by the Bell System of the Western Electric type *TD-2* radio equipment operating in the range 3,700–4,200 megacycles for broad-band telephone and intercity network television service in the United States has naturally led to the use of the frequencies in the same band for the path testing required.

Special microwave equipment has been designed for path testing. This equipment includes a transmitter, Fig. 3, containing a microwave reflex oscillator, type *406A*, which generates about 200 milliwatts of unmodulated radio-frequency energy. The equipment operates from a 60-cycle 120-volt a-c power supply. Arrangements are provided for adjusting the frequency of the transmitter to any frequency in the range 3,850 to 4,200 megacycles, but the frequency 3,950 megacycles is generally used, except where this might result in interference to existing systems. The output of the transmitter is fed to the antenna through a short wave guide system which includes an adjustable attenuator and a directional coupler. The directional coupler supplies a small percentage of the transmitter power to an absorption-type wavemeter for frequency measurement, and a crystal-detector unit for microwave output-power measurement. A block schematic drawing of the transmitter is shown in Fig. 4. The transmitter is arranged for mounting directly behind a 57-inch parabolic antenna, and the entire assembly is carried on a special framework, shown in Fig. 5. The antenna-transmitter assembly can be oriented either in azimuth or elevation by means of remotely controlled motors. The mounting frame is arranged with rollers designed to roll along the side legs of a portable aluminum tower, to facilitate raising and lowering the antenna-carriage assembly as required. The power-supply circuit to operate the transmitter, the connection from the output of the crystal monitor, a lead for adjusting the voltage on the klystron repeller to provide frequency control, and the circuits for controlling the orientation of the antenna assembly are extended in a cable to a power and control cabinet at ground level.

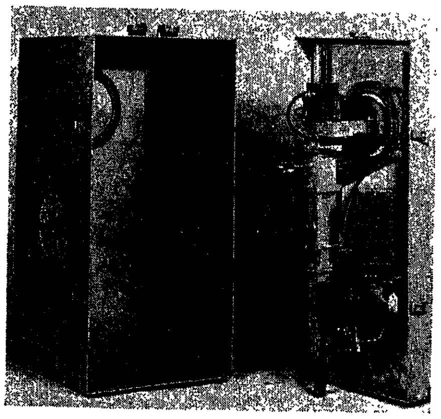

Fig. 6. Microwave receiver for path testing

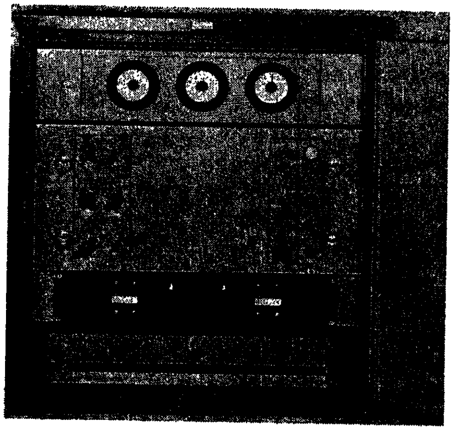

Fig. 7. Receiver control cabinet

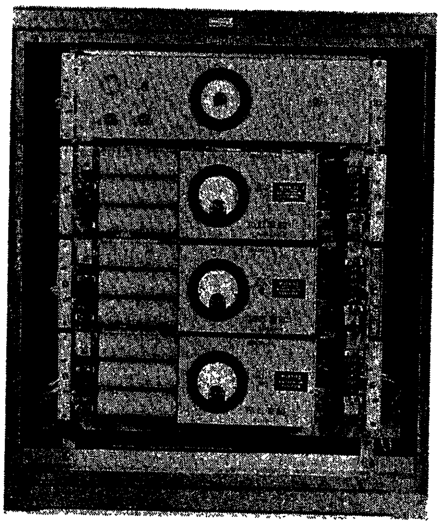

Fig. 8. Receiver power cabinet

The receiver assembly of the microwave path-testing equipment consists of three units: a receiver unit, a receiver-power cabinet, and a receiver-control cabinet. The receiver unit is mounted directly behind a 57-inch parabolic antenna, the assembly being fastened to at carriage identical with the transmitter carriage in order to facilitate elevation to the desired height on the portable aluminum tower. The external appearance of the receiver unit is identical to the transmitter unit shown in Fig. 5. A view of the receiver with the cover removed is shown in Fig. 6. This unit includes a balanced crystal converter, in which the received microwave energy is combined with the output of a reflex oscillator, type *397A*, and associated variable attenuator, to produce a 60-megacycle difference frequency. This 60-megacycle frequency is amplified by a 3-stage preamplifier, the output of which is connected to the receiver-control cabinet (usually at ground level) through a 230-foot coaxial cable. At the receiver-control cabinet, the signal passes through a variable attenuator and the main amplifier, the output of which is rectified by a silicon detector, and connected to the signal-level meter which is calibrated in decibels above and below a zero reference. A high-impedance amplifier-limiter associated with a standard discriminator circuit is also bridged on the output of the amplifier to produce a control voltage, which is fed to the repeller of the klystron oscillator in the receiver unit to control its frequency so as to maintain the intermediate frequency constant at 60 megacycles. Fig. 7 shows the receiver-control cabinet. The receiver power cabinet which is shown in Fig. 8 contains regulated tube rectifiers for the three voltages required to operate the receiver assembly. The entire assembly is designed for operation from a 120-volt 60-cycle power supply. A block diagram of the receiving station is shown in Fig. 4.

As previously indicated, the transmitting and receiving antennas with their

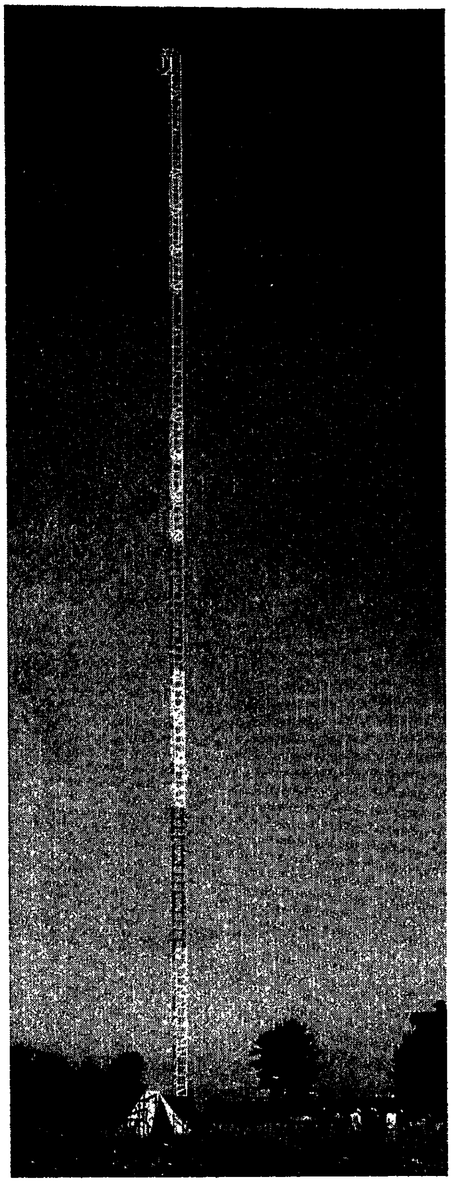

Fig. 9. 200-foot test tower

associated equipment are arranged for mounting on portable aluminum towers. These towers are fabricated of round aluminum-alloy members built up in sections 8 feet long and 22 inches square. These sections are fitted together with aligning pins, which make it possible to stack them one above the other, a maximum of 25 sections comprising a tower 200 feet high. A special erecting frame is provided which makes it possible to assemble the entire tower at ground level, successive sections being added at the bottom after raising the assembled portion by means of the erecting frame. Guys and winches are used to hold the tower vertical. Fig. 9 shows a 200-foot tower in place and Fig. 10 shows a receiver-antenna unit being hoisted up the tower.

Calibration of the equipment is carried out with the aid of measuring equipment, used first at the transmitting end and then at the receiving end of the test path. At the transmitter, the antenna-feed horn is disconnected and the energy at the output end of the transmitter wave guide is measured on a portable relative-power and frequency meter calibrated in decibels, referred to 1 milliwatt. The reading of the transmitter output meter is also recorded during this measurement, and the transmitter frequency is held constant throughout the subsequent path tests by means of this meter and adjustments of the repeller voltage. Any subsequent changes in output of the transmitter when it is properly tuned are noted and taken into account in the test data. The portable power and frequency meter is then used to check the receiver sensitivity, by measurement of the power supplied from a local signal generator adjusted to the test frequency and introduced through a calibrated attenuator into the antenna end of the receiver wave guide. The power is measured with the intermediate-frequency attenuator in the receiver adjusted to give reference reading on the signal-level meter. The path loss when receiving from the distant transmitter can then be determined from the calibration measurements and the intermediate-frequency attenuator setting at the receiver required for reference reading on the signal-level meter, proper allowance being made for the antenna gains, losses introduced by cable connections, and directional couplers in the test equipment.

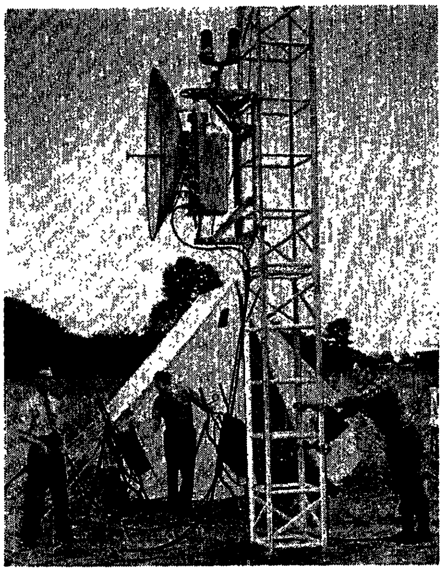

Fig. 10. Antenna-receiver assembly being hoisted up tower

The receiving and transmitting equipments for path testing each weigh approximately 2 tons. The majority of this weight is contributed by the tower, erecting frame, anchors, guys, and winches. The equipment for either station occupies about 1,000 cubic feet, and two medium-sized trucks and trailers are used to transport it. In addition, since the equipment must be operated at remote locations, portable emergency engine-driven generators must be used for power supply. Communication between the transmitting and receiving stations is usually obtained by the use of very-high-frequency portable radio sets.

Tests on Actual Paths

Two sections of the second New York-Philadelphia-Washington *TD-2* radio relay route have been selected for the purpose of describing in detail the results of path-testing measurements. Fig. 11 is a map showing the location of the two sections under consideration, namely, the section from New York (American Telephone and Telegraph Company Long Lines Building, 32 Avenue of the Americas) to a point near Red Bank, N. J., referred to as the Atlantic repeater station, and the section from Atlantic to New Egypt, N. J., about 13 miles east of Bordentown, N. J.

PATH FROM ATLANTIC TO NEW EGYPT

The Atlantic-New Egypt path, which is 23.6 miles long, was selected as typical of farming country with some hills: a type of terrain which is frequently encountered in the east in establishing intercity systems. A profile of the surface of the earth based on a 4/3 earth radius for this path is shown in Fig. 12. The ordinates show feet above mean sea level at New Egypt and Atlantic, and the abscissas, miles from New Egypt. Three series of test measurements were made over this path, transmitting from New Egypt on 4,130 megacycles, and receiving at Atlantic as described in Table I.

As indicated previously, test data were

Table I. Tests from Atlantic to New Egypt

Test	Description of Test
A.....	Measurements of path loss with the antennas at both ends elevated simultaneously in steps of 5 feet above ground, from 100 feet to 195 feet
B.....	Measurements of path loss with the New Egypt antenna fixed at 195 feet and the antenna at Atlantic elevated in steps of 5 feet above ground, from 75 to 195 feet
C.....	Measurements of path loss with the Atlantic antenna fixed at 195 feet and the antenna at New Egypt elevated in steps of 5 feet above ground, from 40 to 195 feet

obtained for maximum elevations using 200-foot towers. This procedure is followed in practically all such tests, except in the case of tests from building roofs or mountain tops where the area is too small to permit proper guying of the full tower. Data at the top of the towers frequently reveal obstructions near the center of the path which are not important when conditions are normal but which may become major obstructions under earth-bulging conditions. The results of the tests on the Atlantic-New Egypt path are shown on Fig. 13.

The limited height of the test towers (200 feet) did not permit obtaining data for clearances on this path greater than about the first Fresnel-zone radius. However, the fact that the maximum-signal strength observed was only about 1 decibel above free space indicates the absence of strong ground reflections on the path, under normal conditions, and subsequent studies did not reveal any likelihood of serious reflections under earth-bulging conditions. The general slope of curves *B* and *C* in the range just below free-space loss is of interest. The fact that the path loss decreases more rapidly with equal changes of antenna heights for curve *B* than for curve *C* is an indication that the controlling path obstruction for antenna elevations greater than 110 feet or so is nearer Atlantic than New Egypt (probably due to trees on hills *F* or *G*, Fig. 12).

From test *A*, Fig. 13 it is determined that the transmission loss is the same as the free-space loss, when the antennas at both ends are elevated 182 feet above ground. A straight line *A* has been drawn on Fig. 12 to show the center line of the transmission path with both ends at this elevation. As indicated in the discussion under the section on theoretical considerations, this indicates that the minimum-path clearance with the antennas at this elevation is approximately 0.6 Fresnel zone.

From test *B*, Fig. 13, it is seen that the crossover with free-space transmission occurs with the receiver at Atlantic elevated 182 feet and the transmitter at New Egypt elevated 195 feet. A line *B* interconnecting these points has also been drawn on Fig. 12.

Finally, from test *C*, Fig. 13 it is seen that the crossover with free-space transmission occurs with the transmitter at New Egypt at 145 feet, and the receiver at Atlantic at 195 feet. A straight line *C* interconnecting these points has also been plotted on Fig. 12.

By inspection of Fig. 12, it appears that the minimum clearance for path *C* occurs above point *D*. By plotting the 0.6 Fresnel-zone line corresponding to path *C*, it is found that its clearance over *D* is 33 feet and over *E* is 45 feet, as represented by the dotted arrows. Also a portion of the 0.6 Fresnel-zone line corresponding to path *A* has been plotted, and this line clears the earth at points *F* and *G* by about 45 feet (dotted arrows). Now if trees on hill *G* are the controlling obstruction, the transmission path would just graze the tree tops, with the New Egypt antenna at 195 feet and the Atlantic antenna at 118 feet above ground (see line *H* on Fig. 12). From curve *B* on Fig. 13, it is determined that the received field with the antenna 118 feet above ground at Atlantic is only 8 decibels below free space, and this appears unusually low. However, if trees on hill *F* are controlling, the grazing path would occur with the antenna at Atlantic 106 feet above ground (see line *J* on Fig. 12). From curve *B* on Fig. 13, the received field with the Atlantic antenna at 106 feet is found to be 10 decibels below free space, which appears reasonable. The controlling obstruction therefore appears to be trees about 45 feet tall on hill *F*. Similar analysis of the data with respect to hills *D* and *E* indicate that there are probably no trees or other obstacles on these hills.

In order to determine the antenna heights required, it is necessary to take into account the reduced clearances which may be experienced under extreme atmospheric conditions represented by an effective 2/3 earth radius. For this purpose a 2/3 smooth-earth contour has been plotted on Fig. 12. The separation between the contours measured along the ordinate at any point indicates the amount by which the clearance of the transmission path will be reduced when the conditions change from an effective earth radius of 4/3 to 2/3. Under the 2/3-earth condition, therefore, the tree tops at point *F* and the hill top at *D* would be pushed up from the arrow heads over these points to the points marked ×. If tower heights were selected so that the center line of the transmission path just cleared the highest of these points, the path would be just grazing under conditions of an effective earth radius of 2/3. Since the path loss at grazing clearance is seldom less than 10 or 12 decibels below free-space transmission, additional clearance is usually added to reduce this loss to about 4 decibels, for an effective earth radius of 2/3. In this example an additional clearance of 1/3 first Fresnel-zone radius has been added as indicated by the

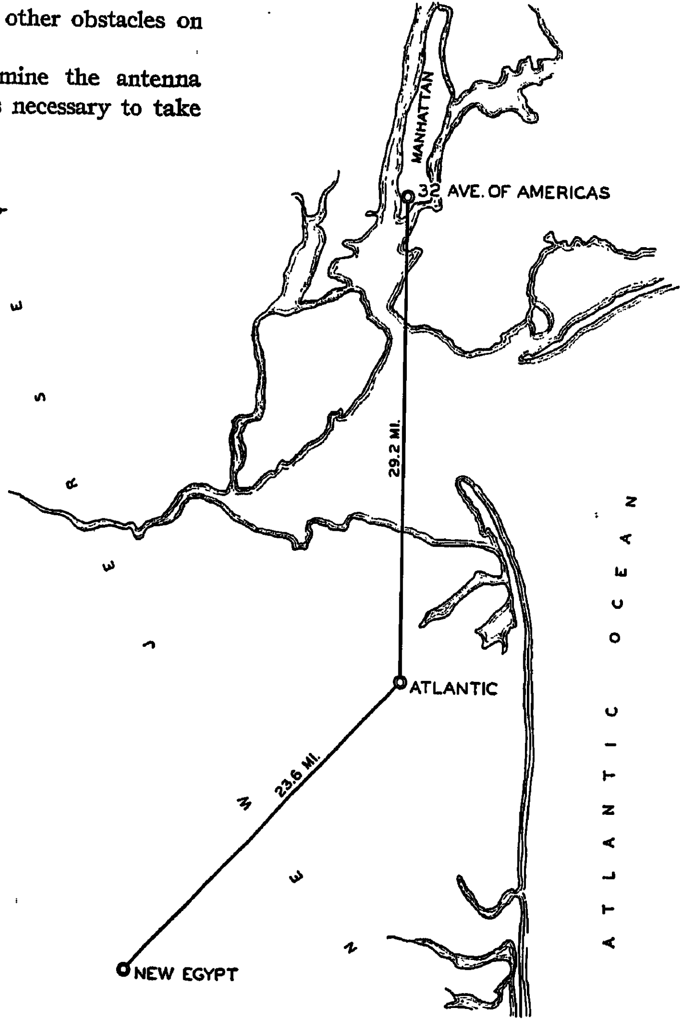

Fig. 11. Map showing testpaths

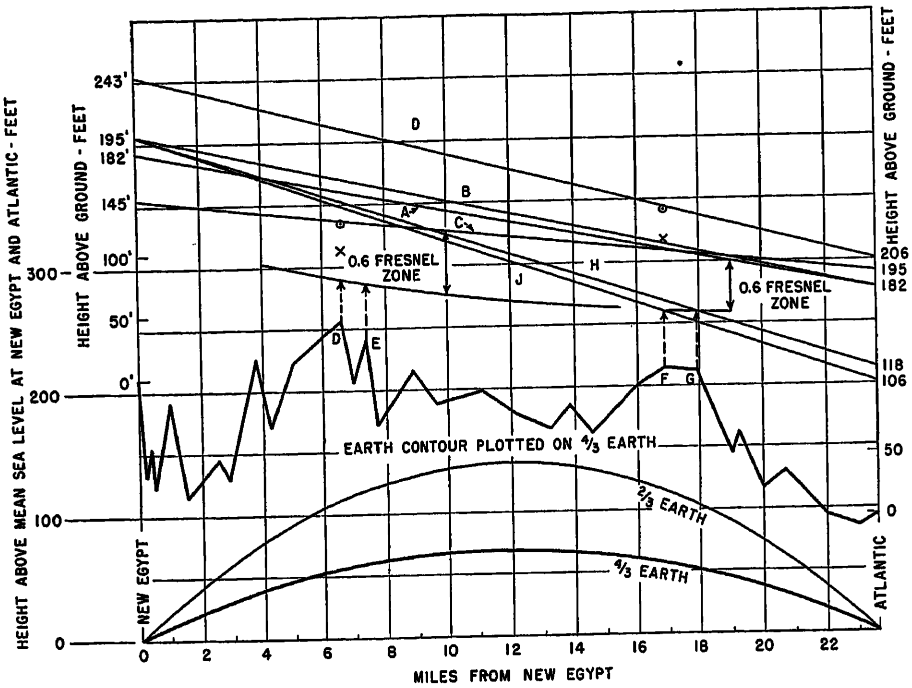

Fig. 12. Analysis of tests on New Egypt-Atlantic path, length 23.6 miles

Table II. Tests from New York to Atlantic

Test	Description of Test
B-8	Measurement of path loss with the transmitting antenna at New York fixed at 60 feet above the tower base and the receiver at Atlantic elevated in steps of 5 feet above ground
B-9	Measurement of path loss with the transmitting antenna at New York fixed at 15 feet above the tower base (on 28th floor of building) and the receiver at Atlantic elevated in steps of 5 feet above ground
C-3	Measurement of path loss with the receiving antenna at Atlantic fixed at 195 feet and the transmitting antenna at New York elevated in steps of 5 feet, from 10 to 60 feet above the roof
C-4	Measurement of path loss with the receiving antenna at Atlantic fixed at 120 feet and the transmitting antenna at New York elevated in steps of 5 feet from 10 to 60 feet above the roof

circles above the × points. A straight line passing through these circles would indicate tower heights of about 120 feet at New Egypt and 250 feet at Atlantic. However, tests of the adjacent section of route south of New Egypt indicated a requirement for an antenna elevation of 243 feet at New Egypt, and in order to keep the tower at Atlantic as low as practicable, it was decided to locate all the New Egypt antennas at the 243-foot level ($237\frac{1}{2}$-foot tower). By drawing line *D* from this point to just clear the uppermost circle in the path (over point *F*), the elevation required for the antenna at Atlantic is found to be 206 feet (200-foot tower).

PATH FROM NEW YORK TO ATLANTIC

The path from New York to Atlantic was selected for consideration here because of the overwater transmission involved. This path is 29.2 miles long, located as shown on Fig. 11. Fig. 14 is a profile of the earth's surface on the southern portion of this path, plotted in feet above mean sea level, assuming a 4/3 earth radius. The profile of the buildings on Manhattan was not prepared as tests and visual sighting observations indicate that they are probably not controlling factors on this path. Incidentally, this path was selected after considerable study and testing involving various antenna locations on the Long Lines Building in New York, as well as various locations in New Jersey.

For safety reasons it was necessary to limit the height of the test tower on the Long Lines Building to only 64 feet, and the test involving raising antennas simultaneously at both ends of the path was omitted, since no significant data could be obtained from such tests with the limited antenna height at New York. Test data were obtained on this path as shown in Table II.

The results of these tests are shown on Fig. 15. Tests *B-8* and *B-9* show the presence of some minor fluctuations of the received signal as the receiving antenna was elevated beyond about 80 feet, with a marked dip due to reflections at antenna elevations between 150 and 190 feet. The curves *B-8* and *B-9* on Fig. 15 cross the line representing free-space transmission at receiver elevations of 81 and 91 feet respectively. Lines representing the center line of the transmission paths at the free-space crossover points for tests *B-8* and *B-9* have been drawn on Fig. 14.

Lines *B-8* and *B-9* of Fig. 14 cross at about 4.8 miles north of Atlantic, indicating that the controlling obstruction is probably located on hill *D*. Six-tenths of a Fresnel zone for this location is 42 feet at the test frequency of 4,130 megacycles, and by plotting this on Fig. 14 it is determined that the obstruction extends about 30 feet above the top of hill *D*. Visual inspection indicates that trees located on this hill constituted the controlling ob-

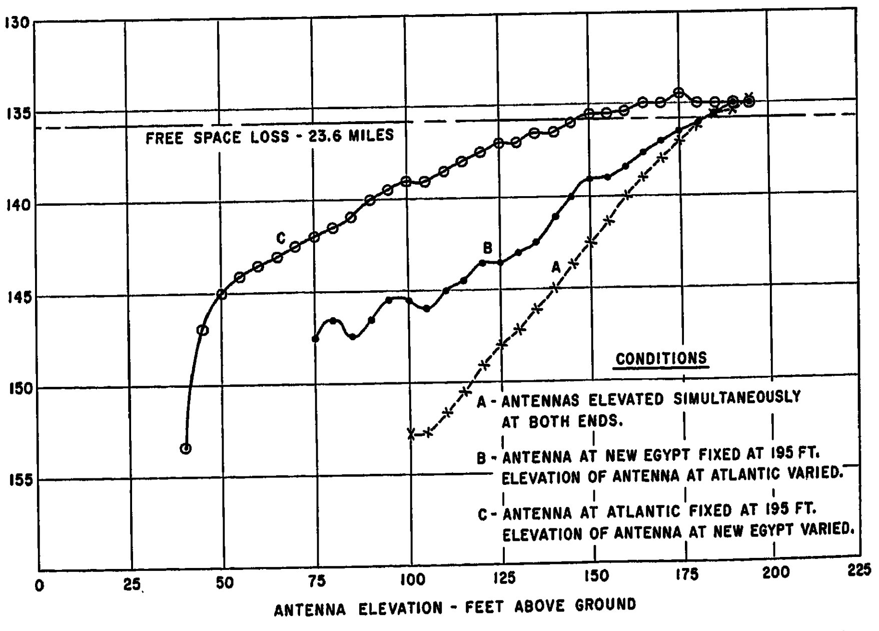

Fig. 13. Test results for Atlantic-New Egypt path, length 23.6 miles. Transmitter at New Egypt, receiver at Atlantic

struction in the path at the time of the tests. The hills marked *E* and *F* are also of interest, and the dotted arrows indicate the approximate height of trees which were found by inspection to be growing on these hills. Under earth-bulging conditions corresponding to an effective earth radius of 2/3, the tree tops on hills *D*, *E*, and *F* would reach the points designated × with respect to the ends of this path, and the circles are plotted to indicate elevations 1/3 Fresnel zone above the trees under this condition. Likewise the elevation of the top of the trees on these hills under flat-earth conditions are shown by the black dots below *D*, *E*, and *F* respectively.

As it was desired to avoid construction of a tower on the Long Lines Building, the elevation of the antenna on this end of this path was fixed at 459.5 feet which is 18.5 feet above the 28th-floor roof. Drawing a line from this point just above the circles over hills *D*, *E*, and *F* gives the minimum height required for the antenna at Atlantic as 145 feet above ground.

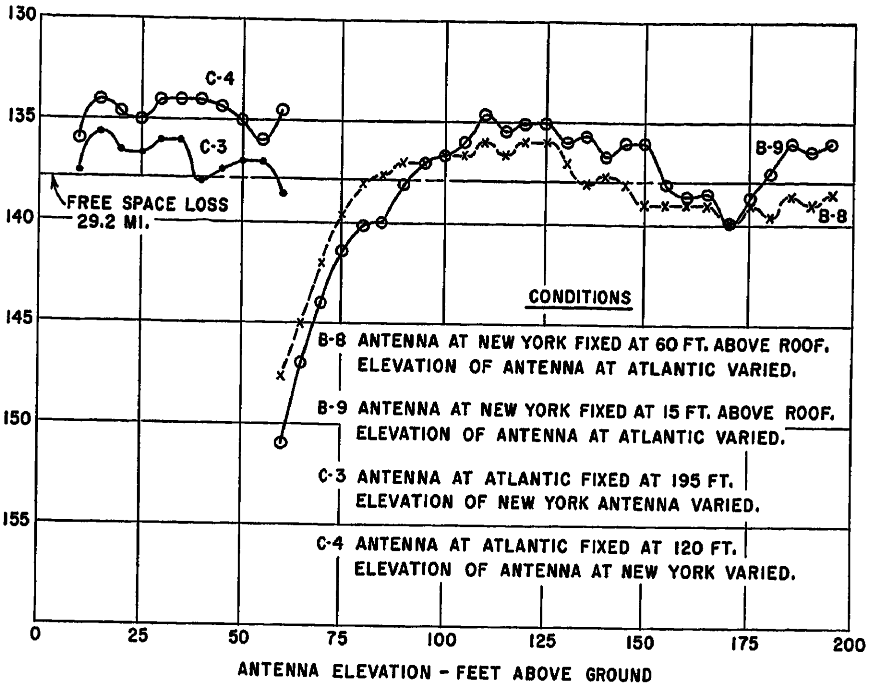

Fig. 15. Test results for New York-Atlantic path; length 29.2 miles. Transmitter at 32 Avenue of the Americas, New York City; receiver at Atlantic

While the antenna pointing south from Atlantic was to be located 206 feet above ground, this elevation was obviously not suitable for the antenna pointing toward New York because serious reflections from the surface of Lower Bay would be experienced. In fact, reference to Fig. 15 indicates the presence of some reflections even at the 170-feet elevation. Hence it was decided to put the antennas pointing toward New York on a platform on the Atlantic tower at the 150-foot level, which makes the center line of the antenna 156 feet above ground. An antenna location at a somewhat lower elevation would be preferable, were it not for the obstructions on hills *D*, *E*, and *F* of Fig. 14. However, the tests plotted on Fig. 15 indicate that the transmission loss over the path will be about equal to free space under normal conditions (4/3 earth radius), using these antenna heights. With greater earth bulging, the water reflection path will be shielded even more, due to the trees on hills *D*, *E*, and *F*.

With a flat earth, the distance in miles from the Atlantic repeater to the reflection point is given by the following equation

$$d=\frac{h_1}{h_1+h_2}D$$

where

h_1 = height of Atlantic antenna above sea level

h_2 = height of New York antenna above sea level

D = length of path in miles

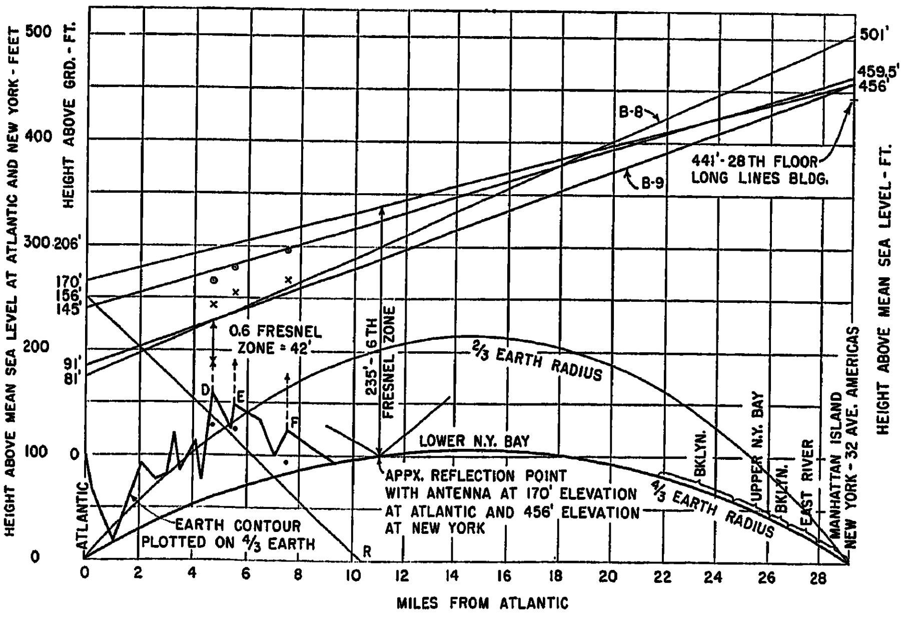

Fig. 14. Analysis of tests on Atlantic-New York path; length 29.2 miles

From this formula, the reflection point is found to be 10.3 miles from Atlantic. A line from the antenna location to this reflection point (*R* on Fig. 14) passes below the black dots indicating the tree tops on hills *E* and *F* under flat-earth conditions. Hence it appears that water reflection will be blocked by the trees under this condition also.

Consider again the dip corresponding to a receiver height of 170 feet in the path loss curve *B-9* of Fig. 15. The center line of this path has been plotted on Fig. 14 between the 170-foot elevation at Atlantic and the 456-foot elevation at New York. Now, by inspection it appears that the water reflection for this path under 4/3 earth radius conditions might take place at a point about 11 miles north of Atlantic. At this point, the center line of the direct path is measured on Fig. 15 as 235 feet above the 4/3 earth surface. The sixth Fresnel-zone radius for a 29.2-mile path is calculated as 230 feet, at 11 miles from one end of the path. This is considered to be a fairly good check on the measured clearance of 235 feet at 11 miles, and hence it is believed that the 6th Fresnel zone is responsible for the dip in the path loss curve. This method is also used on overland paths when there are enough dips or wiggles in the curves to determine where the reflecting surfaces are located. It will tell the height of the ground and, in many cases, also the tree heights. For example, if a nearby hill shields a midpath, bare hill, or field when the antennas are lowered preventing a direct determination of the elevation, the discontinuity in the height-loss curve caused by reflections from the midpath location can sometimes be used as indicated to calculate the height of the reflection surface.

Limitations of Testing Procedures

It will be apparent from the foregoing that, while microwave testing of proposed transmission paths provides information of great value to the engineer, nevertheless, the testing procedure currently in use does have certain limitations. One of these is the fact that testing is normally limited for reasons of economy to relatively short periods of time, and hence the results do not show the magnitude or frequency of occurrence of variations in atmospheric conditions which may affect transmission. While the tests are usually made only at times when it is believed that transmission is normal, this is not always possible, and the test data must be carefully analyzed in all cases to be sure what conditions are prevailing during the tests. The procedure would be considerably simplified if some simple means of more positive determination of prevailing transmission conditions were available.

Another limitation lies in the fact that the tests are made using unmodulated continuous-wave transmissions, and it is impossible by this means to distinguish between ground reflections along the desired path and reflections from obstacles which may give rise to transmission over some other path of appreciably greater length. This test limitation was recently brought to light in the establishment of an intercity television circuit into a city of moderate size. Path tests using procedures such as those described in this paper indicated that transmission would be satisfactory, although subject to certain reflection effects which were believed to be due to a large body of water in the path. When subsequent tests were made by transmitting a television picture, however, a series of vertical black-and-white bars were observed which were found to be caused by energy overshooting the receiver to strike the face of a large building beyond, from which it was reflected to the face of another large building almost in the transmission path, and from there it was reflected directly into the receiving antenna. This double-reflection path had a length estimated to be some 12,000 feet greater than the direct path, and resulted in a signal delay of approximately 12 microseconds with respect to the main signal. Although the level of this reflected signal was considerably below that of the signal over the direct path, it was nevertheless sufficiently strong to seriously impair transmission, particularly during periods when fading was observed on the direct path. As a result of this experience, consideration is being given to the use of modified test equipment which will employ pulse or modulated-wave transmissions, with receiving equipment which is capable of measuring the amplitude and the time delay of reflected signals.

Conclusions

As the result of extensive observations and tests, it has been concluded that the use of testing techniques similar to those described here are of great assistance to the engineer in selecting sites and determining optimum tower heights for microwave-radio relay stations. Such tests provide information which cannot at present be reliably determined by any other means, and while the testing work is time consuming and involves some expense, the avoidance of serious problems which might otherwise be encountered after permanent construction is completed is believed to be more than adequate justification for use of this procedure on major radio-relay routes.

No Discussion

Computation of Impedance and Efficiency of Transmission Line with High Standing-Wave Ratio

W. W. MACALPINE
MEMBER AIEE

IT IS ordinarily desirable to operate a radio-frequency or other transmission line with standing-wave ratio as close to unity as possible. When the voltage standing-wave ratio (VSWR) is less than 10, means such as the Smith chart are available for making impedance computations with an accuracy sufficiently good for many purposes. However, in some cases it is desirable or unavoidable to operate the line with high standing-wave ratios. When the VSWR is around 100 the Smith chart is quite satisfactory for reactance but affords no degree of accuracy in reading resistance. This is due to the difficulty of reading even one significant figure on that scale near the periphery, and also to eccentricity in locating the movable arm or the dividers on the center point of the chart.

A simple method is shown for computing the resistance component when the impedance point lies close to the edge of the Smith chart. Attention is also given to precautions to be observed in computing normalized impedance. Similar procedures are shown for admittances. The effect of attenuation is taken into account.

In a related problem, the usual formulas for power and efficiency can lead to considerable error when the VSWR is high. A precise formula is developed herein for the power flowing at a location in a network, in terms involving the magnitude and angle of the reflection coefficient of the load with respect to the source. This is accurate both for lumped-constant networks and for those with distributed

Paper 53-192, recommended by the AIEE Special Communications Applications Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Southern District Meeting, Louisville, Ky., April 22-24, 1953. Manuscript submitted September 30, 1952; made available for printing March 2, 1953.

W. W. MACALPINE is with the Federal Telecommunication Laboratories, Inc., Nutley, N. J.

constants. It is in a form that makes it of particular value in connection with transmission lines in the transverse electromagnetic mode.

On the basis of the power formula, another is readily derived for the efficiency of power transfer along a section of transmission line. The complete formula is more involved than necessary for most applications but can be reduced to various simpler expressions according to the nature of the problem. One of these is the usual formula found for a line with low or medium standing-wave ratio. Another is much more accurate than the latter for cases where the standing-wave ratio is high. It is simple to use, involving only the ohmic resistances and the normalized reactances of the load and input impedances.

Symbols

The following list does not include some symbols that are defined where they occur in the text.

$A_0=8.686\alpha h$=normal or matched attenuation of a length of line in decibels
B_0/G_0=tangent of the phase angle of Y_0
$g+jb=Y/Y_0$
h=distance along line between two points in units of length
$r+jx=Z/Z_0$
R_0=real part of the characteristic impedance
S=voltage standing-wave ratio
$Y_0=1/Z_0=G_0(1+jB_0/G_0)$
$Z_0=R_0(1-jB_0/G_0)$=characteristic impedance in ohms
α=attenuation constant in nepers per unit length
β=phase constant in radians per unit length
δ=loss angle of dielectric, or power factor when $\delta<0.1$
η=efficiency
$\theta=\beta h$
$\rho=|\rho|\underline{/2\psi}$=voltage reflection coefficient
ψ=electrical angle to a point on the line, measured toward the load from a voltage standing-wave maximum

Transformation of Impedance

The first step in solving a particular problem is to decide on the method that is simplest while satisfying the accuracy requirements. A typical case can be set up as follows with reference to Figure 1.

Given: The impedance $Z_1 = R_1 + jX_1$ at one end of the line, and the characteristic resistance R_0. Also α/β, B_0/G_0 and θ or h/λ, which are determined as indicated in the section on attenuation and line length.

Required: To find the impedance $Z_2 = R_2 + jX_2$ at the other end of the line and the efficiency.

General Rules

Determine the simple normalized impedance $(R_1 + jX_1)/R_0$ and set it up on the Smith chart. If the resistance component can be read accurately (say VSWR less than 10 or 20), it is ordinarily satisfactory and simple to use the chart for the entire computation.

If the VSWR is greater than 10 or 20 and the resistance component cannot be read on the Smith chart with the desired accuracy, the following method is recommended.

Procedure

The normalized impedance should properly be computed by use of equation 4 and set up on the Smith chart. However, in most cases the simpler expression $(R_1 + jX_1)/R_0$ is sufficiently accurate for this first step. If working in admittances, use $(G_1 + jB_1)/G_0$. Determine the normalized impedance $r_2 + jx_2$ (or the admittance if required) at the other point of the line by the usual manipulation of the chart. Take account of attenuation by means of equations 9 and 10 and the remarks thereafter. The reactance $X_2 = R_0x_2$ thus found is sufficiently accurate for most purposes. Then subject to the following conditions, the resistance or conductance component can be computed by use of equation 1 and its modifications in equation 2 according to the given and required quantities.

$$R_2=R_1\frac{1+x_2^2}{1+x_1^2}+R_0(1+x_2^2)\left[\frac{\alpha}{\beta}\theta+\frac{B_0}{G_0}\times\left(\frac{x_2}{1+x_2^2}-\frac{x_1}{1+x_1^2}\right)\right] \quad (1)$$

Observe that R is the ohmic resistance, while x is the normalized reactance. The attenuation of the line in nepers is shown as $(\alpha/\beta)\ \theta$ but can be expressed in other ways, as in equation 10. It is positive when point *2* is on the generator side of point *1*, and negative in the converse case.

Equation 1 is not as tedious to use as its length might indicate, for the terms $(1 + x_1^2)$ and $(1 + x_2^2)$ are each repeated two or three times. Also, in many problems $B_0/G_0 = \alpha/\beta$ affording further simplification.

Conditions

Equations 1 and 2 yield results with accuracy of the order of 1 per cent subject to the following conditions.

1. Neither $1/S_1$ nor $1/S_2$ exceeds 0.17
2. $|B_0/G_0|<0.1$
3. The normalized impedances r_1+jx_1 and r_2+jx_2 or admittances g_1+jb_1 and g_2+jb_2, whichever are used, must lie in the one-per-cent "permitted region" of Figure 2.

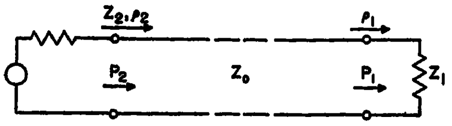

Figure 1. Transmission line of length h

4. The line parameters and given impedance be known to 1-per-cent accuracy. In many problems, this last condition is not satisfied.

Variations of Formula

Equation 1 gives R_2 when impedance is given. When admittance is given or required, similar formulas can be written with terms shown in the following tabulation:

$$\left\|\begin{array}{lllllll} R_2 & R_1 & x_2^2 & x_1^2 & R_0 & x_2 & -x_1 \\ G_2 & G_1 & b_2^2 & b_1^2 & 1/R_0 & -b_2 & b_1 \\ R_2 & G_1R_0^2 & x_2^2 & b_1^2 & R_0 & x_2 & b_1 \\ G_2 & R_1/R_0^2 & b_2^2 & x_1^2 & 1/R_0 & -b_2 & -x_1 \end{array}\right\| \quad (2)$$

The top row shows the terms in equation 1. The second row is for G_2 in terms of G_1, etc. Replace each term in equation 1 with the second row term directly below the original term in the tabulation. Be sure to replace all the x_2^2 by b_2^2 and so on.

It may happen that R_2 is desired, but $r_2 + jx_2$ is not in the permitted region while $g_2 + jb_2$ is in it. Compute G_2 by equation 1 modified by equation 2. Instead of taking the reciprocal of $G_2 + jB_2$, use the equation

$$R_2=R_0^2G_2|x_2/b_2| \quad (3)$$

where x_2 and b_2 are read on the Smith chart in the usual manner for converting impedances to admittances.

Similarly, when G_2 is to be found and $g_2 + jb_2$ is not permitted, compute R_2 and transpose equation 3 to find G_2. The same means is used to convert between R_1 and G_1 when necessary.

Normalized Impedance and Other Preliminary Considerations

Normalized Impedance

The characteristic impedance and admittance are

$$Z_0=R_0(1+jX_0/R_0)=R_0(1-jB_0/G_0)$$

$$Y_0=G_0(1+jB_0/G_0)$$

The impedance and admittance looking toward the load at a point in the line are

$$Z=R+jX$$

$$Y=1/Z=G+jB$$

Normalized and ohmic impedance are related by

$$r+jx=Z/Z_0=(1/R_0)[R-(B_0/G_0)X+jX] \quad (4)$$

$$R+jX=Z=R_0[r+(B_0/G_0)x+jx] \quad (5)$$

accurate to 1 per cent provided

$$R/|X|=G/|B|<0.1;\ r/|x|=g/|b|<0.1;\ |B_0/G_0|<0.1$$

The equations for admittances are similar, with each impedance term replaced by the corresponding admittance term and the sign before B_0/G_0 reversed.

Caution must be observed to retain the proper sign with X, B, x, or b in the formulas. For example if $X = -300$, it must not be entered in the equation simply as 300. Take special care in this for the terms with coefficient B_0/G_0.

The B_0/G_0 term in these equations can frequently be neglected leaving the customary simple equations for normalized impedance. This is especially so in rough preliminary design computations. The B_0/G_0 terms are most important when the load Q is high, or B_0/G_0 is relatively high such as in spiral lines and resonators and with ordinary lines used at the lower frequencies.

ATTENUATION AND LINE LENGTH

If the attenuation of the line is known in decibles per 100 feet, then

$$\frac{\alpha}{\beta}=\frac{0.115(\text{db}/100\ \text{ft})}{30.48}\,\frac{\lambda}{2\pi}\ \text{nepers per radian}$$

Wave length in meters for an ordinary line is

$$\lambda=v/f=300/f\sqrt{\epsilon}$$

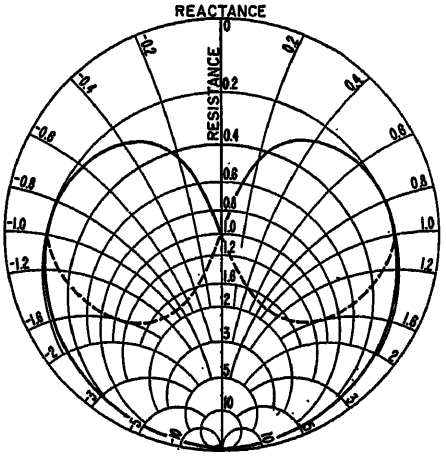

Figure 2. Permitted region for use of formula S=(1+x²)/r. Area outside solid heart-shaped curve drawn on Smith chart is where equation is accurate to within 1 per cent. Area outside dashed curve is where reciprocal of r+jx lies in permitted region, see Appendix I

When attenuation data are not available, compute

$$\alpha/\beta=Rv/2\omega R_0+\delta/2$$

The resistance of a concentric line or a balanced 2-conductor line with copper conductors is

$$R=\sqrt{f}(1/d+1/D)\times 10^{-8}\ \text{ohms per foot}$$

where d and D are the diameters in inches of the active surfaces of the conductors and f is in megacycles.

The tangent of the phase angle of the characteristic admittance is

$$B_0/G_0=\alpha/\beta-\delta$$

The line length is

$$h/\lambda=hf\sqrt{\epsilon}/984\ \text{wave lengths}$$

$$\theta=2\pi h/\lambda=hf\sqrt{\epsilon}/156.5\ \text{radians}$$

where h is in feet and f in megacycles per second, while ϵ is the dielectric constant of the medium relative to air.

Derivation of Impedance Transformation Equation

The following equations are well known

$$1/S=(1-|\rho|)/(1+|\rho|)$$

$$|\rho_2|=|\rho_1|\epsilon^{-2\alpha h}=|\rho_1|\epsilon^{-0.230A_0}=|\rho_1|10^{-A_0/10} \quad (6)$$

With respect to a fictitious load with $|\rho|=1.00$

$$|\rho_1|=\epsilon^{-2\alpha h_1}$$

$$|\rho_2|=\epsilon^{-2\alpha h_2}$$

$$h=h_2-h_1$$

It follows that

$$1/S_2=\tanh[0.115A_0+\tanh^{-1}(1/S_1)] \quad (7)$$

Now utilize the results of Appendix I and Figure 2, and note that equation 7 reduces to equation 9 with an accuracy of 1 per cent when neither $1/S_1$ nor $1/S_2$ exceeds 0.17.

$$1/S_1=r_1/(1+x_1^2)=g_1/(1+b_1^2) \quad (8)$$

$$1/S_2=1/S_1+(\alpha/\beta)\theta \quad (9)$$

$$(\alpha/\beta)\theta=\alpha h=0.115A_0 \quad (10)$$

Finally

$$r_2=(1+x_2^2)/S_2$$

$$g_2=(1+b_2^2)/S_2 \quad (11)$$

When equations 8 to 11 are combined with equations 4 and 5 for normalized impedance, equation 1 results. The preceding equations can be used in a step-by-step method of computing impedance, but usually equation 1 provides a shorter computation.

Note the remarks under equation 1 on the sign of the attenuation. When attenuation is greater than 0.01 neper or about 0.1 decibel, it is desirable to take it into account in manipulating the Smith chart. This is done by means of equations 7 and 9, noting that the radial scale "resistance component" (graduated between 0 and 1.0) is identical with $1/S$. The "1-decibel steps" scale on the chart is too coarse for use in many problems.

Power and Efficiency

The net power flowing toward the load at a point on a transmission line Figure 1 is shown in Appendix III to be

$$P={}_fV^2G_0\left(1-|\rho|^2+2|\rho|\,\frac{B_0}{G_0}\sin 2\psi\right)\ \text{watts} \quad (12)$$

where ${}_fV$ is the rms amplitude of the voltage of the incident wave. The efficiency of power transfer between point *2* on the generator end and point *1* on the load end of a section of line is

$$\eta=\frac{P_1}{P_2}=\frac{1-|\rho_1|^2+2|\rho_1|(B_0/G_0)\sin 2\psi_1}{1-|\rho_2|^2+2|\rho_2|(B_0/G_0)\sin 2\psi_2}\,\epsilon^{-2\alpha h} \quad (13)$$

This equation can be simplified in many cases according to the conditions of the problem.

CONDITION A

$$S_1|B_0/G_0|\ll 1$$

$$\eta=\frac{1-|\rho_1|^2}{1-|\rho_2|^2}\,\epsilon^{-2\alpha h}$$

$$=\frac{1/|\rho_1|-|\rho_1|}{1/|\rho_2|-|\rho_2|}=\frac{S_2-1/S_2}{S_1-1/S_1} \quad (14)$$

where $|\rho_2|$ and $|\rho_1|$ are related as in equation 6. The maximum per-cent error, due to the combined effects of numerator and denominator, is roughly

$$\pm 100S_1B_0/G_0$$

This is the usual formula found for the efficiency of a radio-frequency transmission line. When the impedance can be computed accurately on the Smith chart, the VSWR being less than 10 or 20, equation 14 should ordinarily be used. The values of $|\rho_1|$ and $|\rho_2|$ can be read on the chart, but it is suggested that one be read and the other computed by equation 6, since they usually differ but little.

CONDITION B

$$S_2>>1$$

$$\eta=\frac{1/S_1+0.5(B_0/G_0)\sin 2\psi_1}{1/S_2+0.5(B_0/G_0)\sin 2\psi_2} \quad (15)$$

The per-cent error is roughly

$$100/(S_2^2-1)-100/(S_1^2-1)$$

which is

<1 per cent for $S_2>10$ and <10 per cent for $S_2>3.3$

CONDITION C

$S_2>>1$ and $S_1|B_0/G_0|<<1$

$$\eta=S_2/S_1=1/(1+S_1\alpha h)=1/(1+0.115A_0S_1) \qquad (16)$$

The error is the algebraic sum of those for conditions *A* and *B*. In the expressions involving αh and A_0, this error is increased slightly by an approximation $\tanh x\approx x$ in the use of equation 7.

CONDITION D

$S>>1, |B_0/G_0|<<1$ and $r+jx$ or $g+jb$ in the "permitted region" of Figure 2

$$\eta=\frac{R_1}{R_2}\left(\frac{1+x_2^2}{1+x_1^2}\right)=\frac{G_1}{G_2}\left(\frac{1+b_2^2}{1+b_1^2}\right)$$

$$=\frac{R_1}{R_0^2G_2}\left(\frac{1+b_2^2}{1+x_1^2}\right)=\frac{R_0^2G_1}{R_2}\left(\frac{1+x_2^2}{1+b_1^2}\right) \qquad (17)$$

The accuracy of equation 17 is comparable to that of equations 1 and 2 under the conditions listed for those equations.

R_1 and G_1 are the resistive and conductive components of the ohmic impedance and admittance looking toward the load at point *1*, and similarly for R_2 and G_2. On the other hand, *x* and *b* are normalized values. The real part of the characteristic impedance is R_0.

In problems where it is desirable to use equations 1 and 2 in computing impedance, equation 17 is generally the simplest one to use for efficiency and the most accurate for numerical computations. The latter equation is identical with the first term on the right-hand side of equation 1 or 2 divided by R_2 or G_2 as the case may be.

The exponential does not appear explicitly in several of the equations 14 to 17. This is not an approximation for small values of attenuation, but the exponential has been absorbed into the body of the equation.

The stated errors for the equations are expressed as a percentage of η, obviously not in addition to η. Furthermore, the impedance and line parameters often will be known inaccurately and can introduce considerable additional error into a numerical computation.

Appendix I. Equations for Boundary of Permitted Region

For 1-per-cent or better accuracy in equations 8 and 11 it is now shown that the impedance point must be in the permitted region of Figure 2 for which

$$|\cot\psi|<0.1S^2/\sqrt{S^2-1} \qquad (18)$$

For 10-per-cent accuracy, substitute the coefficient 0.32 for 0.1. When working in admittances, use $\tan\psi$ in place of $\cot\psi$. This gives the same boundary line in Figure 2.

Good formulas for checking rapidly the validity of equations 8 and 11 for 1-per-cent accuracy are

$$r<0.1|x+1/x|$$

$$g<0.1|b+1/b| \qquad (19)$$

provided $|x|>0.3$ or $|b|>0.3$ as the case may be. The accuracy condition can be checked visually on the Smith chart, where the circles of constant *x* must not deviate from the radial direction by more than about 10 degrees at the impedance point in question.

Expression 18 is derived as follows. The complex reflection coefficient can be written

$$\rho=[(S-1)/(S+1)](\cos 2\psi+j\sin 2\psi)$$

The normalized impedance is given by

$$r+jx=(1+\rho)/(1-\rho)=(1+jS\cot\psi)/(S+j\cot\psi)$$

The expression in *S* and ψ can be demonstrated most readily by substituting the preceding value for ρ and equating as a trigonometrical identity. It is an exact formula. Although it corresponds to an impedance formula with attenuation neglected, the fact that attenuation does not appear does not constitute an approximation. The quantities *S* and ψ are parameters that completely determine the reflection coefficient at the point where the impedance is $r+jx$.

Equation 8 can be derived from the last formula

$$r/(1+x^2)=(1/S)(S^4+S^2\cot^2\psi)/(S^4+\cot^2\psi)=(1+a)/S$$

The correction term *a* is always positive.

$$a=(S^2-1)\cot^2\psi/(S^4+\cot^2\psi)\approx[(S^2-1)/S^4]\cot^2\psi \qquad (18A)$$

For 1-per-cent error in equation 8, $a=0.01$ and the expression 18 results.

Appendix II. Effect of B_0/G_0 Terms in Impedance Equations

For this discussion, it is convenient to modify equation 1 by the use of the apparent or approximate standing-wave ratio S' and by a result found in Appendix IV.

$$1/S'=R/R_0(1+x^2)\approx G/G_0(1+b^2)$$

$$\sin 2\psi\approx 2x/(1+x^2)\approx -2b/(1+b^2)$$

Then equations 1 and 2 become

$$\frac{1}{S_2'}=\frac{1}{S_1'}+\frac{\alpha}{\beta}\theta+\frac{1}{2}\frac{B_0}{G_0}(\sin 2\psi_2-\sin 2\psi_1) \qquad (20)$$

The angle of the reflection coefficient 2ψ can be read on the Smith chart. If working with admittances, read the negative of the angle indicated on the periphery for practical purposes in computing $\sin 2\psi$.

The principal point in question is the effect of the B_0/G_0 terms in the over-all computation and whether they can be neglected. The worst case is when $B_0/G_0=\pm\alpha/\beta$. Then we are interested in the relative value of the quantity

$$(1/2)(\sin 2\psi_2-\sin 2\psi_1) \qquad (21)$$

compared to the line length θ. If θ is centered about a voltage maximum or minimum, the quantity 21 is greatest with maximum value of unity. The other extreme is for θ centered midway between these points, when quantity 21 is zero. For small values of θ up to about a radian, the quantity can range between almost doubling the effect of θ down to almost annulling it.

Even with low VSWR, the quantity 21 has the same effect as described on θ. However, when θ is small, it does not have appreciable effect on $1/S$ or the impedance relationship in this case. When θ is large enough so attenuation has appreciable effect on impedances at low VSWR, the quantity 21 is negligible in comparison.

Then the B_0/G_0 terms can be neglected when the standing-wave ratio is low. For higher VSWR, use or omit the B_0/G_0 terms in equations 1, 2, 4, and 20 depending on a mental comparison of the magnitude of quantity 21 in relation to θ in radians.

Appendix III. Derivation of Power Equation

The power flowing at a point in an a-c circuit is given by

$$P=(\text{Real})VI^* \qquad (22)$$

This is the real part of the product of the rms complex sinusoid voltage by the conjugate of the corresponding current.

Equation 12 is easily found when the following expressions are substituted in this equation. At a point in a transmission line

$$V={}_fV(1+\rho)$$

$$I={}_fVY_0(1-\rho)$$

$$I^*={}_fV^*Y_0^*(1-\rho^*)$$

$$Y_0^*=G_0(1-jB_0/G_0)$$

$$\rho=(Z-Z_0)/(Z+Z_0)=|\rho|\epsilon^{j2\psi}$$

$$\rho^*=|\rho|\epsilon^{-j2\psi}$$

The power equation 12 can also be demonstrated by a related method. At a point on a line the power flow is given by $P=V^2G$ where *V* is the rms voltage across the line and *G* is the conductive component of the admittance looking toward the load. When this is expressed in terms of reflection coefficient, etc., equation 12 results.

The equation can also be demonstrated by integrating the power loss in the series re-

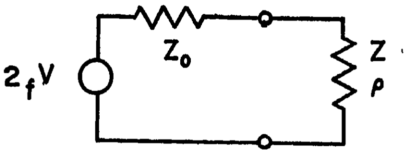

Figure 3. Generator and load

sistance and shunt conductance of the line, between a known load and any other point on the line.

An example and further remarks on the power in a line are given at the end of Appendix V.

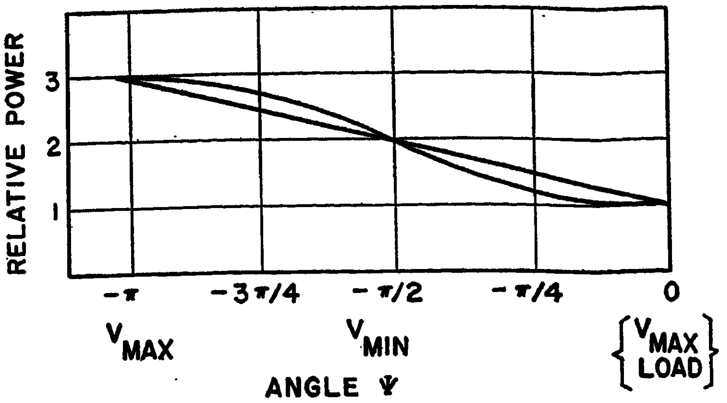

Figure 4. Power flow along line. Straight line is computed power neglecting B_0/G_0 term in equation 12. Wavy line is according to complete equation for case of negligible dielectric loss

Appendix IV. Derivation of Efficiency Equations

The complete equation 13 follows immediately from equation 12. In deriving equation 15 there is used equation 6 and

$$1-|\rho|^2=(1+|\rho|)^2/S=(4|\rho|/S)(1+a') \quad (23)$$

$$a'=1/(S^2-1)$$

The expressions 17 are derived from equation 13 by way of equation 15 with the following steps. From equations 8, 18(A), and 23

$$(1-|\rho|^2)/4|\rho|=(1+a')/S$$
$$=(1+a'-a)r/(1+x^2)$$

$$a'-a\approx(1-\cot^2\psi)/S^2$$

By a deviation similar to that of Appendix I

$$0.5\sin 2\psi=x/(1+x^2)(1-a'')$$

$$a''=[S^2-(S^2-2)\cot^2\psi]/(S^4+\cot^2\psi)$$
$$\approx(1-\cot^2\psi)/S^2$$

This is the same as the approximate equation for $a'-a$ already found. Then

$$1-|\rho|^2+2|\rho|(B_0/G_0)\sin 2\psi$$
$$=(1+a'')4|\rho|[r+(B_0/G_0)x]/(1+x^2)$$
$$=(1+a'')4|\rho|R/R_0(1+x^2)$$

with equation 5 used in the last step. A similar equation is found for admittances. Equation 17 follows readily.

The physical significance of equation 17 is as follows. Subject to the stated conditions, there holds approximately

$$x=\cot\psi$$

$$I=I_{\max}\sin\psi$$

where $I_{\max}$ is the current standing-wave maximum. The power at any point is

$$P=I^2R$$

where R is the resistive component of the ohmic impedance looking toward the load at the point. Equation 17 follows, since

$$I^2=I_{\max}{}^2\sin^2\psi=I_{\max}{}^2/(1+\cot^2\psi)$$
$$=I_{\max}{}^2/(1+x^2)$$

The value of $I_{\max}$ is constant within practical limits for values of S greater than those listed in the statement of errors under the section entitled "Condition D."

Appendix V. Examples and Miscellaneous Remarks

Example of Impedance and Efficiency

A load of $5-j1{,}000$ ohms at 2.0 megacycles is fed by a 60-foot length of *RG-17/U* cable. What is the input impedance and efficiency?

The attenuation of the cable at 2.0 megacycles is found to be about 0.094 decibel per 100 feet. The loss angle of the polyethylene dielectric is less than 0.0002, and the dielectric constant is 2.26. The given conditions can be summarized as follows, making use of equations in the section on attenuation and line length.

$$R_1+jX_1=5-j1{,}000\text{ohms}$$

$$R_0=52 \text{ ohms}$$

$$\alpha/\beta=B_0/G_0=5.6\times10^{-3}$$

$$\theta=1.15\text{radians}(66°)$$

$$h/\lambda=0.183$$

Then $x_1=-1{,}000/52=-19.2$. By the Smith chart $x_2=-0.384$ and so $X_2=-20.0$ ohms. The resistance is found by equation 1 where $1+x_2{}^2=1.148$ and $1+x_1{}^2=370$.

$$R_2=5\times\frac{1.148}{370}+52\times1.148\times5.6\times10^{-3}\times$$
$$\left(1.15-\frac{0.384}{1.148}+\frac{19.2}{370}\right)$$
$$=(15.5+290)10^{-3}=0.305 \text{ ohm}$$

Efficiency, by equation 17 is

$$\eta=15.5\times10^{-3}/0.305=0.051 \quad (5.1 \text{ per cent})$$

Reflection Coefficient Greater than Unity

Suppose a loss line with characteristic impedance $Z_0=R_0(1-j0.1)$ is terminated by a lossless load with impedance $Z=jR_0$. Then the normalized load impedance is found to be

$$Z/Z_0=-0.1+j1.0$$

The negative normalized resistance can be visualized if a phasor diagram of the impedances is drawn. It has no implication of negative ohmic resistance.

The reflection coefficient, see Appendix III, is

$$\rho=1.11\underline{/90.3°}$$

Now it is found that there is interchange of power between the incident and reflected waves, but the sum of all the power components is zero at the load.

$$(\text{Real})_f V_f I^*=1.00$$

$$(\text{Real})_r V_r I^*=-1.22$$

$$(\text{Real})_f V_r I^*=0.11$$

$$(\text{Real})_r V_f I^*=0.11$$

The popular conception that the magnitude of the reflection coefficient cannot exceed unity is correct when either the source or load impedance is a pure resistance. With a transmission line, this is usually justified. In fact, when Z_0 includes an appreciable reactive component, it follows inherently that the attenuation per radian is large. Then even if the reflected coefficient exceeds unity at the load, its magnitude is reduced rapidly along the line and soon is less than unity.

Power in Lumped-Element Network

It may be observed that the derivation in Appendix III of equation 12 shows it to be equally valid for either lumped or distributed networks. For the lumped case shown in Figure 3, Z_0 is the generator impedance, Z the load, the ${}_fV$ is half the open-circuit generator voltage. This equation is not required in most lumped-element network applications since other equations are usually simpler to apply.

With lumped-element networks, the reflection coefficient can be very large. Take for example a load $Z=R+jX$ connected to a generator impedance $Z_0=\boldsymbol{Z}^*=R-jX$. The reflection coefficient is $\rho=jX/R=\pm jQ$. If the open-circuit generator voltage is E, then the power into the load is $P=E^2/4R$ by inspection. It is interesting to compute the power by equation 12 which yields the same result.

One use for the idea of reflection coefficient with lumped element networks is in connection with the application of the principle of superposition. For instance, the load impedance may be replaced by one equal to the source impedance in series with a voltage equal to the actual open-circuit voltage of the source multiplied by the complex reflection coefficient.

Example of Power Flow Along Line

A practical interpretation is given of the power equation 12, showing the net power flowing toward the load at various points along a line with high attenuation.

Let ${}_fV_a$ and ρ_a be the values of incident rms voltage and reflection coefficient at a voltage maximum. Then at any other point

$${}_fV = {}_fV_a\epsilon^{-\psi\alpha/\beta}$$

$$|\rho| = |\rho_a|\epsilon^{2\psi\alpha/\beta}$$

Now equation 12 can be written

$$P = {}_fV_a^2G_0[\epsilon^{-2\psi\alpha/\beta} - |\rho_a|^2\epsilon^{2\psi\alpha/\beta} + 2|\rho_a|(B_0/G_0)\sin 2\psi]$$

Suppose $\alpha/\beta = B_0/G_0 = 0.0318$ in which case the dielectric loss is negligible. Let $|\rho_a| = 0.9$ and find the power for various values of ψ between 0 and $-\pi$ radians.

The results are plotted in Figure 4, where arbitrarily $P = 1.00$ at $\psi = 0$, so ${}_fV_a^2G_0 = 5.25$. As a sample computation, let $\psi = -\pi/4$. Then

$$-2\psi\alpha/\beta = 0.050$$

$$P = 5.25[1.051 - (0.810/1.051) - 2\times 0.9\times 0.0318] = 1.18$$

The curve of power versus position on line in Figure 4 shows that the slope is almost zero at the current minimum and greatest at the current maximum. This agrees with the assumption of negligible dielectric loss, or $B_0/G_0 = \alpha/\beta$. On the other hand, if the conductor loss had been negligible but the dielectric loss appreciable, there would have resulted $B_0/G_0 = -\alpha/\beta$. Then the lobes of the sinusoidal curve of power would have been on the other side of the average power line (that is, where the B_0/G_0 term is neglected). The slope would be greatest at the voltage maximum and almost zero at the voltage minimum which is logical.

The solution of the differential equation of propagation shows uniform voltage and current attenuation of the incident wave and of the reflected wave as they flow in their respective directions. This condition is used in the derivation of equations 12 and 13. However, as shown in the example, this leads to the power dissipation varying nonuniformly along the line. The discrepancy is resolved by the transfer of power between the incident and reflected waves as shown earlier in this appendix.

No Discussion

The XY Toll Ticketing System

H. L. FOOTE
ASSOCIATE MEMBER AIEE

IN RECENT years independent telephone companies have become acutely aware of steadily decreasing net profits on short-distance toll-call operation. The recording, for billing purposes, of certain information concerning the toll call has required the assistance of an operator. For this reason, manual toll switching has been retained in spite of the fact that mechanical systems for performing the actual switching functions have been available for many years. Fixed toll charges and rising labor costs have combined to make it extremely difficult for the operating companies to realize a profit on this phase of their business.

One solution to this problem is the granting of free service on these loss-producing toll lines. While this would prevent further losses, resulting increased traffic would create a demand for additional expensive plant equipment and personnel which in turn would produce no revenue.

A second solution is the reduction of the number of people involved in producing the toll billing records known as "toll tickets," by the installation of automatic toll switching equipment incorporating automatic ticketing means. Several attempts have been made to provide such equipment and two basic types have emerged.

One, the verifying type, requires the calling subscriber to dial his own directory number before dialing the number of the desired station. The other, considerably more complex and expensive, is the identifying type wherein the calling station number is automatically found and recorded without effort on the part of the subscriber.[1] The system described herein is of the verifying type.

Any toll ticketing system, manual or automatic, must accomplish the following three things:

1. The information concerning the toll call must be recorded in some manner.
2. The recorded information must be translated and interpreted for use by the ticketing device.
3. The information must finally be presented in a readily usable form.

Recording the Information

Since the primary objective of any toll ticketing system is the reduction of manual labor in producing the toll tickets, the most desirable system would be the one which would reduce the labor factor to zero. In order to achieve such a goal, the designer is confronted with the need for an inexhaustible medium on which to store temporarily the billing information until that information is printed as a toll ticket. Several such storage devices are available, only one of which is economically sound.

The Recorder

The unique magnetic tape recorder shown in Figure 1 forms the heart of the XY toll ticketing system as the intermediate storage device. The tape in the magazine can record information concerning 100 average toll calls before it requires automatic interpreting equipment to print the tickets, simultaneously preparing itself for reuse. One recorder is permanently associated with each toll trunk, operating completely unattended in all of its functions. The recorder records the calling and called subscribers' directory numbers, the duration of the call (elapsed time), the time of day, and the date.

Figure 2 shows the XY switch manufactured by Stromberg-Carlson Company. This is a universal switch for use in any circuit in a step-by-step dial telephone system. Comparison with Figure 1 will show the similarity between the recorder and the switch. Great savings in tooling and manufacturing costs were achieved by using as many identical parts as possible in the two devices. Both are built on the same plate, use two of the same magnets, mount in the same way, and are jacked into the associated trunk relay equipment by means of identical cord and plug assemblies. Thus, the entire design of the XY toll ticketing equipment can be harmonious with standard XY switching equipment.

Paper 53-184, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Southern District Meeting, Louisville, Ky., April 22–24, 1953. Manuscript submitted January 21, 1953; made available for printing March 11, 1953.

H. L. Foote is with the Stromberg-Carlson Company, Rochester, N. Y.

The author wishes to acknowledge the contributions of F. A. Morris, J. D. Confeld, and H. S. Gleason who should be credited with the major portion of the circuit and mechanical design of the XY toll ticketing system.

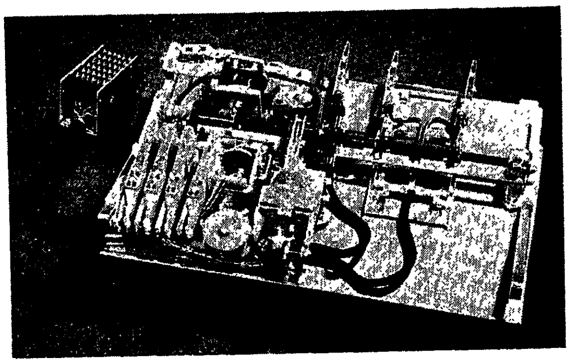

Figure 1 (left). Trunk recorder-reproducer used in the XY toll ticketing system

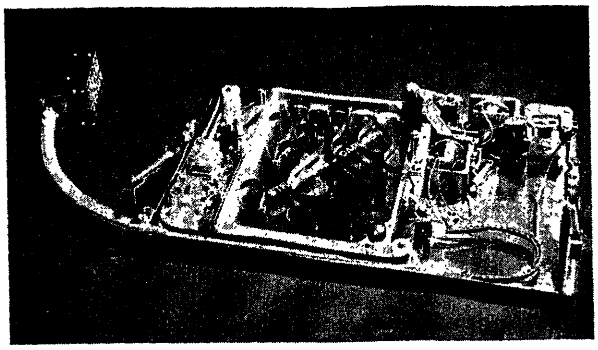
Figure 2 (right). The Stromberg-Carlson XY switch



The recording is made on standard 1/4 inch magnetic tape. Approximately 30 feet of tape are contained in the magazine in the form of an endless loop. The tape is transported by a capstan which can be driven by either of two methods. For recording, the tape is advanced step by step in 0.057-inch increments by means of a ratchet drive. For playback, a clutch connects the capstan to a common motor shaft and the tape is driven at a constant rate of about 3 inches per second. The tape passes over a twin-track recording head and a double-width erase head. Felt-faced pads apply the necessary pressure to assure proper contact between the tape and the heads. Three contact springs, sensing two conductive areas applied to the back side of the tape, control the cycling of the recording and playback process.

THE TAPE HEADS

Figure 3 shows the twin-track record-playback head before and after it has been cast in resin. Each head consists of a single 0.112-inch wide lamination of molybdenum permalloy with a 1-mil gap spacer. The coils are 2,700 turns of no. 46 wire wound on a bobbin. The various parts are mutually supporting and interlocking. The erase head is built on the same principle, the lamination being 0.270 inch wide, and its coil is 50 turns of no. 27 wire.

The upper half of the twin-track head is energized by each dial impulse and makes a magnetic impression 0.002-inch wide on the upper half of the tape. The lower half of the head is energized upon release of the interdigit relay in the trunk circuit which also affects the advance of the tape by a single step. These interdigit pulses serve to separate the several groups of pulses derived from the dialed digits. The two series of pulses are known as "mark" and "space" pulses respectively. To indicate the end of a call, mark and space pulses are recorded simultaneously when the trunk is released.

BLOCK DIAGRAM

Figure 4 shows a block diagram of the XY toll ticketing system, while Figure 5 shows the equipment itself, except for the trunk circuit. The digits of the subscriber's own number are used for two purposes. They are recorded in order to bill the call and they also set up a connection to verify the accuracy of the number dialed. If the call is verified, the verifying circuits are dropped off, and subsequent pulses (of the called number) are passed over the trunk to establish the connection to the distant subscriber. As soon as the called subscriber answers (answering supervision), the trunk transfers the recorder input to a common time impulse circuit, the minute pulser, transmitting one impulse per minute to the recorder during the conversation. When the calling subscriber hangs up (on-hook supervision), the trunk drops the linkage and transfers the input of the recorder to a common clock-calendar. Digital representation of the time of day and date is automatically pulsed into the recorder. Upon completion of this operation, the trunk releases and causes an end-of-call signal to be recorded. The trunk and its associated recorder are then free to accept another call.

If the calling subscriber dials other than his own number the call will not be verified and subsequent pulses are neither recorded nor repeated to the distant office. This condition is indicated to the subscriber by means of a suitable tone. Upon receiving on-hook supervision the trunk will merely enter an end-of-call signal and release. Similarly, in the case of "don't answer" and busy line calls, the trunk will enter an end-of-call signal—omitting the time and date information—and release. The presence of the date and time of day information is the criterion for the playback equipment to print a valid ticket. Abnormal calls are thus ignored by the printing equipment.

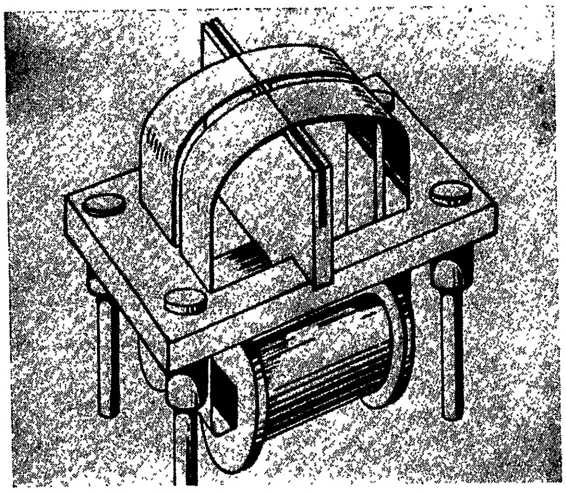


Figure 3. Record - playback head used in the XY toll ticketing system—before (left) and after (right) being molded in resin

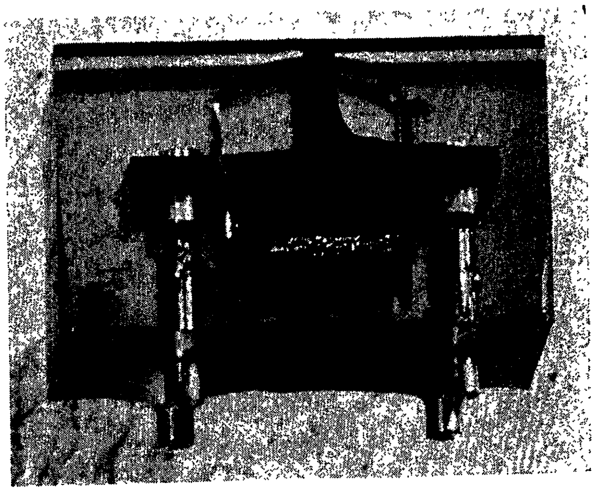

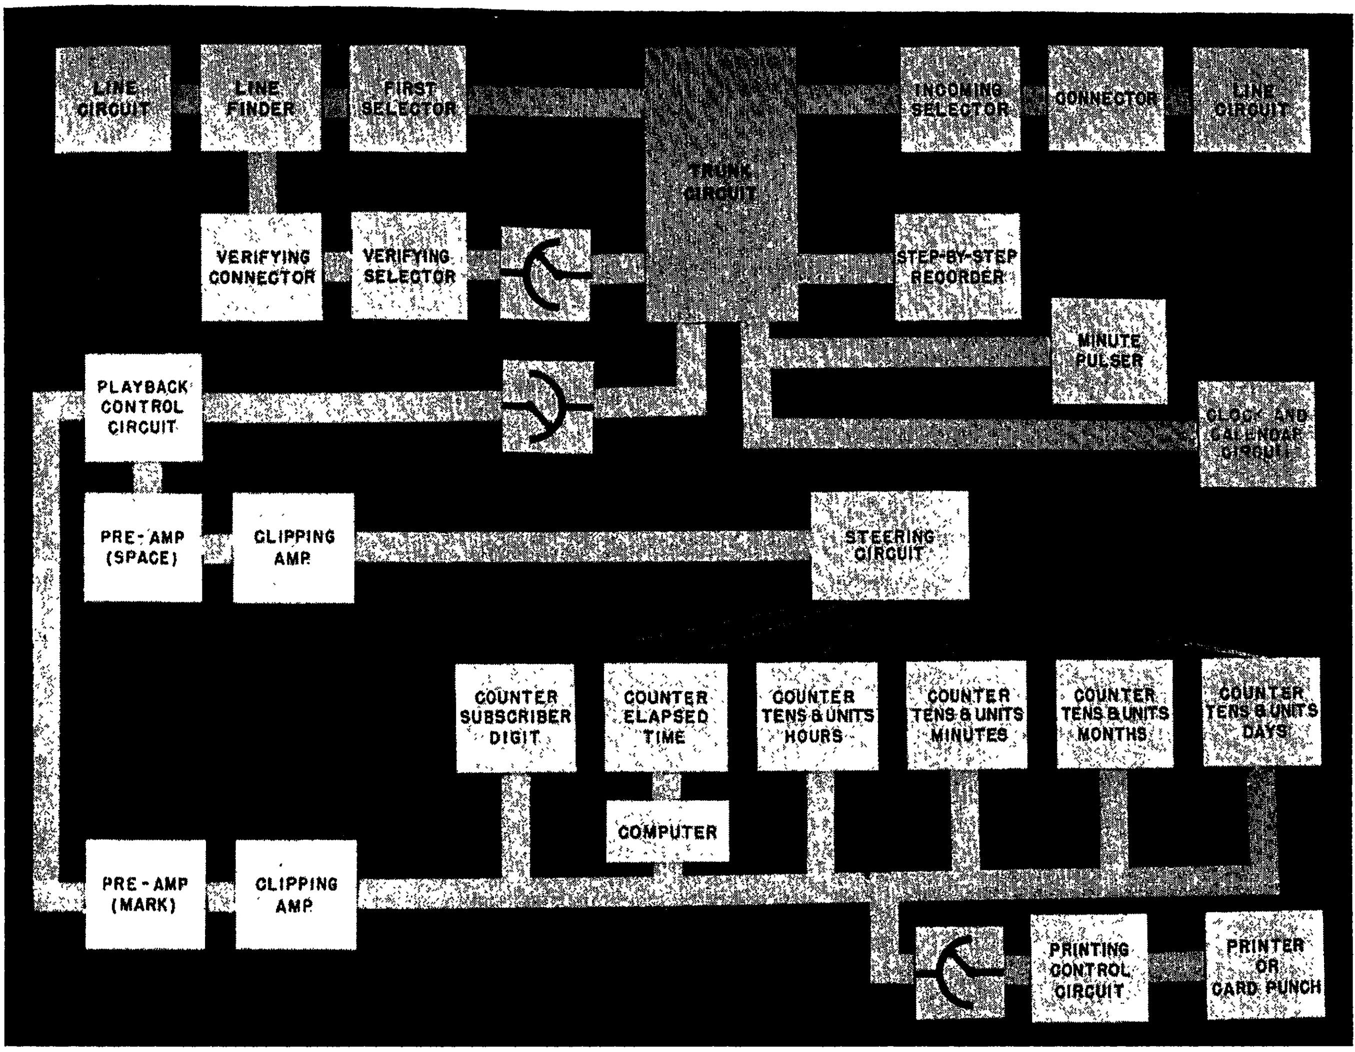

Figure 4. Block diagram of the XY toll ticketing system

Interpretation and Presentation

Common playback equipment attaches itself to each trunk recorder according to a prearranged schedule to permit common interpreting equipment to analyze the information recorded on the magnetic tape recorder. The interpreting equipment operates a ticket printer, common to all recorders, which prints a standard size toll ticket and automatically stacks these tickets, printing up to 10,000 per day. If complete automatic billing is desired, the information can be directed into a card-punching machine instead of the printer. In this case, 15,000 calls can be ticketed per day, since the card punch will operate somewhat faster than the printer.

Playback Control Circuit

Due to the large storage capacity of the trunk recorders, it is necessary and desirable to interpret the stored information only periodically, the period being determined by the toll traffic. Presumably, this would be once a day during a time of light traffic. The common clock-calendar unit is so wired that it will start playback at a predetermined time. The playback control circuit consists of a rotary switch and relays which function on a common equipment basis to augment the trunk during the playback cycle. The rotary switch acts as a trunk finder, stepping until the first idle trunk is found and associating the common control equipment upon seizing the trunk.

In the event that unusually heavy traffic conditions should cause a tape to become completely filled before the normal playback period, the normal schedule is ignored and the services of the playback control circuit requested at once. The rotary switch will advance directly to the full trunk and begin ticketing the calls from the recorder.

The "full" tape condition is sensed by the two conductive areas (foils) on the back of the tape. Should a subscriber seize the trunk and recorder just before the first foil is sensed, the recording of the data concerning the call will carry the tape past this point. Upon receiving on-hook supervision, the trunk immediately busies itself out and calls for playback as described previously. A "safety zone" has been provided to take care of long conversations in this area. Should the subscriber pass the first foil and the conversation continue for 99 minutes, the second foil will be sensed—indicating an absolute "deadline." However, a super-safety area has been provided so that when the second foil gives a forced disconnect, there still remains sufficient tape on which to record the date and time of day. If desired, the call can be continued by a manual operator rather than forcing disconnect.

Printing Control Circuit

The clutch of the recorder of the seized trunk is energized to move the tape to its "home" position. This is determined by the foil on the back of the tape. Control of the clutch is then transferred to the printing control circuit and the outputs of the twin record-playback head are con-

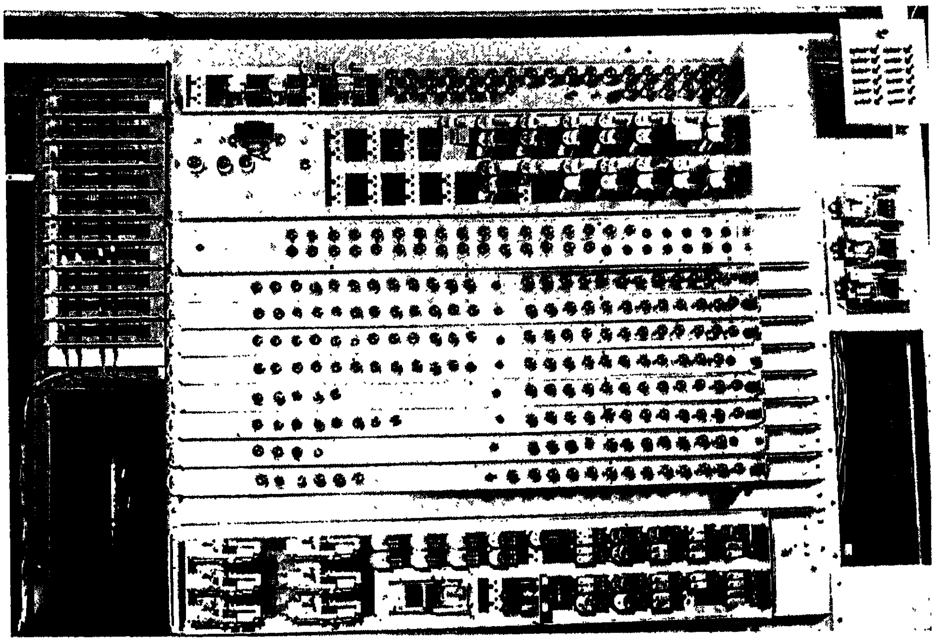

Figure 5. XY toll ticketing equipment (less trunks and recorders)

nected to the mark and space preamplifiers. The recorder remains under the control of the printing control circuit until the tape has been completely played back and erased, whereupon the playback control circuit takes over once again. Before the trunk is released, a single reset signal is recorded for purposes to be discussed later.

Upon releasing the trunk, the rotary switch advances and associates the playback control circuit with the next idle trunk to repeat the playback process. After completing a search through all of the trunks, the rotary switch will reach home and the playback control circuit will normally become inactive until the next scheduled start. After being amplified in the preamplifiers, the mark and space pulses are fed to the clipping amplifiers which further amplify the signals to a level suitable for driving the counting chains. The clipping amplifiers also act as marginal devices and will not transmit low-level signals resulting from interference. The signal pulses are shaped and brought to a uniform size by these amplifiers which have a very large range. Pulses having as little as 30 per cent of "standard" amplitude are transmitted and restored to full amplitude. The cutoff below that point is very rapid so that pulses only slightly less are completely eliminated. Pulses may be many times larger than standard and may still be restored.

STEERING CONTROL CIRCUIT

The function of the steering control circuit is to energize the proper circuits to count and store the recorded digits. When the steering control circuit is primed, it enables the first counter to count and store the first digit. Upon receiving a space pulse, the steering chain will be advanced to the next step, enabling the second counter to count and store the second digit, and so forth. The steering chain will have as many stages as there are total digits of billing information.

COUNTERS

With a playback tape speed of about 3 inches per second, the stored pulses are read off the tape at about 52 per second. Relay counting chains for counting and storing at this rate are extremely complex and expensive. Cold-cathode counting chains, on the other hand, can count very comfortably at this rate. One counting chain is used per digit of billing information, but the several chains vary somewhat in number of counting stages depending upon the maximum number of pulses expected. Those used for subscriber digits must count to ten, whereas those counting tens days, for instance, need count only to three. Where a large number of pulses must be converted into a 2-digit decimal number (for example, the elapsed time can have as many as 99 pulses) there is no single symbol for the quantity 99 and it must be represented as two 9's. This is accomplished by connecting the ends of a counting chain together to form a "ring." This ring will represent the units digit of elapsed time. It will continue to count around, repeating as many times as necessary. However, for every time the units ring returns to zero, one pulse will be fed into an associated chain to represent the tens digit of the elapsed time. Thus, if 45 pulses, representing 45 minutes of elapsed time, are fed into the counter, the units ring will return to zero four times, thus stepping the tens chain to four and will stop on the fifth tube in the ring representing units digit five. This automatically converts a continuous series of pulses into two decimal digits.

INTERPRETATION

The information stored in the several counters must be transferred to the ticket printer a digit at a time. By connecting the anodes of the counter tubes to the banks of a rotary switch it is possible to determine which tube is fired in each of the counters. Note that the information thus stored may be read, and the ticket printed, in any order. A printed ticket is shown with a manually written ticket in Figure 5.

Due to the requirements of the ticket printer it is necessary to translate the decimal information into a permutation indicative of the numeral or letter to be printed. This translation is accomplished by a group of relays which are connected by the rotary switch to the anodes of the counter tubes. The ticket printer employs a 7-unit code so arranged that the operation of any single translating relay will result in printing a numeral. Combinations of two relays will result in printing a letter. The ticket printer and the printing control circuit are interlocked by the simple expedient of advancing the rotary switch by means of a pulse transmitted from a cam in the ticket printer.

Some of the information on the toll tickets is determined by means other than recorded data. The names of both the originating and called offices are determined by the operation of relays under the control of the playback control circuit which put the proper letter codes on the proper terminals of the rotary switch banks. Likewise, the digits representing the year are strapped on the proper bank terminals. Information needed by the printer such as carriage return, line space, ejection, etc. is strapped in.

The printing control circuit acts to correlate the functions of the playback control, steering, counters, and printing control circuit. Included in the printing control are the "destination code" relays which determine what trunk is being ticketed and thus control what office letters are printed on the ticket. These same relays are also used to adjust the

computer for the proper base time and base rate.

The printing and playback control circuits are carefully interlocked so that playback cannot proceed unless the counters are in a receptive condition nor can control by the printing control be relinquished until the information is completely interpreted. To make certain that the counters do not contain any information left over from previous ticketing or other interference the playback control transmits a reset signal each time a new trunk is seized. As an additional precaution a reset signal is also recorded at the beginning of each tape as mentioned earlier. The reset signal is simply an end-of-call recording, which, when not preceded by normal ticketing information, serves to restore all of the counting chains to the starting condition. After the two safety resets, the counters receive and store the call information, storing all information about one call before any other action takes place.

The Computer

The computer makes use of the elapsed time and destination code information to derive the charge for the call. It too uses cold-cathode counting chains to calculate the charge. Essentially, there are two chains and two rings. One chain counts off the minimum time for the particular call, the number of stages in the chain being adjusted by the destination code relays. If the call is based on a 3-minute period, for example, there will be three stages in the chain.

The first ring counts off the number of 5-cent increments (since all short-haul charges increase at the rate of 5 cents per minute), the second ring counts the ten cents, and the second chain counts the dollars.

The minimum charge is primed into these counters by means of the destination code relays. If the call is based on 15 cents minimum charge, the 5-cent tube and the number 1 tens cents tube will be primed and the charging will start at that point.

The elapsed time pulses are fed into the computer which at first counts them in the minimum-time chain. When the end of this chain is reached, the remaining pulses are diverted into the first money ring which will add 5 cents for each additional minute—the total being kept by the remaining two counters. The calculated charge is read by wiring the anodes of the counters to the rotary switch just as the numerical information in the other counters.

Ticket Printer

The basic mechanism of the ticket printer shown in Figure 6 is an electric typewriter to which the Commercial Controls Company adds what is known as a "translator" to make it respond to electrical control. Essentially, the translator is much the same as the selecting mechanism in a teletype machine.

For the XY toll ticketing system the ticket printer is further modified to the extent of adding a device for feeding roll paper into it and converting the continuous roll into individual tickets neatly stacked.

The paper rolls are sufficient for 10,000 tickets, the paper being standard toll-ticket width. It is fed to the platen through guide channels, and after passing around the platen and being printed, it passes through another guide channel to a solenoid-operated chopping knife. After being cut off, the ticket is ejected into a stacking hopper.

Power Requirements

The only power required for recording the toll-call information is the normal office battery at 48 volts d-c. For play-

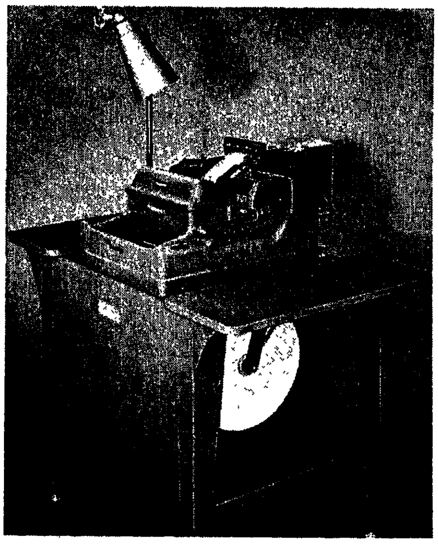

Figure 7. The ticket printer used in the XY system

ing back and ticketing, 110-volt a-c power is needed. The anode voltage for the cold-cathode tubes is derived from a simple 500-milliampere 150-volt d-c power supply.

Conclusions

The XY toll ticketing system meets the needs of the small and medium size telephone companies in their endeavor to solve the problem of decreasing profits in short-distance toll operation. By combining three basic arts—mechanical switching, magnetic recording, and electronics—the tickets for the toll calls are prepared in any desired form completely without manual attention, thus reducing to a minimum the high labor cost involved in toll billing. The 100-call capacity of the recorders and the 48-volt d-c recording operation prevent loss of revenue during a-c power failures. The use of cold-cathode tubes in the majority of the electronic circuits precludes the frequent changing of tubes since their life depends only on the number of on-off operations to which they are subjected. The *RCA-5823* tubes used have a life of approximately 40 million operations—a life equivalent to that of most of the other components of the system.

POISSONIAN or distributed source fields occur often in present-day problems dealing with such subjects as torsional stress analysis, heat transfer, viscous fluid flow, eddy currents, and electric and magnetic fields. Since the mathematical solution of Poissonian fields has only been possible in several special cases, physical analogues have been developed for 2-dimensional fields. A highly successful physical analogue is the sandbed fluid mapper.[1-3] This paper describes an electric analogue mapper which was originated and developed by the authors. The analogue can give directly usable 2-dimensional solutions of high accuracy.

The Analogue Field Map

The mapper utilizes a resistive plotting surface and a coupling capacitor. The coupling capacitor is formed by the resistive surface and a parallel coupling electrode. A displacement current acting through this coupling capacitor sends a distributed current into the resistive surface. As shown in the Appendix, this distributed current flow represents Poisson's equation. Boundary conditions are introduced by suitable conducting terminations of the resistive surface. The coupling electrode shape and area correspond to those of the distributed source. The displacement current density is readily controlled by the spacing of the coupling electrode and the resistive surface. Most of this paper will discuss mappers of constant displacement current density.

In practice, Teledeltos recording paper (manufactured by the Western Union Telegraph Company) is used as a resistive surface. A dielectric material separates it from the coupling electrode, a conducting sheet of aluminum foil or silver paint. Silver paint is used for the conducting boundary of the Teledeltos paper. A circular map made of these materials is illustrated in Fig. 1. A uniformly distributed source region is represented since the dielectric is uniform in thickness. This map could, for example, represent the magnetic field within a circular conductor of infinite length. In operation the terminals of the mapper, that is, the conducting boundary line of the resistive paper and the conducting sheet, are connected to a source of alternating voltage. The resistance of the paper is small in comparison with the reactance of the coupling capacitor. For this reason the voltage drop across the resistive paper is a small percentage of the applied voltage and therefore a substantially uniform source of current density appears in the resistive paper over the conducting sheet. This uniform current flow represents the problem of the uniformly distributed source field. A null-type measuring circuit is used in conjunction with a probe to plot the equipotential lines on the resistive paper. These lines correspond to one set of the orthogonal system that is the solution of the desired field.

For the capacitively coupled field mapper to be a workable analogue, the current density appearing in the resistive paper must be inversely proportional to dielectric thickness; this requires that the voltage across the dielectric be the same at every point. However, the mapper works on the principle of a measureable voltage drop across the map surface. The error caused by this imperfect analogy was mathematically investigated for the circular map and found to be entirely negligible for any practical mapper.

Equivalent Circuit

A simplified circuit representation of the mapper would be useful in further work. An equivalent circuit is shown in Fig. 2. It has proved to be highly accurate for all maps thus far measured. The impedance of the coupling capacitor C is generally 100 to 500 times as large as R_S, which represents map surface resistance. The resistance R_L is apparent in measurement and is believed to denote loss in the coupling capacitor. Typical values of R_S range from 400 to 4,000 ohms. The point of maximum voltage on the resistive surface is the kernel. It is point K on the diagrams. The maximum surface voltage E_k will be referred to as the kernel voltage.

Measurement Methods

The measurement of equipotential lines presents difficult problems which may best be understood by examining conditions under which a typical mapper might operate. The resistive paper is held near ground potential while the coupling electrode is excited to a potential of about 100 volts. With average conditions, less than 1 volt will appear across the map surface. In weak field regions the voltage gradient is extremely low and precise measurements must be made if points are to be located accurately. Minor changes in C or R_S can produce large changes in the measured position of equipotential lines. For this reason the stability of mapper components is extremely important. Capacitive drift (change in coupling capacity with time) and resistive drift (change in paper resistance with time) do exist and increase the difficulty of accurate measurement. These effects will be discussed more fully later.

All of the measuring circuits tried were of the null type. A vacuum-tube voltmeter would be ineffective because of the low voltages present and accuracy required. A null-type detector has proved convenient because it can give an audible signal not demanding that the operator be continually shifting his vision from the plotting surface to a visual indicator. The low-voltage levels present indicate that steps should be taken to minimize stray couplings. This is shown to be true in actual practice, as without proper techniques deep nulls are impossible. The circuit diagrams will show where shielding is employed. A guard electrode placed near the high-potential coupling electrode is invaluable in reducing stray flux. Such a guard electrode is shown in Fig. 1. A sensitive null indicator is required in all cases. Head-

phones in conjunction with a battery-operated bridge amplifier make a good combination. A selective filter in the detector amplifier circuit is helpful in reducing the effects of hum pickup from nearby a-c lines. A sharp needle is the best probing tool since a dull point makes positive surface contact difficult. These points are applicable to all of the circuits used. Map requirements have led to the development of three basic types of measuring circuits.

The first circuit is shown in Fig. 3. The variable circuit elements R' and C are adjusted so point A has the same potential as the kernel. Any fraction of the kernel voltage may then be measured by setting the slider of R at the desired percentage of full kernel voltage. A Wagner ground circuit is used to eliminate the effects of stray detector capacity to ground. This circuit produces good nulls and satisfactory accuracy but requires bothersome adjustment of the Wagner ground circuit for each different potential measured. Capacitive and resistive drift also cause troublesome shifting in the measured position of equipotential lines. For these reasons the next measuring method is preferred.

The transformer circuit, shown in Fig. 4, gives excellent results. Not only does it use less equipment than the previous circuit but it is able to counteract the effects of capacitive drift in the map.

Fig. 7 (above). The solution of a uniformly distributed source field by two methods. The closed curves are equipotentials obtained from the capacitively coupled mapper. The set of flow lines was obtained from a sandbed fluid mapper. The excellent orthogonality of the sets shows close agreement between the two solutions

The transformer gives a 180-degree phase shift so that point A may be adjusted to the same potential as the kernel. Capacitor C serves to correct phase shift in the transformer and its associated circuit. Since the equivalent capacitor of the map has by far the highest impedance of the series circuit, it is the main factor in controlling the total current through the map and the transformer primary. Thus, the voltage across R may be conveniently adjusted by changing R'. If the reactance of the map capacitor should increase slightly due to drift, then the current through the circuit would decrease slightly. This in turn would cause a slight drop in the kernel voltage and in the voltage across R. Since the potential of the kernel and point A rise and fall together, capacitive drift has no effect on circuit balance. This method does not compensate for the effects of resistive drift which may be minimized by proper handling of the resistive paper. The circuit is easy to adjust as there is only one control to change in measuring different potential lines. The stray capacity C_S can cause trouble if R is too large. Operation has been satisfactory if R is kept below about 500 ohms. This can easily be done by governing the turns-ratio of the transformer. In all maps measured a turns-ratio of n_1/n_2 equal to four has been satisfactory. A bridge-type transformer provides excellent isolation. It should be noted that the guard electrode is not returned to ground but is shunted across the oscillator. This has been found necessary to make certain that the transformer carries current governed only by the map capacitor; otherwise, the circuit would not completely counteract capacitive drift.

A vacuum-tube circuit is shown in Fig. 5. The measuring resistance R takes the form of a load in a cathode-follower amplifier. The step-up transformer is necessary since the voltage gain of the stage is less than unity, and since the cathode-follower input voltage is less than the kernel voltage. The grid terminal of the tube is kept in contact with the map somewhere near the kernel. Map loading is negligible because the input impedance of the tube is exceedingly high. Since the voltage across the measuring resistance varies as the voltage across the map, the circuit responds to neither capacitive nor resistive drift. This circuit is effective in operation only if the tube potentials are carefully stabilized. The measuring method has all the advantages of the transformer circuit, but does require more equipment.

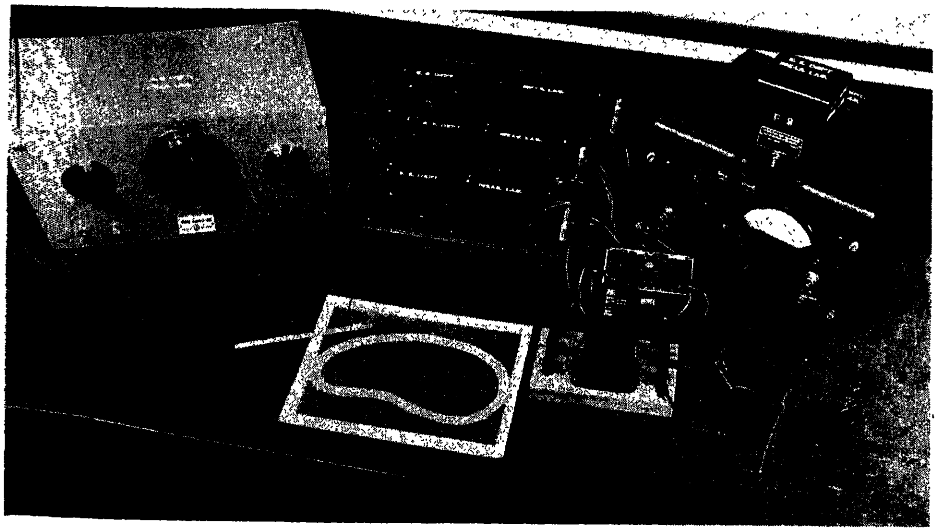

Fig. 6. A typical experimental setup. The transformer measuring circuit is used

The transformer circuit has been found very satisfactory and has been used in the majority of measurements. With proper control of resistive drift it is accurate, simple, and easy to use. A typical setup is pictured in Fig. 6. There are, no doubt, many other methods which will give excellent results. The examples given show what can be done with suitable circuitry. The choice of method will depend upon the user's requirements.

Causes of Error

Errors in line positions are due to five causes: inaccuracy of measuring equipment, voltage drop across the map surface, nonuniformity of the dielectric, nonuniformity of the resistive paper, and boundary fringe flux. As mentioned before, errors due to surface voltage drop are extremely small in a practical mapper. This type of error is roughly proportional

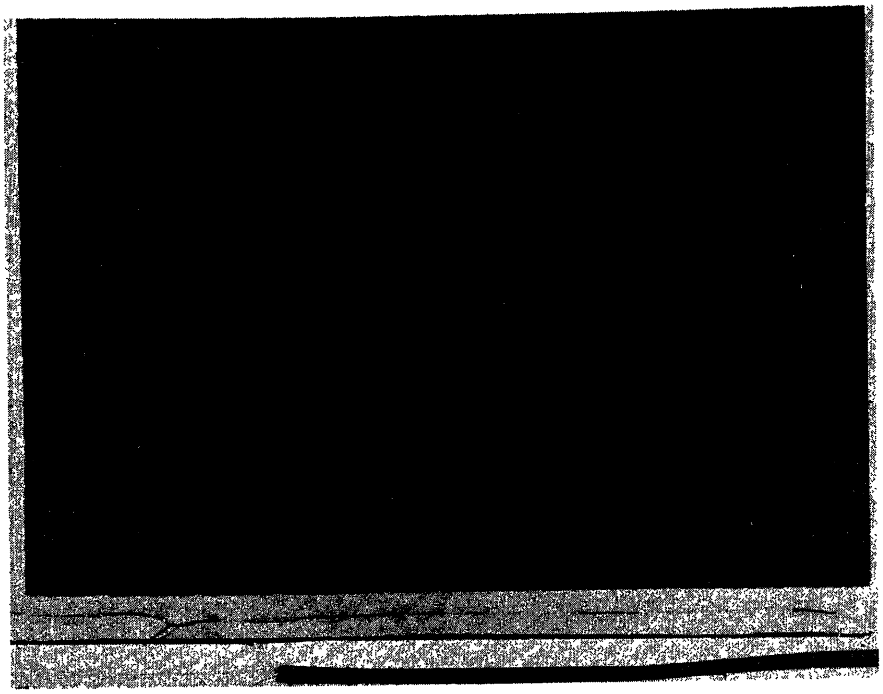

Fig. 8. Actual mapper representing the magnetic flux within a rectangular duct of infinite permeability and length. The duct holds two rectangular, symmetrically placed conductors with equal, uniform current densities in the same direction. Shown is the left half of the duct with the centerline at the right. One of the conductors can be seen in the lower left corner. Shown are flux lines and the kernel K

to distributed source area, the resistance per square of the paper, and the admittance per unit area of the capacitor. For a circular map of moderate area (100 square inches), thin paper dielectric (several mills), and usual frequency of operation (1,000 cycles per second), the maximum error in line position from this source is less than 0.01 per cent of the map diameter. Since the upward current density is dependent upon the dielectric thickness and the dielectric constant, these factors must be carefully controlled if accuracy is to be achieved. A homogeneous dielectric of high dimensional accuracy is necessary. Care must also be taken to insure the uniformity of the adhesive layers which are used to assemble the map. Another source of error is resistive paper nonuniformity. The nonuniformities of Teledeltos paper will be discussed in some detail later. At the edge of the conducting sheet the flux to the conducting paper will not change abruptly because of fringe flux effects. This fringing can cause a slight error at the distributed source boundary. It is believed that this error is extremely small in a practical map where the dielectric thickness is small compared to map area. When boundaries of the resistive paper and the coupling electrode coincide, the fringe flux may be eliminated by extending the coupling electrode. This has been done in Fig. 1.

Conducting Paper

Teledeltos paper has proved to be a good resistive surface medium. It is readily prepared and maps of great complexity can be built quickly at negligible cost. Conducting boundaries are simply applied using silver paint. The paper is available in two types, high and low resistance. The low-resistance paper, type *L-39*, has a resistance of approximately 2,000 ohms per square and is used because it gives less surface voltage drop.

Teledeltos paper is not perfectly uniform in its resistive properties. The major variation in resistance seems to depend on direction of current flow. A maximum difference in resistance occurs when current flow is first parallel and then perpendicular to the direction in which the paper was rolled. Variations as high as 16 per cent and as low as 2 per cent have been measured in different samples. If selection of the paper were possible, this error could be eliminated or greatly minimized. The error in line position caused by this variation depends upon map geometry. In most cases the error is very small. Other relatively minor nonuniformities are believed to exist. It is hoped that a resistive paper of high uniformity will be made available for mapping purposes. Such a paper would have great value for mapping either Laplacian or Poissonian fields.

An important factor in the use of Teledeltos paper is its sensitivity to moisture. Changes in humidity have produced resistance variations in excess of 1 per cent. Such variations are the main cause of resistive drift. The drift can be minimized by proper map construction. The face side of Teledeltos has a dull finish and is quite porous while the reverse side is shiny and nonporous. If the face side is removed from air contact by cementing it to the dielectric, the drift will be quite small. Hand moisture can cause noticeable drift and it is advisable not to touch the map while plotting. If it is desired to eliminate drift completely, it can be done by coating the paper with a thin layer of acrylic plastic from a spray-type bomb. This practice is not recommended unless necessary since it makes probing quite difficult. In most cases the first precaution is entirely adequate.

Dielectric Material

There is a problem in finding dielectric materials that are homogeneous and dimensionally accurate. The problem is further complicated if an effort is made to eliminate capacitive drift. The form of mapper construction makes it extremely difficult to construct a stable coupling capacitor. It is better to eliminate the effects of capacitive drift by suitable measuring circuitry than to eliminate the capacitive drift itself. If high accuracy is not needed, common dielectrics such as paper and plastics may be used. A good grade of window glass is an excellent material since it is dimensionally accurate (within a few per cent), resistant to attack of adhesives, and easy to obtain. The final choice of a dielectric will depend on how severe the user's accuracy requirements are.

Map Construction

To illustrate possible map-making techniques, the construction of a uniformly distributed source mapper will be described. The dielectric, in this case a sheet of glass, is sprayed with acrylic plastic until it is just wet. The Teledeltos paper is then applied and rolled smooth. Considerable pressure on the roller is necessary to remove excess plastic and to insure a uniform plastic film. The uniformity of the film may be checked easily by viewing the paper through the glass. Since the plastic sets fairly rapidly, some speed is required in executing these steps. This method of assembly is fast and produces results far superior to those using the more common cements, glues, or pastes. The coupling electrode may be of either silver paint or aluminum foil. The foil is quickly applied, using the same technique as is used with the Teledeltos paper. If small bubbles appear they can be removed easily, by piercing them with a pin and then rolling them flat. Correct foil uniformity will result in a mirror-like surface. The foil should then be trimmed so that it covers only the area where distributed flow takes place.

The silver paint is useful in the patching of torn foil. Silver paint may replace the foil but its application is more time-consuming and costly. The map is then ready for its associated wires, conducting boundaries, and guard electrode.

Conducting boundaries are easily affixed to the Teledeltos paper with silver paint. The silver paint is a commercially available product used in printed circuit work. Where high accuracy is desired, the paint may be applied with a ruling pen. A boundary width of 3/8 inch has been found adequate. Tape is used to hold the wires in contact with the map boundaries. Electric connection is then made by daubing the wires to the boundaries with silver paint. To assure high conductivity such connections are made every few inches. The wires may be held more securely if they are kinked or looped. Connections to the coupling electrode are made in the same manner. To protect the map and its connecting wires, it is helpful to mount it on stiff cardboard. A foil guard electrode is cut slightly larger than the coupling electrode and is affixed to the top of the mounting cardboard with cement. A lead is then attached to the guard electrode and a hole punched through the cardboard and guard electrode for the capacitor lead. A sheet of paper is used to separate the guard electrode and the bottom of the coupling electrode; the components are then assembled and taped together. When the shield wire is attached and secured to the mounting cardboard, the mapper is ready for operation.

Fig. 9. An area in the xy plane used in the development of Poisson's equation

Results

The accuracy of the capacitively coupled mapper is good. A circular map as in Fig. 1 was constructed with a glass plate dielectric with a diameter of 20.0 centimeters. The maximum error in equipotential line position was less than 0.1 centimeter. Average error was much less. Complex fields have been checked with sandbed fluid mappers. Such a check is shown in Fig. 7. The fluid map is by Prof. A. D. Moore. Excellent orthogonality of equipotential lines and representative fluid flow lines indicates close agreement. The fluid flow lines also seem to originate from the kernel which was found by the capacitively coupled mapper.

Fig. 8 shows an actual mapper as used to solve a magnetic field problem. Note how the symmetry of the problem enables the mapper to be simplified. The current enters the resistive paper in the distributed source area at the lower left. It leaves from the conducting boundaries at the top, left, and bottom. Here the equipotentials represent magnetic flux lines. No refraction of flux lines occurs at the distributed source boundary. This is as it should be when the permeabilities are the same on either side of the boundary.

Conclusion

At present the accuracy of the mapper is limited by resistive paper and dielectric nonuniformity. Even so, results obtainable are excellent. The maximum error in line position should not exceed 1 per cent of the maximum map dimension and average error should be much less. The time involved in making and using a mapper such as the one described is in the order of 3 to 4 hours. The value of any potential line can be determined easily. In most cases the equipotential lines are the ones desired in the final solution.

The mapper should easily be applicable to regions of nonuniform displacement current density. Though such a mapper has not yet been constructed, little trouble is anticipated. The method of capacitive coupling might also be applied to the electrolytic tank, by-passing the problem of nonuniform resistive paper. The electrolytic tank might also make possible the solution of 3-dimensional fields with axial symmetry.

Appendix

If the capacitively coupled field mapper is to solve 2-dimensional fields of the distributed source type, it must satisfy Poisson's equation. In the following development the voltage drop across the resistive paper is considered very small in comparison with the applied voltage. Therefore the displacement current density appearing in the resistive paper is inversely proportional to the dielectric thickness. Let J equal the displacement current density at any point in the distributed source area. Let K equal the resistance per square of the resistive paper. Consider the sum of the currents leaving a small area in the xy plane as shown in Fig. 9.

$$\frac{\partial I_x}{\partial x}\Delta x+\frac{\partial I_y}{\partial y}\Delta y+J\Delta x\Delta y=0 \qquad (1)$$

The voltage drops across the area are

$$\Delta V_x=\frac{\partial V}{\partial x}\Delta x=I_xK\frac{\Delta x}{\Delta y}$$

$$I_x=\frac{1}{K}\Delta y\frac{\partial V}{\partial x}$$

$$\frac{\partial I_x}{\partial x}=\frac{1}{K}\Delta y\frac{\partial^2 V}{\partial x^2} \qquad (2)$$

$$\Delta V_y=\frac{\partial V}{\partial y}\Delta y=I_yK\frac{\Delta y}{\Delta x}$$

$$I_y=\frac{1}{K}\Delta x\frac{\partial V}{\partial y}$$

$$\frac{\partial I_y}{\partial y}=\frac{1}{K}\Delta x\frac{\partial^2 V}{\partial y^2} \qquad (3)$$

Substitute equations 2 and 3 in 1 and the result is

$$\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}=-KJ$$

which is Poisson's equation for two dimensions.

Discussion

Walter E. Rogers (University of Washington, Seattle, Wash.): This is an important paper, and the Gilbert twins are to be commended for their contribution to a field in which there is such general interest. I look forward to the extension of their development to nonuniform distributed sources, something which has not been achieved with the sandbed fluid mapper or the membrane analogue.

I would like to point out that while the electrical measurements discussed here are rather elaborate and time-consuming, they are certainly not more so than are the presently used methods[1] of measuring the displacement of a soap film or rubber membrane; nor is the electrolytic tank without measurement difficulties. The capacitively coupled field mapper is superior to the sandbed in the matter of fine detail and in the exact location of the kernels. This is an opinion which would be substantiated, I think, if the authors and Professor Moore would submit a photograph of the original sandbed map of Fig. 7 of the paper with their answer to this discussion.

Analogues are important academically because they are an invaluable aid in the challenging problem of teaching students to visualize potential fields. We plan to include the Gilberts' development along with Professor Moore's fluid mappers and some membrane analogues which are presently used in our laboratories at the University of Washington. To this end, would the authors please state how the loss resistance R_L of their equivalent circuit becomes apparent in the measurements? Is it that points A and K in Fig. 3 of the paper are not at the same potential unless R' is included?

There is one other detail in the paper which needs clarifying. Are the equipotentials, which surround the kernel in Fig. 8, taken at equal increments of potential with respect to that of the kernel? In the region of the kernel, the gradient seems small in comparison with Fig. 7. I observe, however, that a vertical line through the kernel and a horizontal line to the left of the kernel are both stream lines. This indicates that the kernel is correctly located.

REFERENCE

1. See reference 2 of the paper.

J. H. Fooks (Westinghouse Electric Corporation, Sharon, Pa.): The authors are to be commended on their excellent contribution to experimental mapping methods. The thoroughness of their investigation with regard to errors involved and, particularly, their solution of the capacitive drift problem via the transformer measuring circuit should clear the way for the immediate application of this method to industrial field problems.

The possibility of simulating nonuniform displacement current densities by varying dielectric thickness was of particular interest. This is readily accomplished in a fluid mapper by using a sandbed of varying depth. Offhand, I cannot see how this could be done easily in a capacitively coupled mapper using a reliably uniform dielectric material such as glass. Considerable care would have to be given to the selection of a more workable material. Perhaps the authors would care to say how this might be done.

The time involved in constructing and operating a capacitively coupled and a fluid mapper is, perhaps, much the same if the fluid mapper is carried through to a finished photograph of the field.

Almost all of our application of experimental mappers has been confined to 3-dimensional fields of axial symmetry. Fluid mapping is readily adaptable to this case by varying the flow spacing, whereas the capacitively coupled mapper must await the advent of a suitable resistance paper. It is not inconceivable that such a paper might be forthcoming. The capacitively coupled 2-dimensional mapper might be used to approximate the solution of a 3-dimensional field or to show field trends. This has frequently been done mathematically to simplify methods of solution.

In the past, the tools of experimental mapping methods and field mapping have not been used to any great extent in field instruction or problem solving. This has been unfortunate since the visual analysis of fields and field trends provides the quickest and most lucid solution of field phenomena with reasonable accuracy.

Within the past several years experimental mapping has received a tremendous stimulus through the excellent work of Professor Moore in the invention and development of fluid mapper methods. It is gratifying to see the interest in this development and the trend in new text material to include sections on practical mapping methods.

It is to be hoped that, with the availability of fluid mappers and similar experimental methods such as described in this paper, the visual simulation of field phenomena will receive its due recognition.

A. D. Moore (University of Michigan, Ann Arbor, Mich.): Learning about sandbed fluid mapper methods for simulating the distributed source, the authors soon turned to the invention and development of the new analogue they have so ably reported on in their paper.

The equipotential lines obtained by their method are orthogonal to the flow lines obtained over the sandbed, in a given case. They have applied their method to several sandbed cases already available from the writer's work, and came out with a high degree of correspondence. This, by the way, constitutes a check on both methods.

Professor Rogers indicates that simulation of nonuniform distributed sources has not been achieved with sandbed fluid mappers. Rather, it has been achieved but not yet reported. The writer has built a slab with a rectangular sandbed, in which a sloping screen makes the sandbed depth vary by a ratio of 3 to 1 from one end to the other. The flow density appearing on top of the bed then is nonuniform, varying approximately inversely as the sandbed depth. In addition to sloping the screen, there are at least two other methods for achieving nonuniform distributions with the sandbed.

The Gilbert contribution is a welcome addition to our knowledge dealing with fields. Field problems constantly arising are of such range and complexity that we need all of the analogues we can get.

J. F. Calvert (Northwestern University, Evanston, Ill.): The authors are to be congratulated on the development of what I believe to be an entirely new approach to the solution of 2-dimensional fields with distributed sources. It would appear that they have devised a method which can be readily used by any engineer and scientist with normal skill in electric circuit and measurement techniques, and it would seem safe to predict that this method will be generally accepted. I hope the authors will (1) show several more examples of the results obtained by this technique; (2) discuss the possible extension of the equipment to 2-dimensional problems where the distributed sources are not of uniform strength; and (3) further discuss the possible applications to 3-dimensional fields, including the probable difficulties and limitations as they may see them at this time.

W. R. Simmons (Argonne National Laboratory, Chicago, Ill.): The analytical solution of problems involving Poissonian or distributed source fields has always been a long and tedious task except for those few cases where known solutions exist. The method described in this paper will expedite the solution of many of these 2-dimensional problems. This method should be of interest to the engineer since most practical engineering problems involving Poissonian fields do not have known solutions. Further, it should be noted that the materials required to set up a problem by this method are inexpensive and answers with sufficient accuracy for engineering work can be rapidly obtained.

The method described in this paper may be particularly valuable in solving 2-dimensional heat transfer problems which involve Poissonian fields. This type of problem constantly confronts the nuclear heat transfer analyst. By suitable construction of the analogue, heat transfer problems involving any or all of the following conditions can be solved: (1) Poisson fields; (2) Laplace fields; (3) materials of various thermal conductivities; and (4) convective heat transfer from a surface to a fluid.

Poisson fields can be built up in a number of ways. However, the method devised by the authors is one of the more ingenious methods. The Laplace fields are obvious since only conduction is involved.

Materials of different thermal conductivities (or resistivities) can be simulated by constructing the analogue so that more than one path of the same shape is available for the electric current. These parallel paths can be electrically connected by carefully applying silver paint in a discontinuous manner around the boundaries.

Convective heat transfer from a surface to a fluid can be easily included in an analogue constructed from Teledeltos recording paper. This is one of the principal advantages of an analogue of this type. This is accomplished by adding to the surface where convective heat transfer takes place an additional length of Teledeltos recording paper. This additional length should be equal to the ratio of thermal conductivity to the heat transfer coefficient (k/h) in order to properly represent the film resistance. This additional length (k/h) of conducting paper must be cut in strips perpendicular to the surface from which the convective heat transfer occurs. This insures an electric current flow which will be orthogonal to this surface. In this manner problems involving 2-dimensional Poissonian fields and convective heat transfer from nonisothermal surfaces can be readily solved.

The heat transfer section of the Argonne National Laboratory has developed a similar type of analogue. However, we approached the problem somewhat differently. We are primarily interested in actual temperature differences associated with certain heat flows through Poisson and/or Laplace fields with convective heat transfer from a nonisothermal surface. Therefore, we have developed a d-c system which gives us directly values which are proportional to temperature differences and does not involve evaluating a conformal map.

Edward O. Gilbert and Elmer G. Gilbert: The authors appreciate the interest shown in the capacitively coupled mapper. It would be well to clarify the points mentioned by Professor Rogers. The potential lines in Fig. 8 of the paper have values of 0.8, 0.6, 0.4, and 0.2 E_k with the singular point at 0.246 E_k. Potential lines in Fig. 7 are at 0.9, 0.8, 0.6, 0.4, and 0.2 E_k. The presence of R_L is directly known from the settings of R and R' in Fig. 3. It is apparent that R_L is not detected by the other circuits. Note that K and E_k are not known initially, but must be determined by a series of rapidly convergent trials.

The resistive paper modifications discussed by Mr. Simmons should prove very useful. Values of resistance per square had by paralleling resistance sheets are limited to discrete steps. An array of small, uniformly spaced conducting dots would provide another approach to the problem. Such an array might be applied to the resistive paper using a stencil and silver paint. It is hoped that more versatile resistive materials will be developed by someone in the future. The electrolytic tank could handle wide changes in resistivity with some increase in physical complexity. Capacitive coupling to a tilted tank would facilitate the solution of 3-dimensional problems with axial symmetry. Here, the dielectric material would form the bottom of the electrolytic tank. The additional problems encountered should not be too great as electrolytic tank methods are well advanced.

The nonuniform distributed source can be generated in several ways. A multilayer dielectric could be formed in contour fashion to provide a step approximation to a desired thickness function. Dielectrics such as celluloid, vinyl plastic, and paper have proved reasonably successful in constructing uniform source mappers; their extension to multilayer dielectrics should be convenient and inexpensive. Displacement current errors of less than 10 per cent are foreseeable. Even better accuracy would be possible with machined dielectrics. A subdivided coupling electrode and a uniform dielectric would allow a more versatile approach. Each segment of the coupling electrode could be assigned a desired current. One mapper could then solve problems with many different distributed source configurations.

The authors hope that this brief discussion will answer the questions of Professor Calvert and Mr. Fooks. Development of the modifications mentioned should greatly increase the usefulness of the capacitively coupled field mapper.

Reliability in Industrial Electronic Equipment

ELLSWORTH D. COOK
ASSOCIATE MEMBER AIEE

THE EXPECTATION of the purchaser of industrial equipment is no different from that of the purchaser of any other form of equipment or, in fact, from our own when we purchase things for use or pleasure. Reliability is expected. Such reliability, however, includes more than long life, important as that may be; it also means long periods of freedom from readjustment and similar annoyances. The following observations relative to factors which enter into such reliability were obtained from experience in the field of industrial electronics, especially as found in the heavy industries. A word of caution is in order at this point: The impression that electronic equipment is hopelessly involved with repeated failures is not a true one. What is reported as in need of correction is actually based upon the known facts that performance to date has been such as to commit industry to the use of electronic means, and that the desired improvements are possible and worthwhile.

It is unfortunate that no magic formulae exist by which equipment can be produced with the desired reliability. The means of accomplishing the objective are known to all of us, but have something in common with certain medicines in that we would prefer not to have to use them. Like medicines, since the ideal ones are not yet available, we use those remedies we know and have.

Since sufficient improvement in component reliability has not yet occurred which automatically would permit a major improvement in equipment reliability, engineers must use such expedients as their combined experience shows to be helpful. These are the simple, commonsense, but totally unromantic methods of established good engineering practice in design, installation, maintenance, and service. What must concern engineers for the present, therefore, is continued emphasis on these practices and further extension of their use. While all of these functions are important, at the present time most emphasis must be placed on good design; first, of the component and, second, of the equipment. However, because the methods cited for the equipment as a whole have a limited effectiveness, emphasis must be given to the encouragement by word and other support to the component manufacturers in their efforts to improve the reliability of their products.[1]

With so many electronic engineers involved in military developments, it sometimes comes as a surprise that the field of industrial electronics is experiencing a substantial expansion. With this expansion, the need for greater emphasis on reliability is increased. There is a need for wider understanding of what makes one piece of equipment reliable and another unreliable in each field, and there is a need for better knowledge of how to keep good equipment in reliable operation. While the technical subject matter is not materially different in the various fields of applied electronics, the emphasis placed on the various elements do differ to a marked degree. Thus, in the broadcast field, it is essential that the program stay on the air; but in the power field, where production, and even life itself, is sometimes jeopardized by failure of equipment, the need for guaranteed performance reaches a new order of magnitude. Perhaps the fact that in America the clocks of so much of the nation now depend upon the power system will illustrate this expected freedom from failure. In heavy industry, experience has shown that failures are most frequently due to faults of a mechanical nature. Thus, mechanical design is likely to be every bit as important as the purely electronic aspects of the device, and designs which

would be mechanically acceptable in the radio field cannot be tolerated in heavy industry.

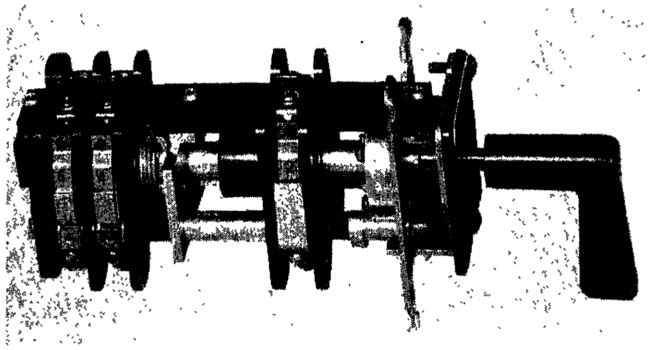
Design Aspects of Reliability

It is not of so much importance that a unique and efficient electronic circuit be provided as it is that the equipment be able to stand the every-day treatment which is normal in that industry. The use of such industrial equipment dictates many aspects of the design insofar as the desired reliability is concerned. Choice of materials which may be used and knowledge of methods of fabricating often assume new importance. Equipment which must be located beneath the pass line in a hot-strip steel mill will be subjected to heat and a bath of water, steam, and scale, and in many installations the water will, without doubt, be contaminated with acids. From Fig. 1, the normal habitat of such equipment may be seen. Unquestionably a stainless-steel tank would serve admirably as the cabinet, but if this tank must also hold light insulating oils, it is by no means certain that stainless steel should be used. The question of how to weld such a structure to retain the oil would now assume a far greater importance than whether or not to use degeneration in some amplifier within such a cabinet.

Ordinarily, enclosing cabinets for electronic equipment would not be considered in a discussion of reliability. However, if they are not reasonably dust tight, or are not built so that parts are readily accessible for service and inspection, these functions are likely to be slighted to the detriment of the performance. Fig. 2 shows a recent improvement that offers much in that regard. The swinging inner panel, the large flat surface to apply dust and moisture sealing gaskets, the strong handle which closes the cabinet under great pressure against these gaskets, and the minimum of cracks and openings have been found to be definite improvements over cabinets used previously in industrial applications.

In examples such as the above, another design problem can arise. Totally enclosed cabinets can accumulate considerable moisture due to repeated alternate heating and cooling. Cases have been found where the connection cables breathed, permitting moisture to enter. This entrapped moisture can lead to equipment failure in many ways, not all of which are immediately obvious, but one of the more well-known ones is due to creation of acids. In this connection, moisture-absorbing drying agents are not always an adequate solution, and, in certain industrial equipment it has been found profitable in some applications to keep a cabinet interior under pressure with moisture-free inert gases, as a means of increasing the reliability of performance.

The design of mechanical parts, methods of fastening, and support of components are of importance in all products, but these considerations must receive different treatment in different fields. The mechanical stops used on certain switches and similar parts may be entirely acceptable in certain fields, but in industrial use, these can be the reason why that part is not acceptable, and this fact must be considered by the designer in obtaining system reliability. Fig. 3 shows an example of an industrial power switch which has provided good service in electronic applications in industry. Its sturdy handle, stops, and other parts are especially noticeable. In one field, it may be just as important to successful operation to use good insulation to support high-voltage components as in another, but where heavy industry is concerned a different approach is generally needed. The configuration of insulating material may be of no consequence in certain devices, while in others operating at high voltage, it may be a



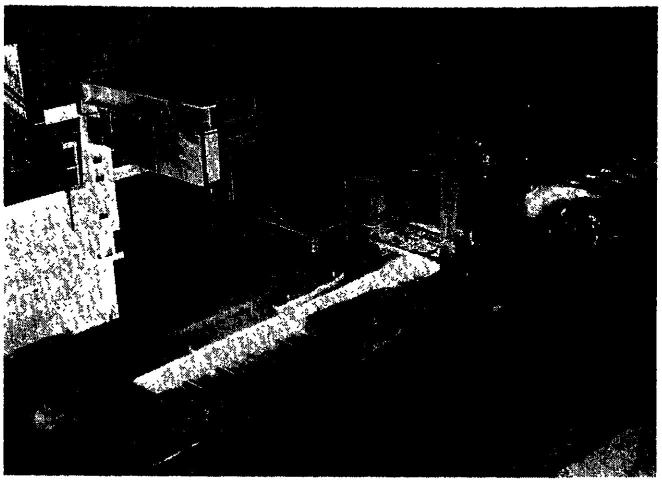


Fig. 3 (above). Heavy-duty rotary switch for industrial use

Fig. 4 (right). First installation of noncontacting width gauge on hot-strip steel mill at Irvin Works

cause for ionization currents and frequent breakdown.

Several examples will show the nature of these differences in approach. The crowded component boards of certain miniaturized electronic equipment are a hazard in industrial electronic devices. Larger creepage distances are desirable. Where a tapped hole may be used in a piece of fabricated insulation of the resin-bonded variety and a component may be fastened to it by means of a machine screw in equipment which will be handled with care, equipment intended for applications where the vibration of heavy industry is involved requires either a threaded metal insert, so installed as to avoid splitting of the insulation under normal operating conditions, or a clearance hole through the insulator with metal clamp pieces on either side must be provided. Shock-mounted components may be necessary to avoid microphonics in almost any field of applied electronics, but the materials which serve for communications work cannot always be used, without incurring a service problem in industrial electronics. Materials like rubbers do not maintain stable positions of rest and when subjected to heat, strain, and certain atmospheres, sometimes lose their desirable characteristics. In such instances, spring filter systems and mechanical-type shock absorbers are often necessary. In other cases, in which an electronic engineer might ordinarily employ shock mountings, equipment must be operated so that certain components will maintain fixed positions relative to other devices. Here other means to eliminate the effect of vibration must be found. For example, it was desired to use an X-ray tube, originally designed for diffraction work, in an electronic device for cold-strip steel mills. The massive parts, mounted on a glass structure, would not tolerate the increased vibration encountered and, because the X-ray source had to maintain a fixed relation to the detector unit, shock mounting was impossible. In such cases, either a different or a redesigned tube would have to be employed. Fortunately the latter alternative was possible.

The use of some methods of mounting parts, such as those employed with certain transformers, where a few holes are provided in a thin metal base, and which might be acceptable in some fields of electronics, would be totally unsuited in the heavy industry field. The transformer case would have to be redesigned for the more severe handling it would encounter. Heavy tubular-paper condensers which are sometimes mounted on their connection wires in a radio chassis, or secured by means of tying or a compression clamp in other applications in this field, should be enclosed in a container which would provide greater mounting security.

Bolts which might be adequate to secure a part in ordinary use frequently have to be increased in size all out of proportion to the strength requirements, because of the frequency with which they may have to be removed, or because the service personnel is not accustomed to treating bolts with the respect of an instrument maker. Not infrequently a designer has found that if a large number of small bolts is required to secure a part, the threads of either the bolt or its mating part are stripped in service and, because of the difficulty of repairing the damage, that bolt is not replaced, with the result of ultimate failure of the component involved. Such cases arise where a cover and gasket are used to close an oil-insulated component or a pressure chamber. Regardless of the fact that certain methods of caring for the circumstance could have been found which would have prevented the failure, ultimately the orders will go out for that manufacturer's equipment, if it can be found, which was designed to avoid that circumstance. For similar reasons, it is found, not infrequently, that otherwise useful equipment will be unused if too much trouble of this sort is experienced.

Another problem frequently encountered in the design of reliable industrial electronic equipment, which is not common to most other electronic designs, is that of lubrication. Industrial electronic equipment frequently requires motors of fairly respectable size to move its parts, or has accurate mechanical parts such as gear systems, levers, ways, slides, or guides which demand metals having certain wearing properties. Certain of these may require the use of steel which should not be plated. Such items require lubrication for one reason or another. An example may be in order: It was necessary in a recent industrial device to move two assemblies weighing about 40 pounds each with some appreciable accuracy in regard to position and path of travel. The installation of this equipment is shown in Fig. 4. Therefore, the supporting member upon which this motion had to take place had to be strong, rigid, and resistant to wear. Steel was the final choice of material, and the surface could not be plated to prevent rust and corrosion. This structure is shown in Fig. 5. Therefore, it was necessary to provide lubrication, not so much because it was desired to reduce friction, although this was important, but mainly to prevent rust and corrosion. Since the device was exposed alternately to long periods of high temperature, followed by a shorter period of low temperature, sometimes in the freezing range, condensation of atmospheric moisture was inevitable. Thus, the method of lubrication and the choice of the lubricant presented a considerable problem. The solution was a special lubricant, and

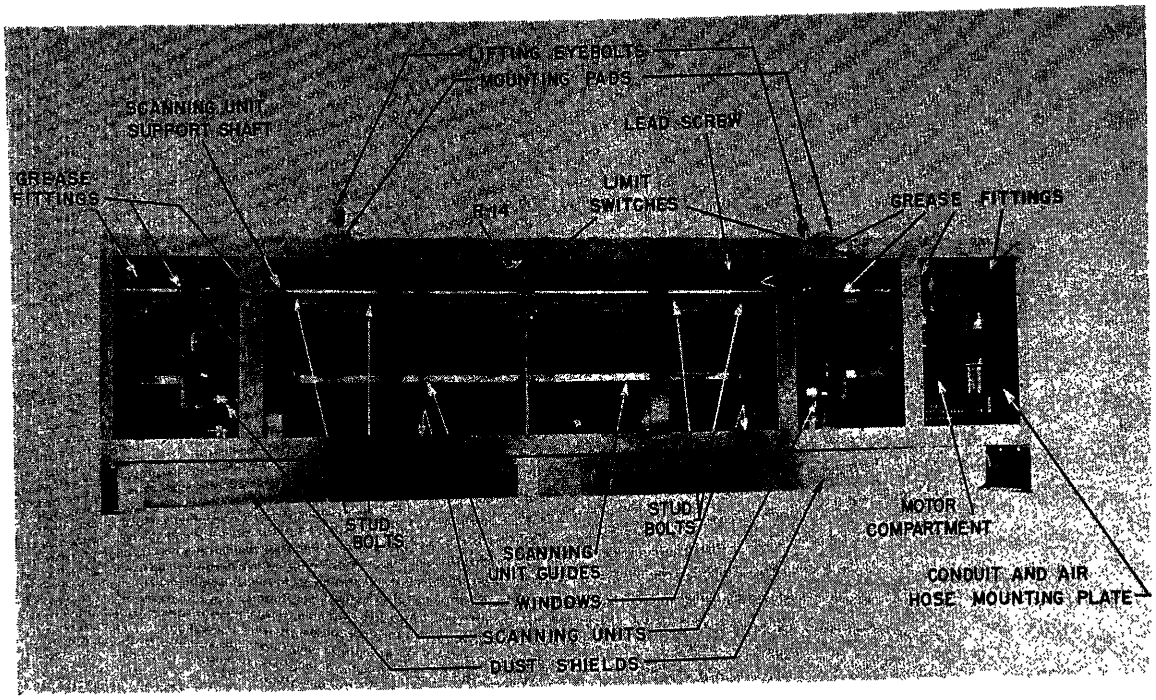

Fig. 5 (left). Detector head for width gauge (covers removed)

a method of keeping the surface properly covered at all times had to be found. The assembly in question is shown in Fig. 6. Had this problem been "solved" by inserting a note in the Instruction Book to the effect that a regular daily schedule of lubrication would be necessary, the equipment would have been subject to more down time than would have been acceptable, and it would ultimately have been removed from the production line because rust and corrosion would have ruined the ways, after which failure to give the desired service would have occurred.

Lubrication is frequently a design problem because of the choice of proper lubricant, or because of the necessity to find a simple way to provide for its renewal. It may be necessary to drive a potentiometer or a mechanical counter at a speed which requires gears, and it is astounding how frequently the designer makes no provision for lubrication other than to expect the user to put a little oil or grease on the gears occasionally. A part which is hard to reach in order to renew the lubricant will be neglected. This is too frequently the condition met in industrial design, so in any list of the problems such a designer must face, the problem of lubrication cannot be neglected if reliability is important. It is fortunate indeed that in this field it is not often that the temperature range must be as wide as it is in certain military equipment.

Heat introduces another problem in industrial design and must be considered in the design of reliable equipment. Of course, most designers attempt to keep temperatures within acceptable limits; it is normal to locate components so as to avoid causing overheating of other parts. This is not limited to the industrial field, but there are some environmental conditions which pose special problems from a reliability standpoint. Many industrial processes require large amounts of heat, and hence equipment used in such industries meets different ambient conditions than those found in other fields. Components are not always available which can withstand direct exposure, and simple means for heat removal may not always

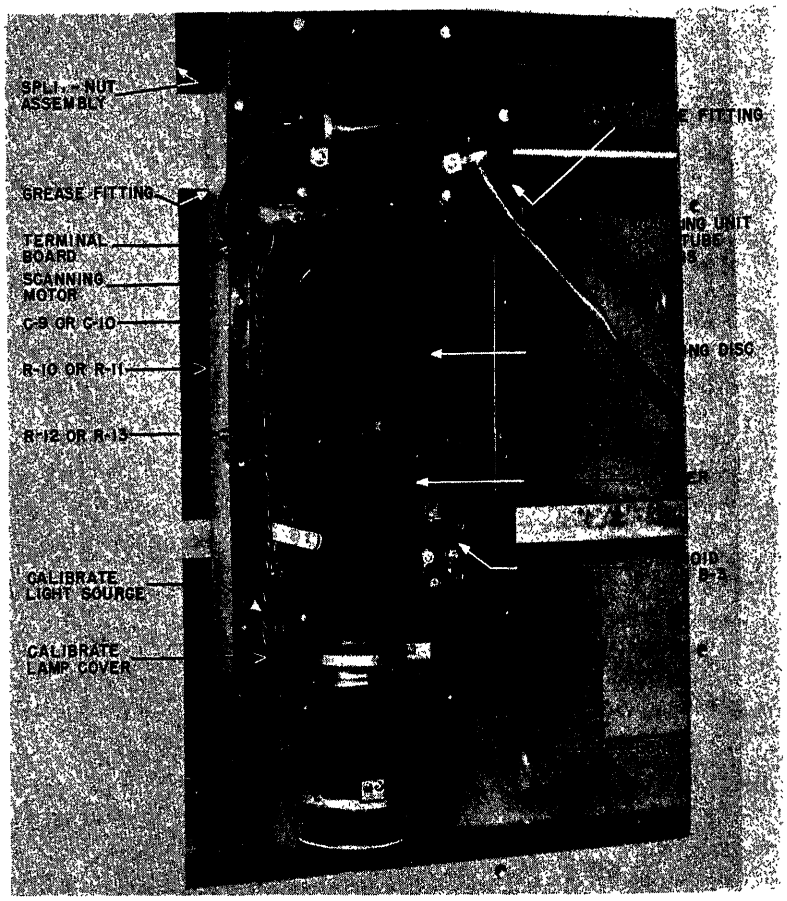

Fig. 6. Scanning unit for width gauge

be possible. Photoelectric cells, oil-filled capacitors, resistors whose values are critical (as in measurement circuits), or even transformers of ordinary design do not fulfill the reliability requirements at elevated temperatures. Yet the economics of today forces the use of electronic equipment in many instances simply because other means are not adequate or do not exist. It is not infrequent, therefore, that auxiliary cooling means must be employed. Here the designer meets two problems. These are the necessity for providing:

1. Simple and easy access for maintenance testing purposes;
2. Protective devices to announce any failure of the cooling means.

If the first is not solved, maintenance gets neglected and ultimate failure of the equipment occurs. A proper solution for the second is difficult, because some of these protective devices are reliable enough for certain fields but not for others, and a wide range of choice in such devices does not exist.

Since convenience in servicing frequently determines if not only the desirable but also the necessary things can be done in the available time, the design chosen assumes great importance in achieving service reliability. Industrial applications cannot always achieve the frequency of service testing or correction of operating deterioration which may be desirable; hence, design to obtain greater freedom from the need of frequent adjustment or a long life in a component must not be lightly side stepped by a neat phrase in an instruction book which, in effect, transfers the problem to the user. Electronic devices are prone to alter their performance due to a change of such matters as the ambient temperature or moisture, the voltage or frequency of the primary power supply, or a change of tubes. Circuits can ordinarily be designed to overcome or at least minimize many such defects, yet it is surprising how often such factors are overlooked in both the development and design stages, with the result that the equipment can be tolerated in the industrial field only if no alternative exists. A measurement instrument which requires frequent readjustment to retain its calibration, regardless of however cleverly conceived, excites far different feelings on the part of the industrial user than it did in the case of its development engineer. Cleverness of concept is of importance only if it serves without the need for greater skill or attention on the part of the user.

The statement that satisfactory reliability depends upon good design, and that good design includes proper choice of components will be readily accepted. But what is not so simple is to decide in advance what constitutes a satisfactory design or component. This becomes especially true of a new line where only a few equipments are to be built. It becomes even more difficult where the parts are purchased, and no knowledge or control can be had of the manufacturer's processes. Figs. 7 and 8 show a piece of apparatus designed as a developmental sample with what most engineers would have regarded as satisfactory components, but the design shown in Figs. 9 and 10 reveals what improvements were made in this regard when field experience, obtained from the developmental sample, was incorporated into the production design. The problem becomes more difficult when this course of events is not possible. Fig. 11 shows one part of the same equipment of Fig. 9 that endured considerable mistreatment and still was found to be in working condition when received at the factory for replacement. The problem in industrial design is to choose components which stand up under service conditions such as this equipment has endured, and then to use them in a way to favor their functioning under field conditions. It is a disheartening experience to have an expensive structure fail merely because a limit switch had been chosen which had been used to prevent excessive travel of some part, and had been designed so its mounting holes permitted reassembly in a reverse manner by a service man, with the result that it did not function at the proper point in the motion of the part to be protected.

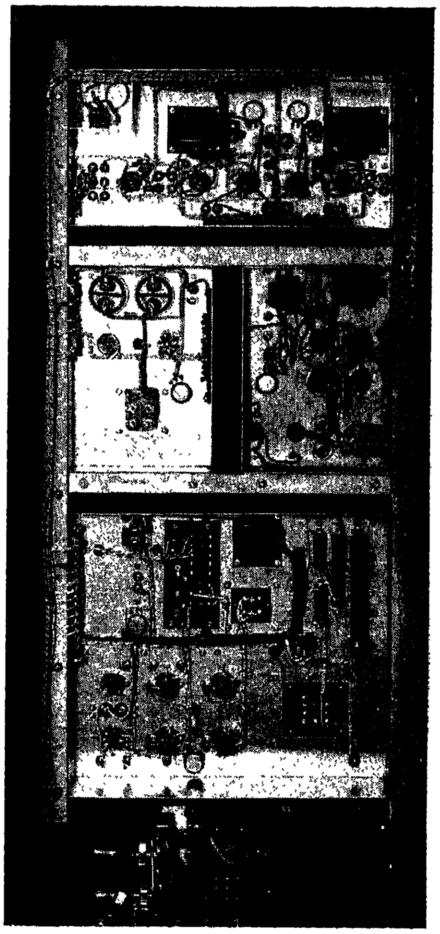

Fig. 8. Electronic cabinet for developmental sample of X-ray thickness gauge for hot-strip steel mill

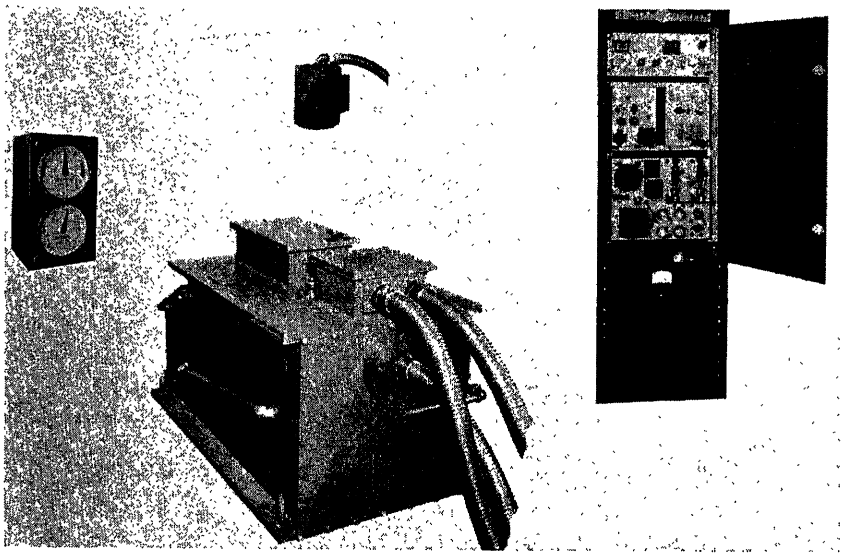

Fig. 7. Developmental sample of X-ray thickness gauge for hot-strip steel mill

In this connection, it is well to avoid moving contacts, as well as to use components well under rating. Greater freedom from motor troubles will be experienced if 3-phase induction motors are used rather than single-phase motors which have been more usual in industrial work,

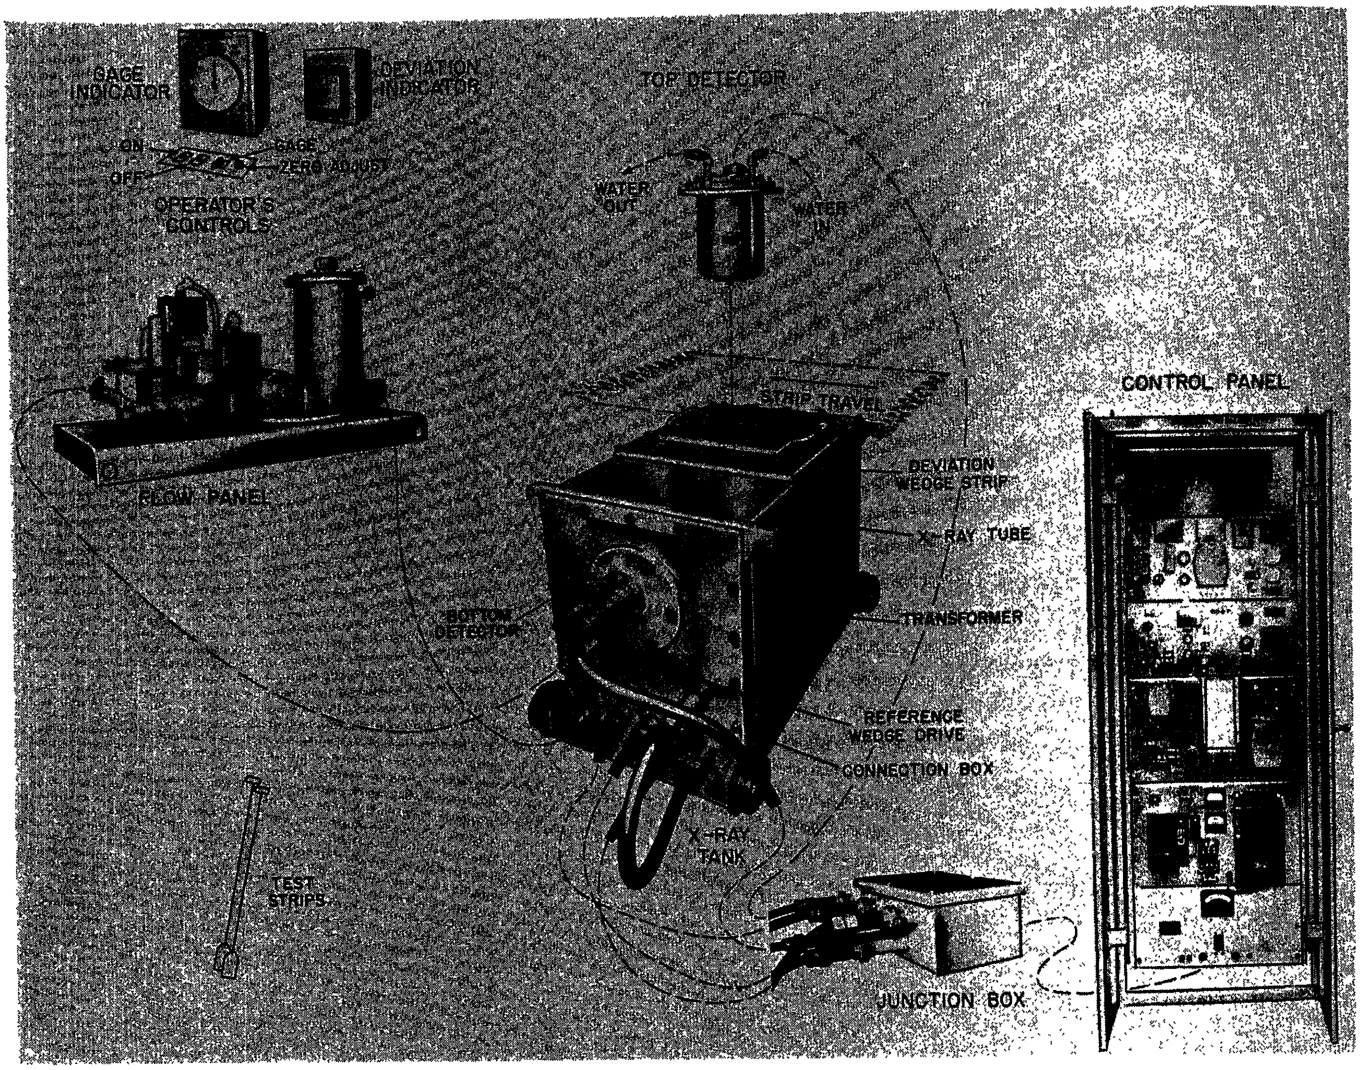

Fig. 9. Product sample of X-ray thickness gauge for hot-strip steel mill

merely because the starting switches of single-phase motors have been known to refuse to function under certain conditions of atmosphere, especially if corrosive fumes and moisture are present. Fig. 12 shows just such an application, where it was found desirable to use the 3-phase motor, and at low loading.

Connection wiring, for example, is now made with thermoplastic insulation and, under controlled conditions, it is excellent. It also has many superior properties, one of which is important where fungus is involved, but will it serve in industrial life where the combination of all operating conditions, and especially the temperature, are not exactly known to the equipment designer? Tube sockets of various designs are available, but what happens to their insulation and contacts under normal industrial use, as well as when accidents cause overheating? The literature available on purchased parts can hardly be said to be fully instructive to the equipment designer.

The designers of the components, as well as the equipment, ordinarily attempt to forsee many of the field problems, but they do not always know how the transporting agency will handle the equipment and hence may not design it for the handling conditions it will receive. Hidden damage from these causes is more serious than obvious breakage. How many transformer failures have been caused by laminations damaging insulation due to such shocks? Methods of securing parts which will withstand shipping shocks without loss of future performance have received some benefit from military electronic programs, but there is still much room for improvement. Vibration and shock in summer time is one thing, but in the icy cold of winter, parts made of rubber, or those which would receive some natural resilient protection from varnishes and such compounds, may become brittle; such conditions are frequently far different, and much more damaging to equipment. Nor can the customer wait till summer provides the conditions which may give some additional measure of protection in this manner from the rough handling involved.

Installation Aspects of Reliability

Once the equipment arrives at its destination, installation is the next step. Installation must be considered as a part of the problem of reliability. Instead of an eager installation crew, anxiously awaiting the equipment which previous correspondence relative to prompt delivery might lead one to suspect, it frequently happens that the equipment must stand around, often in rain, snow, or dirt, and be hit, moved from place to place, and sometimes even damaged before circumstances combine to permit installation. Design and packaging for such conditions must be forseen, or hidden damage may result which will not exhibit itself until some later time. Failure from this cause is just as serious as if the components themselves had failed for other reasons.

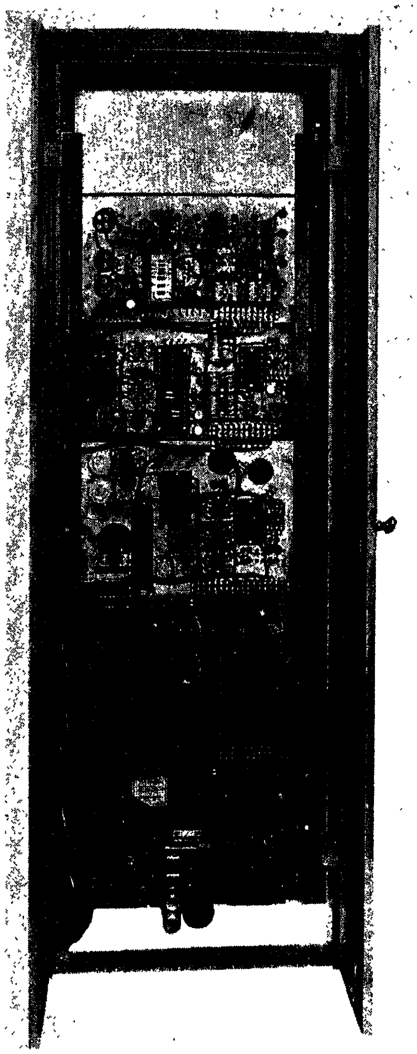

Fig. 10. Electronic cabinet for product sample of X-ray thickness gauge for hot-strip steel mill

There are other problems involved in reliable operation which arise from installation. Exposure to electrical noise is a problem that the circuit engineer is supposed to understand very well, while the mechanical engineer is supposed to understand the problems introduced by vibration. Proper operation in spite of such problems must be forseen before concrete foundations, rooms, or expensive facilities are provided to receive the equipment; otherwise, marginal utility and customer dissatisfaction are likely to result. This is part of the necessary application engineering. An equipment used to control industrial processes has to be engineered in its installation just as surely as it does in development and design. An operator's pulpit frequently requires certain location of instruments, indicators, and control accessories which may demand connection leads of such length or cause an electrical exposure which the designer did not forsee, and hence for which provision was not made. Low signal levels, poor signal-to-noise ratios, and excessive control-circuit resistance can be the reason for unreliable operation, as the other operating facts combine in varying ways from day to day.

Such a simple thing as grounding circuits can often introduce future problems which affect accuracy, and even the life of components. Examples can be cited from experience where heavy machine currents flowed through delicate electronic equipment to its detriment, merely because the ground on the electronic equipment had a lower resistance than that on the mill equipment. In such cases, the need for adequate application engineering to insure successful, as well as reliable, performance can be painfully evident. Heavy power currents in the ground system of an electronic equipment can introduce electrical noise of an amount which would seriously alter the reliable performance otherwise available from the equipment.

Another installation problem that has affected reliability is concerned with ambient conditions. Certain industries do not have clean atmospheres for electronic equipment in their mill, but often can provide such conditions only in special rooms, such as motor rooms, or out of doors. Cases have been experienced where the electronic equipment was located in a space where the ambient temperature at certain periods was such as to allow maximum hot-spot temperatures in components to approach, and even to exceed their normal temperature limits. It is one thing to meet average ambient conditions in the design, but quite another to be sure that the ambient conditions never exceed the limits set by reliable design. Long periods of abnormal ambient conditions of temperature or moisture can be as fatal to good performance as poor design would be. In such cases where this problem can be forseen in advance of design, it can be solved by using components below their normal power ratings or by applying proper protection. In cases where the design cannot be changed to accommodate what amounts to a special circumstance, special solutions must be applied. This can be the case for temperature, humidity, and fumes. Moreover, temperature cycling is also a known cause of drift in characteristics, and even in equipment failure. The point being stressed here is that the installation cannot be overlooked in any consideration of reliable performance of equipment.

Maintenance and Service Aspects of Reliability

Two final problems which must be solved in providing the customer with satisfactory performance of his equipment are those of maintenance and service. All things change to some extent; electronic equipment, at least with presently available component parts, only has a definite time period before either adjustment or repairs is needed. This is especially noticeable in equipment which performs a measurement function. Keeping equipment in proper operation is directly determined by the maintenance and service programs followed. The determination of what has deteriorated will be revealed by a regular maintenance schedule and a log of the results, while the proper repair of worn or damaged component parts will be determined by the adequacy of the service.

Experience has shown that not all customers are willing to use manpower on regular preventive maintenance schedules for electronic equipment. When, however, the problem of down time is serious enough, and electronic equipment is a vital solution to the production problem, the customer will provide for such a program if he understands its necessity. Much effort has been expended in getting greater life expectancy in component parts, but unless much greater progress is made in this regard, especially in vacuum tubes, etc., two concomitant

TERMINAL BOARDS FOR INCOMING CABLES

Fig. 12. Three-phase motor drive for cameras in detector head of width gauge for hot-strip steel mill

things are inevitable:

1. The application of electronic devices to industry will be greatest in essential fields and where no other methods serve adequately;
2. Regular preventive maintenance programs will be unavoidable, if necessary down time is to be avoided.

It has been demonstrated that where a maintenance log is kept on a regular basis, down time has been reduced. Table I shows a limited amount of data, extracted from one such log taken from a customer's records. The results of only two tubes in one small part of the equipment are listed; similar data for other parts of the equipment would serve no additional purpose here and hence was not included, nor were results on other test points.

In the case of vacuum tubes, a replacement program based upon percentage deterioration from installation value in some significant factor, such as mutual conductance or anode current, under some special condition, was employed with success, as shown in Table I. Here, the attempt to maintain any given value of the factor, as long as it was adequate, was of less importance then the deterioration in use. This procedure is one suggested approach to the problem of increasing system reliability by an attempt to find tubes where impending failure is likely. It arises because it is known that the present tube testers are not entirely reliable in themselves in predicting if a tube is satisfactory at any given time.

In replacing vacuum tubes, it has been found desirable to avoid using new tubes without some previous burn-in period, in all cases where reduction of down time is of great importance. Other programs have been suggested, such as first establishing some heater voltage or supply voltage at which vacuum tubes known to be satisfactory fail to provide completely satisfactory operation, and then dropping such voltage to some value slightly higher than the limit so established. If any failure in performance is found at this value, the vacuum tubes which caused the failure of equipment performance are supposed to be replaced with good tubes. Programs such as this are not as acceptable to the user as the means previously mentioned, and hence are less likely to be followed. The need for readjustment or replacement of certain components has been revealed by the changes or drifts that occur from a previously established voltage of current reading at preselected points in the circuit or, in some special cases, by wave shapes of certain specified signals at designated measurement points. Here

Table I. Maintenance Log for V-501 and V-502 Tubes

1. Tube: V-501(2X2A)—900-volt rectifier
   Location: Power supply
   Installed with gauge; reading on tube tester = 140+140 on 5/18/49

85 on 4/1/50	115 on 5/31/50	140 on 2/18/51	108 on 9/27/51	120 on 3/28/52
85 on 4/21/50	↓ 15 test periods	↓ 7 test periods	↓ 7 test periods	↓ 13 test periods
85 on 5/5/50				
82 on 5/18/50	67 on 1/18/51	105 on 9/24/51	99 on 3/14/52	115 on 12/12/52
discarded on 5/31/50	discarded on 2/18/51	discarded on 9/27/51	discarded on 3/28/52	still in operation

2. Tube: V-502(6SJ7)—voltage-regulator
   Location: Power supply
   Installed with gauge on 5/18/49; reading on mutual-conductance meter = 82

82 on 5/18/49	96 (new tube)	85 (new tube)	95 (new tube)	89 (new tube)
97 67 69 67 68 64 65 ↓ 8 test periods	↓ 21 test periods	↓ 8 test periods	↓ 18 test periods	↓
42	75	78 on 9/24/51	80	84 on 12/12/52
discarded at next test period	discarded at next test period	discarded at next test period	discarded at next test period	still in operation

again, a log of past results will be found most useful. This procedure may sometimes employ, as the standard for such purposes, the average readings obtained from a number of examples for that line of equipment; but, because of the manufacturing tolerances employed in the value of components, it is more likely to require the determination of a set of such readings on the individual piece of equipment in question. The latter makes problems for the instruction book and also adds to the problems of special service from the home office. It is, however, more representative of the customer's equipment.

Training of Personnel

There is an additional factor of importance in the problem of reliability of equipment in the field. This is the training of the personnel used in each of the seven distinct groups which are involved with the equipment itself. These groups are application engineering, development, design, test, installation, maintenance, and service.

It is indeed difficult enough for either the development or design personnel to intimately know the operating conditions and requirements of even one branch of industry, and if various kinds of equipment must be applied to various industries, the services of an adequate application engineering group for each industry are necessary. In small organizations this function may have to be performed by some other group such as the designers who then must take the time to determine the requirements of the industry involved. In any case, the equipment will serve more reliably if it is designed for the specific operating needs of its application.

It would amaze the uninitiated to find how difficult it is for even experienced personnel to decide upon a set of specifications for an equipment to serve an industry in which they are presumably expert. Plants vary in layout and methods to an extent that sometimes results in several design modifications to meet various local conditions. Factors such as number of operating shifts, union rules, whether it is customary to maintain building temperatures over nonoperating weekend periods, the industrial habits of those who must do the installation work, the nature of the wastes which affect the atmosphere in which the equipment must work, the complexity of the required operation to be performed, and a host of often unsuspected matters known only to experts in that field can and do influence the design necessary for any given degree of reliability. It is not surprising, therefore, that the training of those who must do the application engineering is important if maximum reliability is to be achieved in the equipment.

The effect of the training and ideals of the development, design, and test groups are more obvious in this regard, depending upon the complexity of the equipment, and perhaps require only a brief mention. There is, however, one aspect that is often overlooked. The objectives of one manufacturing industry are not always those of another and, unless this fact is fully appreciated in its effects some difficulties are likely to be encountered. The wiring, mounting, and, in fact the design of the components which are customary in certain branches of electronics are not feasible in many industrial applications. This calls for special training of at least the development and design groups to provide the needed characteristics. Such matters as the ambient conditions affect and are responsible for design differences. The effect of certain kinds of dust and moisture conditions which may exist at a broadcast transmitter differ from those in a paper plant or steel mill, and such factors must be designed into the equipment. Hence, the enclosing cabinets acceptable to one branch may not be acceptable to another. Manufacturing and test procedures and practices which are practical for radio-receiver production are not equally so for industrial application. Even the personnel ordinarily employed in radio-receiver testing could not be interchanged with those employed in the testing of industrial equipment without special training. In some cases, even a different class of personnel is required. For example, the test personnel on heavy industrial equipment must often have a high degree of technical training, especially if only a few equipments of any one kind are to be produced, otherwise, very elaborate test instructions must be prepared, and the work intimately supervised by engineering talent.

In the case of installation groups for industrial electronic equipment, the problem of training depends upon the complexity of the equipment and its operating requirements. But either highly detailed plans for the installation must be prepared, and adequate supervision provided, or special training of the installation crew is required. The requirements of electronics are admittedly not those of the electric power field, and those not trained in the respective field of either could hardly be expected to provide the special requirements of the other without supervision, plans, or training. Since many matters are left to the discretion of those responsible for installation, their training can be a matter which affects the reliable performance of the equipment. It would not be difficult to forsee ways to lessen the reliability of performance of equipment by failure to observe these facts. For example, a previously installed equipment which may be operating satisfactorily can be affected by the installation of additional equipment in its vicinity. Regulation of power supply lines is a notorious factor in its effects upon electronic equipment. Equipment with photoelectric devices can suddenly cease to provide satisfactory service upon the installation of welding equipment, with its intermittent flashes of light. Operation of equipment with search coils, such as metal detectors, has been ruined by the use of portable welding equipment, which was designed to employ ground return of the welding currents through the metal frame of the building, even though such equipment was used in remote areas.

The last two groups, namely, the maintenance and service groups, which may or may not be the same personnel, also have readily understood training needs. In this case, the experience of one large manufacturing concern involved in the application of electronic equipment in heavy industry has been that these groups are best trained on their own equipment at the manufacturer's plant. Others have found it possible to sell such service to their customers. However, this plan is less desirable from the customer's standpoint than having his own personnel (if these can be adequately trained), simply because in case of an emergency they can be more readily available. A recently observed circumstance in a customer's plant may be of interest in this connection: The production force of the manufacturer was paid on the basis of quantity of product produced which met specifications. They found their earnings increased following the application of a certain electronic equipment, and hence were very insistent that this equipment be in operating condition at all times. The plant management therefore found it desirable to issue instructions to the maintenance and service group to supervise the condition of the electronic equipment religiously, and to drop all other work not having special priority in case of emergency failure of that equipment. It is not difficult to understand that these men were specifically trained in their work. The emphasis placed upon such matters and how various companies achieve their objectives is revealed by the interesting practice of certain companies in applying a large hourly charge in their financial accounts against the maintenance and service groups for any down time.

Naturally, the emphasis which must be placed on the various aspects of the problem of reliability in industry applications differs from industry to industry and, indeed, differs between equipments of varying degrees of importance in any one industry, just as the emphasis will not be the same among manufacturers of similar equipment. Moreover, the degree of reliability demanded will not be the same in all fields of electronics, nor will all factors receive equal consideration. But inasmuch as it cannot be claimed that the components from which such equipment is produced are entirely reliable, emphasis on these factors is justified by the extent of their contribution to improved reliability in the performance of the final product in the customer's plant; this, after all, is the objective sought.

D. R. MARSH
NONMEMBER AIEE

THE NEW JERSEY Turnpike carries by far the greatest traffic load of any toll highway, anywhere. Its peak day totalled 84,132 vehicles; its peak month, 2,004,000; for the year 1952, 18,239,000. Its cost will total some $285,000,000; that of its communications system and related facilities, less than 0.1 per cent of this figure.

The Turnpike now reaches from Deepwater, N. J., on the Delaware, to the George Washington Bridge across the Hudson. Extension is expected for connection with the New York State Thruway now in construction. Its length will then be about 130 miles. Its radio system gives coverage for mobile units over this entire distance, plus telephone and teletype interconnection of its three police stations with the State Police Headqurters at West Trenton.

The system embraces:

1. Five cochannel very-high-frequency (VHF) stations, operating in the 150-megacycle band, to mobile units from discrete locations;
2. Seven 950-megacycle microwave stations, which are the backbone of the system;
3. Some 75 mobile units of the police, maintenance, emergency service, and supervisory groups;
4. Some 86 toll booths at the present 17 interchange stations.

Some of the salient factors entering into the development of specifications for the system were somewhat as follows:

1. An analysis of probable traffic load requirements. This included consideration of the estimated activities of toll, general maintenance, police, and supervisory groups, and emergency services for patrons;

2. An analysis of allocation possibilities for VHF channels covering the length of the Turnpike, as planned and projected. Here, the advantages versus the disadvantages of operation in the 150-megacycle band, as against the 450-megacycle band, were weighed. Propagation characteristics of the 150-megacycle band were superior, but channel availabilities were extremely few. On the other hand, commercial development in the 450-megacycle band had been limited.

Throughout the study, attention was held centered upon spectrum economy, which, within New Jersey, was a prime essential in view of proximities to the great New York and Philadelphia metropolitan areas. Also, mobile units must be free to roam the full distance without necessity for frequency change, and this dictated the use of a single pair of VHF channels plus the critical evaluation of possibilities for cochannel and adjacent channel interferences.

But two suitable channels within the 150-megacycle band were available: 154.83 and 155.19 megacycles; these were used. Their separation is but 0.36 megacycle, which called for study of special means for effecting suitable isolation of transmitter and receiver antennas if economies were to be derived through the use of single towers for the support of both.

3. Topographical studies were made with attention centered upon maximum economy with respect to location of VHF relay stations at points where planned buildings could house equipment; and, in the interest of further economy, the number of relay stations was minimized. Suitable propagation tolerances were injected, and where, due to topographical features, there appeared to be merit in so doing, experimental propagation studies were carried through.

4. Economies of both spectrum and cost pointed toward the desirability of concentrating VHF radiation along the axis of the highway. Thus, a 2-element, broadside antenna using half-wave dipoles was designed, experimentally checked, and specified for both reception and transmission, these to be mounted upon the same tower at each station in an essentially coaxial relationship, and with vertical spacings which had been determined, both mathematically and experimentally, as sufficient to reduce mutual impedances to quite inconsequential values. This arrangement found the use of cavity resonators, or the like, unnecessary; and transmitter operation causes no desensitization of the corelated receivers, notwithstanding the small channel and physical separations.

5. An antenna solution of somewhat different character was applied, for the resolving of that difficulty encountered when a mobile unit finds itself in midzone between two simultaneously-operating cochannel stations. Here, even though both carry the same speech modulation, interference is developed by phase differences in the audio-frequency components of the two carriers. The receiver cannot discriminate.

A novel 2-element, directive, car-top antenna was devised, wherein one element is driven, the other parasitic. A 5-to-1 front-to-back field ratio is obtained. Reversal of the field pattern is brought about via a feed-line switching relay, actuated, in turn, by a toggle switch on the dash-mounted control plate. Thereupon the parasite is driven, and vice versa.

With, say, 25-mile spacing of relay stations, the effect of antenna pattern reversal is about the same as that had were the vehicle instantaneously lifted to a point some 4 miles up or down the highway, depending upon whether the switch is in either the "fore" or "aft" position. The interference area is, thus, erased.

This antenna also served an important economic purpose. It made possible the use

of 10-watt mobile transmitters, which could be powered without costly amplification of standard battery-generator car equipment.

6. Because of expected heavy commuter-traffic loads in the metropolitan areas, and overall congestion over week ends and holiday periods in summer, greatest practicable flexibility of the system was deemed a prime essential. Furthermore, control should, it was held, be centered at the New Brunswick Administrative Headquarters, with auxiliary control, either for the system as a whole or pertinent sections thereof, available to the police substations at Newark and Moorestown. This dictated the tying of the 5 VHF stations together—and multichannel microwave facilities were used for this purpose. Details as to flexibilities will be covered in the technical description that follows.

Microwave equipment is accommodated at the 5 VHF stations, where the single support tower carries all antennas. The Newark police substation is contiguous to the airport there, on which account microwave terminal antennas are mounted but some 20 feet above grade level, and oriented upon the Snake Hill microwave relay 5 miles to the north. The West Trenton station is a microwave branch terminal only, although the support tower there now also accommodates other State Police radio facilities.

Mutual impedances between immediately adjacent microwave transmitting and receiving antennas are essentially nil, their respective dispositions being vertical and horizontal.

In order to fulfill the specification detailed by the Turnpike Authority, many special facilities and adaptations of standard equipment were required. Considerable effort was devoted to choosing basic components to fit a standard pattern. The diversified functions appearing at each of the terminal and repeater stations demanded custom design and manufacture of distribution and control equipment, having many interlocked and carefully coordinated circuit functions. The design and development of the Turnpike system was, therefore, divided into two basic phases, one the choice and application of standard items and the other, the analysis and design of distribution and control equipment.

Over-all System

The functions required at each of the control and administrative dispatch locations are shown in Fig. 1. It can be seen that up to five independent channels were necessary to provide the desired services. They were arranged as follows:

1. Newark to Snake Hill
S = service party line
2N = VHF control and audio

2. Newark through Snake Hill to New Brunswick
S = service party line
2N = VHF control and audio
1 – intercom party-line telephone
T = party-line teletype

3. Snake Hill to New Brunswick
S = service party line
2N = VHF control and audio

4. New Brunswick to Bordentown
S = service party line
3 = VHF control and audio

5. New Brunswick through Bordentown to Trenton
S = service party line
1 = intercom party-line telephone
T = party-line teletype

6. New Brunswick through Bordentown to Moorestown
S = service party line

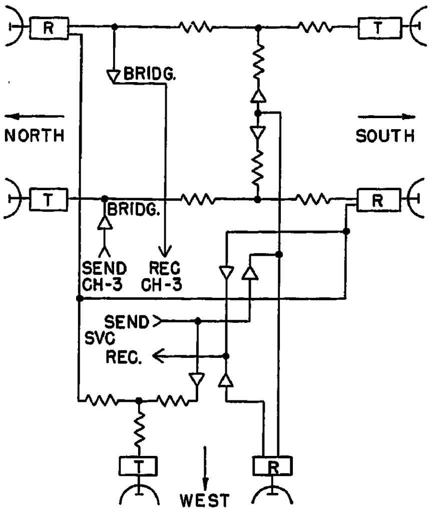

Fig. 3 (right). Bordentown leg repeater

2S = VHF control and audio
1 = intercom party-line telephone
T = party-line teletype

7. Trenton through Bordentown to Moorestown
S = service party line
1 = intercom party-line telephone
T = party-line teletype

8. Moorestown to Swedesboro
S = service party line
2S = VHF control and audio

Essentially, the system consists of three terminals and four repeaters. All of the repeaters are of the type normally designated as a drop; however, the arrangement used for this system required some variations. The drop repeater at New Brunswick included a provision to separate the VHF control and audio, north and south, and the Bordentown drop repeater provided a leg circuit to Trenton.

For those not familiar with microwave practice, a definition of station types is in order:

1. A terminal station is located at the end of any portion of a system, which may be the extremes of the main line or a side leg circuit. The main elements are a transmitter and receiver, with their associated antennae and terminating facilities.

2. A drop repeater is located at intermediate points within the main line or leg portions, and provides a medium to pass

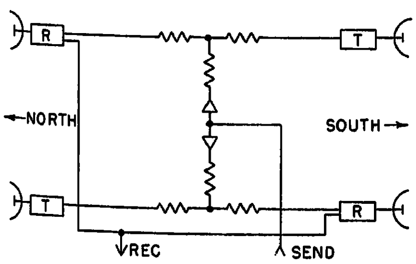

Fig. 2 (left). Snake Hill-Moorestown drop repeater

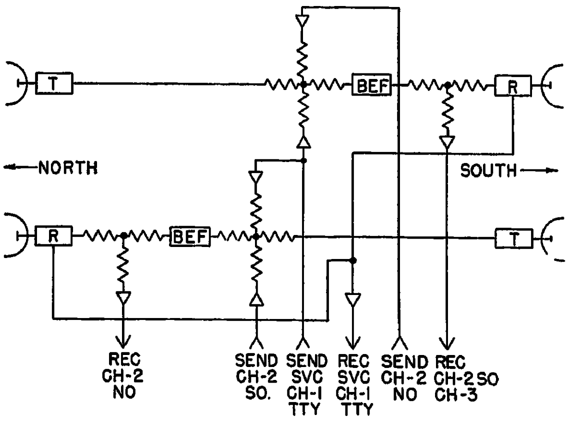

Fig. 4 (right). Modified terminal repeater

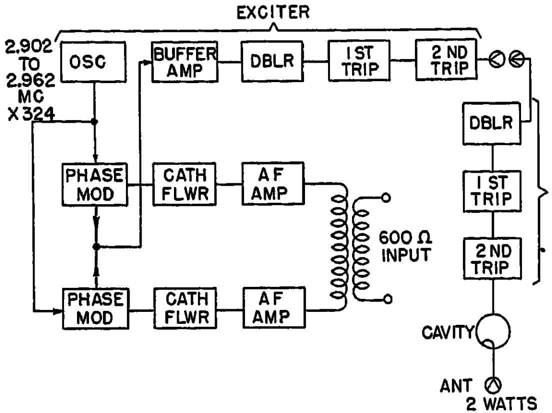

Fig. 5(A) (left). Microwave transmitter, 960 megacycles

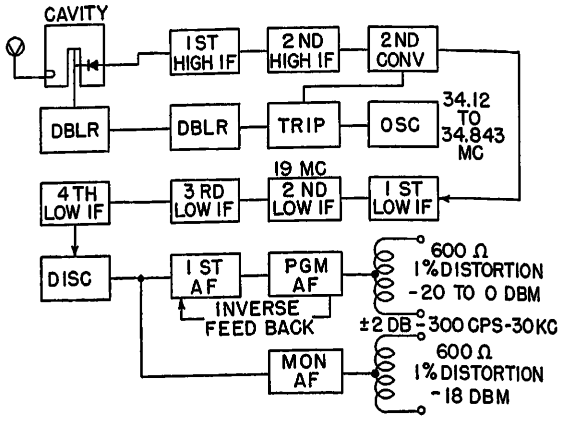

Fig. 5(B) (right). Microwave receiver, 960 megacycles

information in both directions, and also allows information to be terminated locally. The basic units required are transmitters and receivers, with their antennae, to work in two directions, and a bridging and insertion network of amplifiers.

3. A leg repeater is used to bring information from a point off the main line and insert in one or both directions. It consists of a drop repeater which is terminated in a terminal station. In some instances local information will be bridged across the send-receive line.

4. A terminal repeater is essentially a back-to-back connection of two systems at their terminal points, providing some through-information channels, and dropping or inserting others.

The repeater stations, as used on the Turnpike are detailed in Figures 2, 3, and 4. Fig. 2 is the straight drop repeater, as used at Snake Hill and Moorestown. The receiving line is provided by bridging the outputs of fixed-gain amplifiers located in the microwave receiver. These amplifiers are normally designated as a monitoring output. The through connection is accomplished by interconnecting the microwave-transmitter audio input with the receiver-program audio output. The program output is an adjustable low-distortion amplifier, also located in the microwave receiver. To insert information in both directions, a resistance tee and bridging amplifier network is connected, to provide a common outgoing audio input. The amplifiers used for this purpose are individually assembled on rack strips, and are designed to have essentially flat response to 150 kilocycles. Their output is adjusted by fixed plug-in tee pads, and provides a maximum of 35 decibels gain. The input sensitivity of the transmitter must be carefully correlated with the various sources of on-going and local information; as well as consideration for the maximum band width required, in order that minimum distortion and maximum signal-to-noise ratio be accomplished.

Fig. 3 is the leg repeater used at Bordentown to provide information to West Trenton State Police headquarters, and through information to the Moorestown-Swedesboro section. Basically this arrangement follows the pattern of the drop repeater, using the drop circuit to connect the leg circuit to the main system. The local service channel and terminating facilities are bridged onto the main sending and receiving circuits, using the broad-band amplifiers for isolation and level control.

Fig. 4 is a modified terminal repeater as used at New Brunswick. This station is the central administrative dispatch of the entire system, and requires terminations sufficient to route or divide the VHF-control and audio information to all sections of the Turnpike. It combines the facilities of a drop repeater and a terminal repeater, by inserting band-elimination filters to divide the through circuits from the terminal circuits. To the service, interphone, and teletype channels it serves as a drop repeater, but to the VHF-control and audio circuits it appears as a back-to-back terminal allowing information to be interconnected in any arrangement desired. It can be seen that as in the other repeaters, the broad-band amplifiers are used to control the levels and provide bridging isolation.

Referring again to Fig. 1, the interconnection of the VHF circuits is arranged for four operating systems, all of which can function independently as automatic relaying systems, or can be supervised by the central dispatcher.

1. Circuit 1 interconnects all elements as a single party line, permitting any section to automatically relay through any other section, and allow the dispatcher to broadcast or communicate with any unit over the entire length of the highway.

2. Circuit 2 interconnects stations of the north portion and the south portion as separate systems, permitting each to conduct traffic as required, independent of the other.

3. Circuit 3 interconnects the north portion with the Bordentown station, and allows the Moorestown-Swedesboro section to operate as a unit.

4. Circuit 4 divides the north portion into two independent stations and connects the Bordentown station to the Moorestown-Swedesboro group.

The flexibility emphasis is placed on the north section of the highway, which obviously carries the largest volume of traffic.

There are terminating facilities at all stations, both terminal and drop repeaters; however, only the service channel is common to all. The interphone and teletype are party-line dropped at the four State Police offices, to provide high-volume routine traffic circuits. The VHF control and audio circuit appears at all stations except Trenton. Five of the stations are equipped with a VHF transmitter and receiver. The Newark terminal functions as a VHF dispatch point, using the Snake Hill VHF facilities whenever it is separated from the remainder of the system. Other VHF dispatch consoles are located at Moorestown and Swedesboro.

Microwave and Channeling Equipment

Figs. 5(A) and 5(B) are block diagrams of the *RCA CW5-B* 960-megacycle transmitter and receiver units, which were used

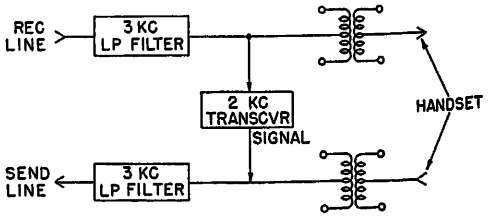

Fig. 6. Service channel audio and signalling

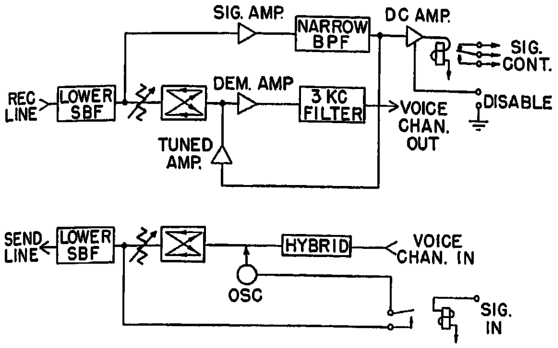

Fig. 7 (left). Single-side-band-suppressed-carrier multiplex channel

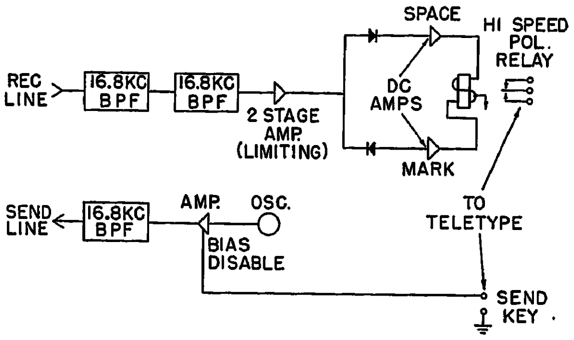

Fig. 8 (right). Teletype channel

at the terminal and repeater stations to provide the necessary audio band width to carry the multiplexed channels. The transmitter consists of a broad-band frequency-modulation and phase-modulation unit, frequency modulation being accomplished below 2,000 cycles, and phase modulation being effective up to 30 kc. The audio information is applied through a push-pull amplifier and cathode follower to the phase modulator, the cathode follower being used to lower the impedance and improve the linearity over the modulation band width. The exciter unit provides an approximate 50-megacycle output to drive the transmitter and provide a 2-watt carrier output. The crystal control-oscillator frequency is multiplied 324 times and is tuned in the final stage with a specially designed cavity which encloses the output tube.

The microwave receiver is designed to provide less than 1-per-cent distorted output over ±2-decibel 0.3- to 30-kc range at 2 output sources. The program output can be increased from −20 to 0 decibels-referred-to-1-milliwatt, by the use of inverse feedback and, therefore, has available a gain control for this purpose. The monitor output is a fixed gain stage without inverse feedback, providing −18-decibels-referred-to-1-milliwatt, output. The receiver is a double superheterodyne, using a cavity resonator and crystal diode for the first converter stage. The second conversion frequency produces a 19-megacycle low intermediate-frequency having a 0.5-megacycle band width.

The service channel, as shown in Fig. 6, was provided for the use of the maintenance and engineering groups, and used the lower 3,000 cycles of the base band. It is separated from the upper portion by low-pass filters having 40-decibels attenuation above 3 kc. Within this pass band, a 2-kc tone is transmitted to operate signalling buzzers at all the equipment locations.

The intercom telephone, VHF control, and audio channel equipment is shown in Fig. 7. These channels use the frequency-division principle of multiplex and employ the single-side band suppressed-carrier transmission method. This is a time-proved communication practice, which has proved most easily adapted to this type of operation. At the expense of fundamentals which may be familiar to some, it would be well to discuss the general characteristics of a single-side band suppressed-carrier transmission system. The voice information is applied through a hybrid coupling to a balanced-ring modulator system, consisting of a quad of varistors. At the balance point of this system, a carrier frequency is injected. This produces upper and lower side bands without a carrier. Passing the two side bands through a suitable filter, the upper side band is eliminated, and only the lower side band is transmitted to the base-band input of the microwave system.

To receive this signal, the lower side band is selected by a similar filter and again is applied to a balanced varistor ring. In a standard channel, a local oscillator tuned to the same frequency as the transmitting oscillator resupplies the carrier frequency at the input of the demodulator amplifier, the output of which would be supplied to a voice channel circuit through a 3-kc filter. Because of the necessity for low distortion and minimum oscillator-frequency drift, which is desirable when applying these signals to a VHF transmitter for retransmission, it is desirable to synchronize all receiving channels to the transmitting channel. This is accomplished by utilizing the ringing-signal circuit, which is normally used to operate a telephone-ringing generator or dial circuit. The ringing signal is normally supplied by bypassing the balanced varistor of the transmitting circuit, reinserting the carrier at the input to the lower-side-band filter.

This, then, provides a signal carrier with the lower-side-band voice frequencies, which, when received at the other end, is amplified at the output of the receiving side-band filter, and passed through a narrow band pass-filter to a d-c amplifier to operate a signalling relay. In this system, this information is applied to the balance varistor ring through a tuned amplifier, replacing the normal local oscillator. This provides a single frequency throughout the system. You will note in Fig. 7 that the d-c amplifier is also provided with a disabling circuit. This is a bias applied to cut-off the plate current, and is controlled by external relay contacts when used in conjunction with the protective lockout system. Using this method it is possible to achieve better than a 40-decibels

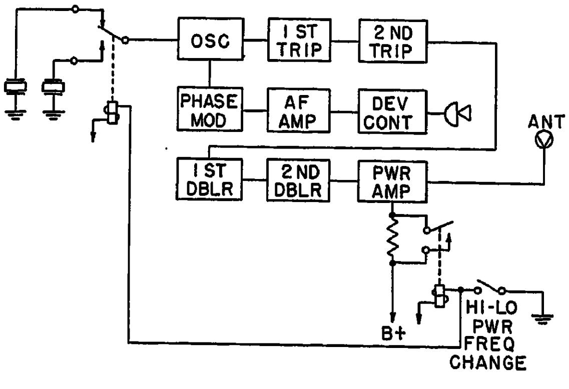

Fig. 9(B) (right). Mobile transmitter

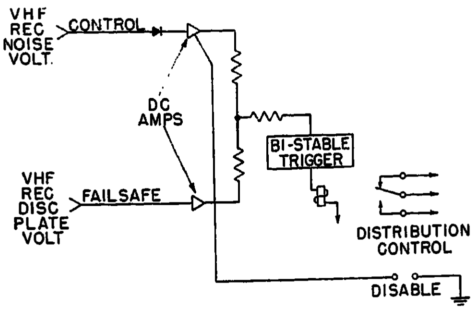

Fig. 10 (left). Very-high-frequency carrier operated relay

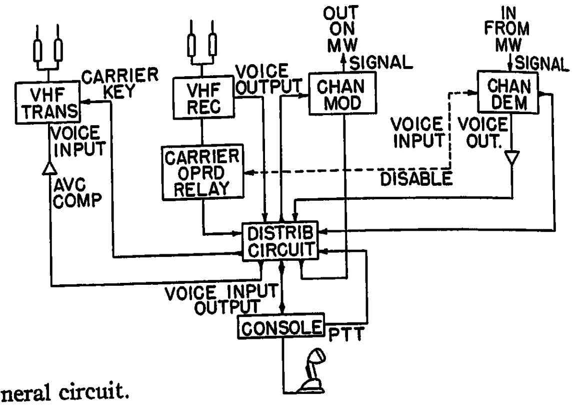

Fig. 11 (right). Very-high-frequency control system

signal-to-noise ratio at the voice frequency terminals.

The teletype circuit is shown in Fig. 8. This is a single-tone carrier, keyed by a model *15* teletype printer thru a bias-disabled amplifier and band-pass filter. The mark signal is represented by no carrier, and the space signal by carrier transmission. The signals are received through a cascaded narrow-band-pass filter by a two-stage limiting-type amplifier, the output of which is rectified to provide control bias for the space signal. The mark amplifier is protected from the space signal by an oppositely connected rectifier, to maintain its plate cut-off during the space signal. When no signal intervals occur, the normal bias causes this d-c amplifier to draw current. The two currents are applied to the opposite windings of a high-speed polarized relay, which in turn, is interconnected to the receiving loop of the printer. The tone transmitter and receiver are arranged in a half-duplex circuit, allowing the machine to receive its own signals as well as any other machine's. This arrangement is convenient for break-in and party-line operation.

VHF Station Equipment

Figs. 9(A) and 9(B) detail the basic circuits employed in the VHF base-station receivers and transmitters. The HI-LO power and frequency-change features are a part of the mobile transceivers only, which use the same general circuit. The transmitter is the phase-modulated frequency-modulation type, which multiplies the crystal frequency 36 times to produce a 50-watt carrier at 154 megacycles. The deviation control used at the stations is a separate automatic volume control-compressor-type amplifier, providing 4 decibels output variation for 30 decibels input change. This same unit is used to control interconnecting levels at New Brunswick; therefore, we will defer its description until we discuss the central dispatch facilities. The VHF receiver is a double-conversion superheterodyne using a single crystal oscillator with a multiplier system. The low intermediate-frequency stages drive 2 limiters and a discriminator to provide 20 decibels of noise quieting for less than 0.5 microvolt of signal at the antennae. The audio amplifier is muted, when no signal is present, by a rectifier and d-c amplifier which control the grid bias of the first audio-frequency tube. The preemphasis and deemphasis characteristics are designed to follow a 6-decibel per octave curve. The overall distortion is less than 5 per cent under all but maximum automatic audio-level control conditions.

The control of the system by the VHF base station receiver is effected through a carrier-operated relay, detailed in Fig. 10. This unit utilizes a rectified component of the receiver noise voltage to bias the control amplifier, the output of which is applied to one section of a common divider. The other portion of the divider is connected to a second d-c amplifier, which receives its bias control from the VHF-receiver-discriminator plate circuit. The function of these two biases is to provide a control voltage which will combine reliable operation with a fail-safe protective feature. The control voltage which is derived from the rectified noise voltage of the receiver, obtained from the discriminator output, changes in a negative direction when carrier is received. This is due to the quieting effect of the frequency-modulation receiver. Such a condition easily could be simulated falsely, when the sensitivity

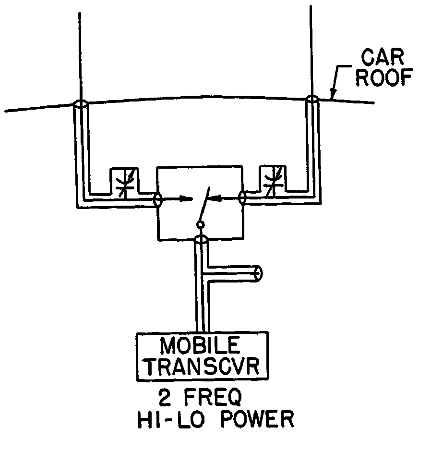

Fig. 12(A) (left). Mobile directive antenna system

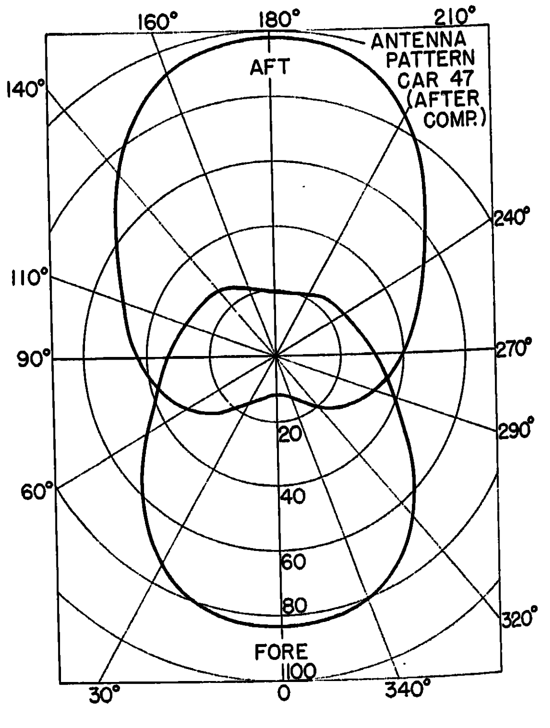

Fig. 12(B) (right). Antenna pattern car 47 (after compensation)

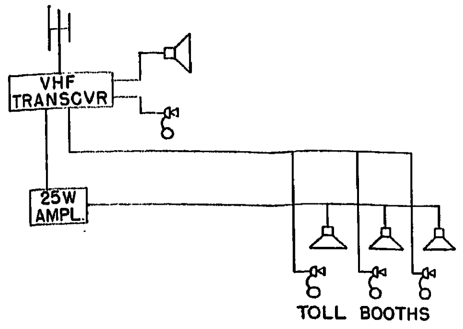

Fig. 13. Interchange system

of the receiver deteriorates to a point similar to that at which the noise voltage would decrease with carrier quieting; this would provide a false control voltage. Since the discriminator plate voltage depends upon the normal sensitivity of the receiver, it will reflect any decrease in sensitivity through the second d-c amplifier. This will shift the operating point of the divider sufficiently so that the normal control voltage will have no affect on the bistable trigger-relay control circuit.

This type of carrier-operated relay can be adjusted to a very accurate signal operating margin, and has good stability in the presence of extraneous noise in the receiver. It is very fast in its response, which is highly desirable in initiating the automatic chain of relay functions necessary to activate the carriers along the line. You will notice that a disabling circuit is also indicated on this unit. This is accomplished by supplying a large positive bias to the control circuit whenever the disabling contacts are opened. The disabling function is accomplished by interconnecting the normally made contacts of the multiplex channeling-signal relay and the carrier-operated control relay in a crisscross fashion. In other words, whichever relay operates first disables the other, enabling it to maintain preferential control during the period of transmission.

The over-all relationship of the channeling equipment and the VHF base-station transmitter-receiver and carrier-operated relay are diagrammed in Fig. 11. At each of the 5 VHF base stations, a distribution circuit is provided which controls 3 sets of audio and signalling control circuits, with associated audio distribution and impedance matching paths. Each VHF station operates as a result of any 1 of 3 sources of information:

1. The stations own VHF receiver;
2. The microwave multiplex channel output;
3. The local dispatch console.

If a carrier is received at the local VHF receiver when it is idle, the carrier-operated relay will immediately disable the incoming microwave channel and switch the output of the receiver to the input of the VHF transmitter and the modulating circuit of the outgoing microwave channel. This audio information will also appear at the remote console.

When any one receiver or local dispatcher point activates the multiplex channel at a time when the equipment is idle, the channel unit will immediately disable its local VHF receiver and carrier relay, and supply audio and signalling information to the console and the VHF transmitter. Whenever local dispatching is effected, the telephone-line d-c control circuit operates the distribution circuit to supply audio and control information to the VHF transmitter and to the outgoing microwave channel. An amplifier is located in the output of the channel demodulator to correlate the output level with the levels of the VHF receiver and console.

Interchange and Mobile Stations

All VHF communication facilities serve two groups of transceivers located on or adjacent to the highway. One group is the entrance and exit interchanges, the other the various vehicles attached to the Authority's departmental organizations. The latter group is divided into four components:

1. State Police patrol cars
2. Turnpike administration personnel
3. Highway maintenance personnel
4. Customer service stations

The mobile transceivers use transmitting and receiving circuits which we described in Figs. 9(A) and 9(B). The receiver sensitivity is slightly less, being 0.8 microvolt for 20 decibels of noise quieting. The transmitter uses a clipper-type deviation control, which instantaneously limits the carrier swing to ±15 kc. The hi-lo power change and frequency change is used for limited range car-to-car communication. Since this frequency is the same as the base-station transmitter, only one receiving frequency is required. This has the additional advantage of leaving the car open to receive messages from the dispatchers at all times, and relieves the automatic-relaying circuits of considerable traffic.

In a system such as this, where 5 transmitters are radiating simultaneously, there will be, of necessity, overlapping areas between any two base stations. At a point where signal levels are approximately equal, a strong zone of interference will be produced, due to the phase differences in the audio components of the two carriers and the inability of the receiver to eliminate either carrier. To overcome this, a special mobile directive antenna system was devised by the Paul Godley Company, which provided a selective directional pattern under the control of the vehicle operator. The basic components of this system are shown in Fig. 12(A). The two antennae are located slightly less than a quarter wave apart, and are phased by means of the electrical length of the transmission line to utilize the undriven antenna as a parasitic director, providing a 5-to-1 field strength ratio. To match the impedance effect of this parasitic element, a stub is inserted in the transmission line to the mobile transceiver. The electrical length of the antenna transmission line is varied by means of the shunt reactive element located at the coaxial switch. This antenna system is equally effective on both transmission and reception. A typical propagation

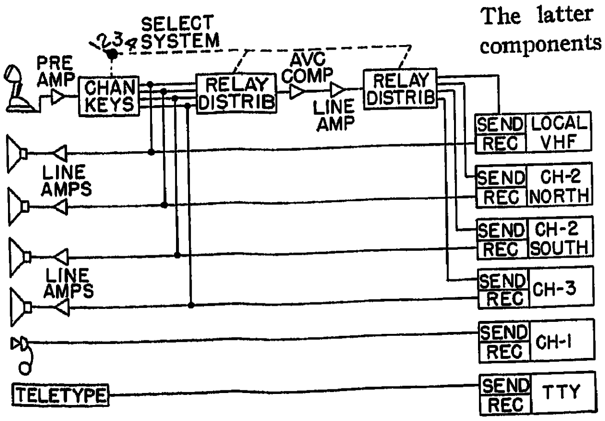

Fig. 14 (left). New Brunswick console

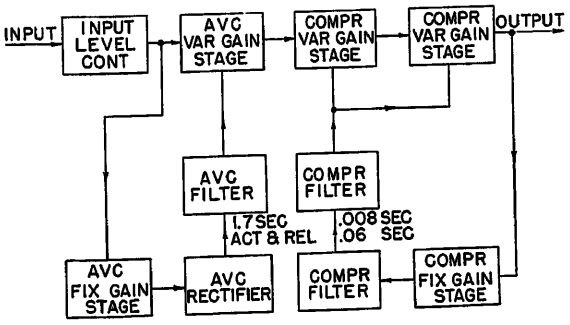
Fig. 15 (right). Automatic - volume-control compressor



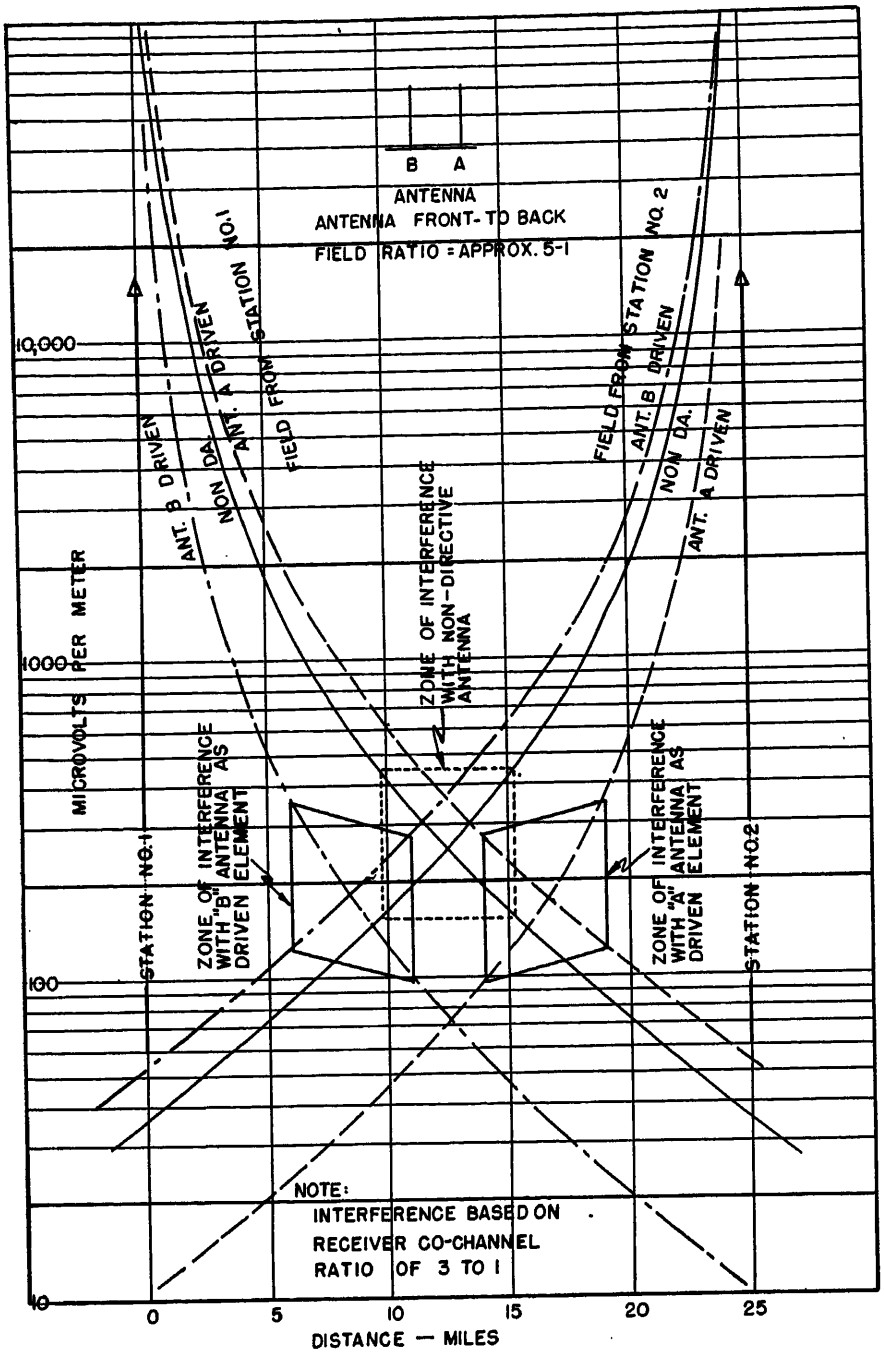


Fig. 16. Car-top mobile directive antenna

pattern is displayed in Fig. 12(B).

The interchange transceivers are a-c operated low-power units, having 15 watts carrier on the same frequency as the regular mobile channel. A 3-element directional antenna is used to provide positive communication with a specific station. This arrangement allows them to communicate on the same basis as the mobile units. Fig. 13 details the facilities provided for the toll booths. Each booth is equipped with a telephone handset and loudspeaker, the loudspeaker being muted when the handset is removed from the cradle.

Control and Dispatch

The principal operating circuits are set up by the New Brunswick operator. We have previously touched on the basic functions he establishes in the section on general system facilities. Fig. 14 shows the means by which the 4 system arrangements were brought under the direct control of the administrative dispatcher. The console facilities are shown on the left.

One position only is shown, but a duplicate position is provided to permit handling heavy emergency traffic. Each position is provided with a boom-mounted microphone, preamplifier, and 4 telephone-type keys. The key-up provides foot-switch carrier control, and the key-down, which is springloaded, provides press-to-talk operation. The neutral position allows the system to operate automatically.

The system selector is common to both positions, and is used to set up the relay-distribution network at the equipment racks for the system arrangement desired. The relay-distribution unit sets up the conditions which will provide paths between the receiving and sending circuits to reroute the interconnection information to the proper outgoing channels. In conjunction with this, the console keys allow the microphone to be directly inserted into the chosen circuit, giving the dispatcher control over the circuit, in preference to the automatic facility.

The console keys are so interlocked that the two positions cannot be operated simultaneously, but are available on a first-come first-served basis by either dispatcher. Busy indicators are provided to alert the dispatcher as to the channels which are in use. Each channel, including the local VHF station, is terminated in a separate speaker. The output of the channel is not normally connected to the monitoring speaker and amplifier, except when a signal is coming in, this operation being effected by the use of the incoming signalling circuits actuating a muting-relay arrangement.

You will note between the two groups of relay distribution that an automatic-volume-control compressor amplifier and line amplifier are used to regulate the inter-channel levels. The diagram as shown in this figure shows only one position of the system switch, each of the other three positions being a repetition of this, with a different distribution of the send and receive lines. This calls for 3 sets of automatic-volume-control compressors and line amplifiers to control the outgoing levels under all bridging conditions.

By using the automatic-volume-control compressor, it is possible to maintain a uniform 0-decibel-referred-to-1-milliwatt audio input to the channel modulators, thereby raising the general system intelligibility under all operating conditions. It would be in order, at this point, to describe in some detail the operation of the automatic-volume-control compressor amplifier, which is shown in Fig. 15.

This equipment is designed to control input-signal variations of 30 decibels, within a 4-decibel output range. It is a combination of automatic volume control

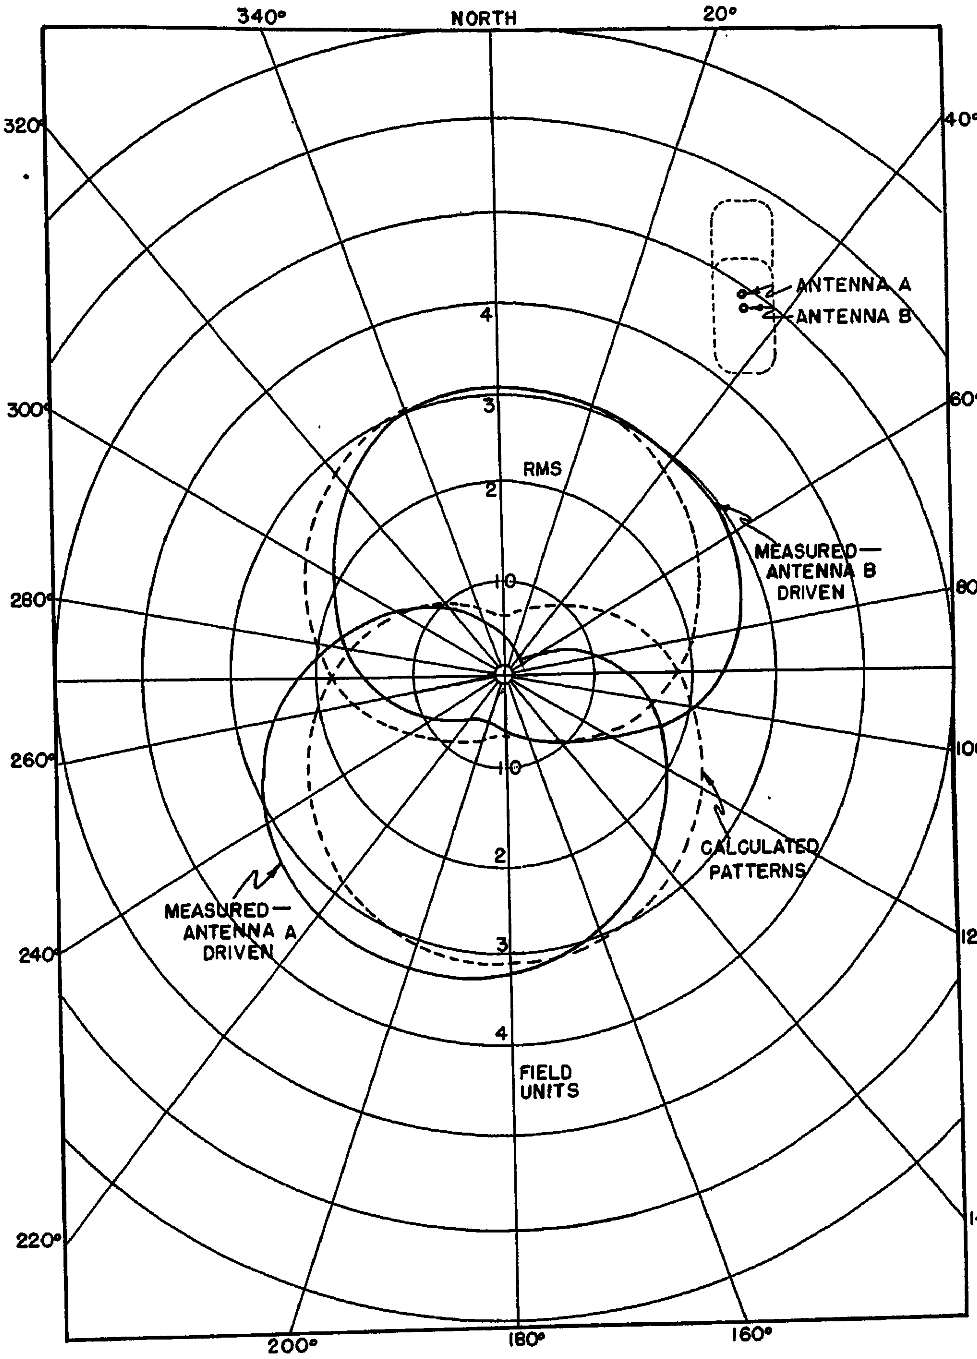

Fig. 17. Car-top mobile directive antenna, horizontal plane pattern

with a relatively slow time factor, and a fast-acting compressor to limit the instantaneous audio excursions. The incoming audio is amplified by a fixed-gain stage rectified, and applied through a resistance-capacitance time-constant filter to a variable-gain stage. This acts to provide a relatively constant signal level to the compressor input, limiting the maximum excursions, but, at the same time, maintaining the output level regardless of decreasing input levels. The operation of the compressor portion is controlled by a sample of the output information through a fixed-gain stage and rectification, which is applied, in turn, simultaneously to the 2 variable-gain stages, the attack time being 8 milliseconds, and the releasing time 60 milliseconds. The frequency response of this type of amplifier is flat within 1 decibel from 300 to 7,000 cycles, which is more than adequate to handle the normal 300- to 3,000-cycle range employed in this type of system. This results in a steady audio-level output from the base station, which increases the intelligibility in the moving vehicles under high ambient noise-level conditions.

There are, as previously mentioned, three other dispatching points, which are equipped to control the system at the discretion of the administrative dispatcher, but in preference to the mobile and interchange stations. These units are equipped with a microphone and amplifier, which is switched by the press-to-talk circuit to serve as a monitoring or talking facility. A single metallic pair is used to provide the audio path and d-c control circuit. The d-c control circuit operates from line to line, using telephone repeater-coil winding centers as terminals for operating the relay coil on the distribution unit.

Summary

To summarize the practical operation and application of this system, we can describe 4 major types of system operation which are accomplished:

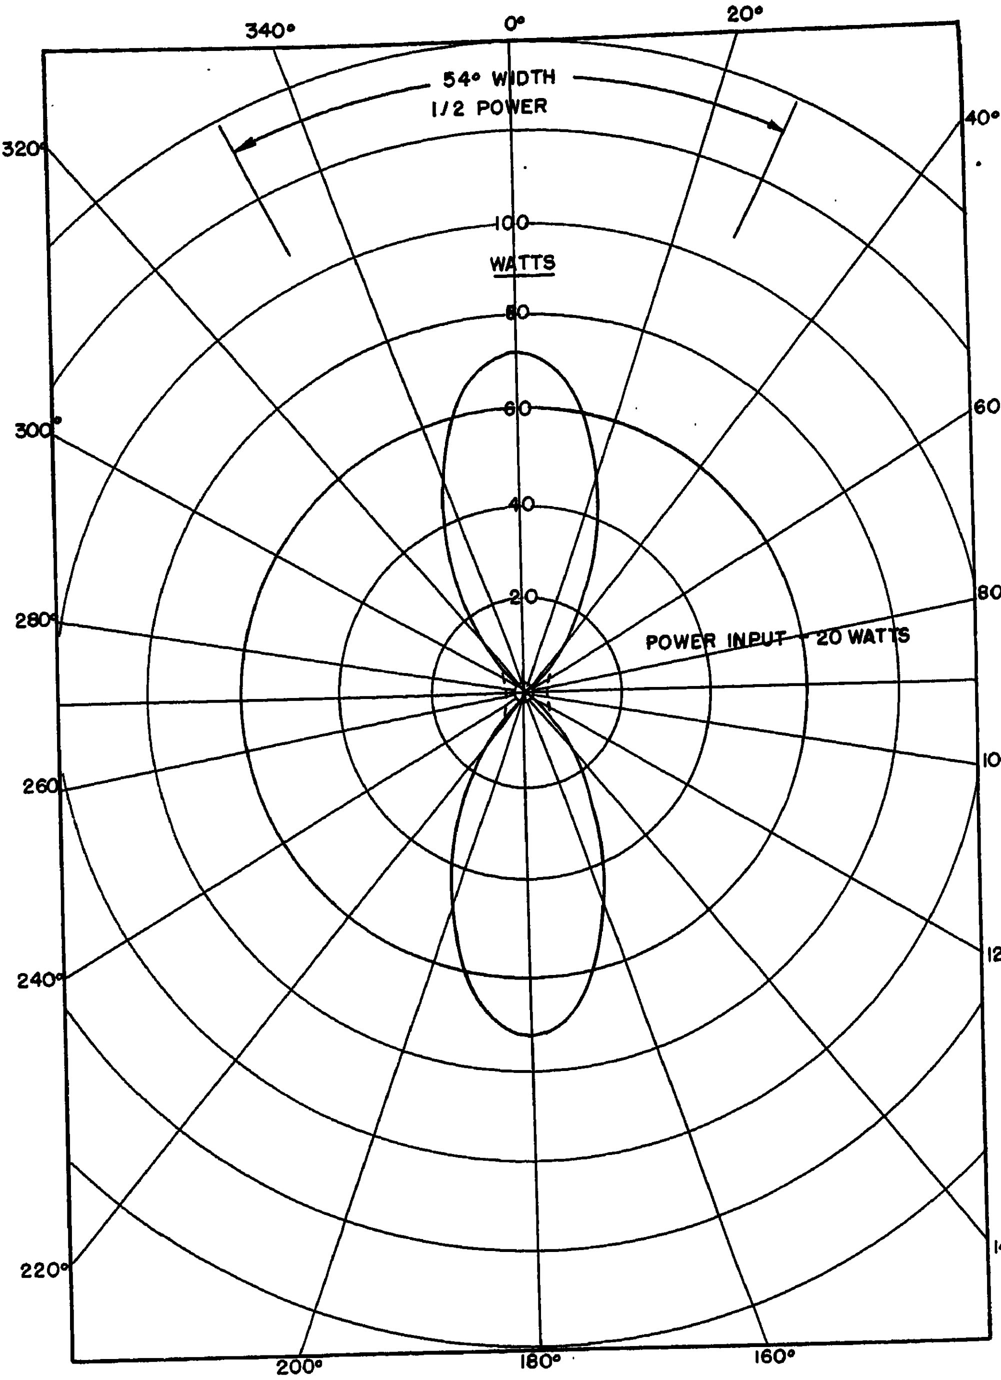

Fig. 18. Very-high-frequency base-station directive antenna, horizontal plane radiation

1. Mobile-to-mobile relay;
2. Interchange-to-interchange relay;
3. Mobile-to-interchange-to-mobile relay;
4. Point-to-point communications.

The first three of these operations are completely automatic, and provide flexible communications along the entire length of the Turnpike. A description of the sequence of operations will help to visualize the complex paths and control operations necessary, and the means by which the facilities which have been described are employed. Assuming that a mobile station wishes to initiate a call to another mobile station located at some other point on the Pike, he will activate his carrier with his press-to-talk switch, and with his antenna-directional switch positioned for the nearest station. This is easily determined, since the Turnpike locations are known by the mile markers. The mobile carrier signal will quiet the VHF base-station receiver, thereby activating the carrier-operated relay. Two things occur at this point, the first being that a ground circuit opened by the carrier relay in the multiplex-channeling equipment allows a disabling bias to be applied to its receiving-signal amplifier. This provides protection for the carrier-relay control sequence for this operation, and at the same time, disables the channel output to the distribution system. The second thing is the initiation of the control sequence in the distribution system, to activate the VHF transmitter carrier and enable the channel modulating and signalling circuit. Simultaneously, the audio output of the receiver will be applied to a dividing network, making audio information available to the local VHF transmitter and to the channel modulator. If a local dispatch control unit is tied in at this particular station, it also will receive the same information. This means that the information on the mobile carrier is now simultaneously distributed locally and at the other 4 VHF stations. The mobile unit which it was desired to contact will hear this signal, as it is made available from the distant transmitter or the microwave channeling system, or in some cases, he will be close enough to hear it direct from the local VHF transmitter.

The microwave signalling information will have also supplied disabling information and audio distribution information to the other 4 receivers in the system. The disabling information is applied directly to the other VHF station carrier relays by means of the normally grounded contacts of the channel-signalling control relay. If the system is connected as a party line arrangement, which is position 1 of the administrative dispatcher's control console, the control and audio information will drop to the audio and d-c circuits at New Brunswick and be reinserted through a relay interconnect facility automatically. As high as 7 relays in automatic sequence will be in use on signals passing through New Brunswick. The New Brunswick operator will simultaneously monitor any transmission.

Because of the channeling arrangements requiring this large number of relay operations, considerable attention had to be devoted to determining the relay time constants and the delays in the transfer of information in order to prevent system lockup. It is equally important that no more than one source of the same audio signal be connected to the channel, since the phase distortion would be intolerable. Such a condition is possible if a mobile transmitter radiates a carrier at a location which is favorable to two adjacent stations. Under the same circumstances it is also possible, with the right timing, for a relay race to start which would alternately key the transmitters without any control by the operators.

The control of these conditions is effected through a series of interlocked circuits in the distribution units, and is materially aided by the ability of the mobile operator to direct his signal towards a specific receiver. The operation of the interchange-to-interchange and the mobile-to-interchange follow the same paths as described in the mobile-to-mobile.

The point-to-point communication facilities, consisting of the telephone and teletype channels, provide direct communication facilities between all of the police division headquarters, the interphone being used to relieve the normal VHF channel of routine traffic. The teletype system is used on a party-line basis, allowing group messages to be transmitted and received from any point where the machines are provided, and is flexible enough to allow any number of additional tone-transmitting and receiving equipments to be added. Not all of the available channel space is used in this system and it is contemplated that, as other services may be required, an additional channel can be added.

Finally, but not the least important, is the maintenance and test facilities which have been provided to permit easy analysis of system troubles. Each station is equipped with a jack field which provides 4-wire termination of all pertinent base-band and voice-band circuits. In conjunction with the jack field, a bridging monitoring amplifier and local handset is provided to permit entering any one of the channels or local VHF transmitter to make direct operational test, without disabling the remainder of the system.

In designing the New Jersey Turnpike communication system, many problems were encountered over and above the facilities which we have described, but to attempt to cover them all would be a large task. However, we believe that we have described the more important features, which adequately display the typical problems encountered in large-system development.

No Discussion

A Million-Watt Naval Communication Transmitter

J. C. WALTER
MEMBER AIEE

Synopsis: This article describes one of the world's most powerful radio telegraph transmitters. Recently built for the United States Navy, it is conservatively rated at 1,000-kw output over the 15- to 35-kc frequency range. Its use will ensure reliable communication with the United States Fleet even when high-frequency services are interrupted by magnetic disturbances. Unique features include the first use of super-power electron tubes having a power gain of at least 250; 10-microsecond fault protection; a variable master oscillator with 0.001 percent frequency stability, and provisions for frequency-shift teletype signalling.

NAVAL communication service requires positive direct transmission to mobile forces at sea and aloft, wherever they may be. The United States Navy is building a super-power radio transmitting station in the Pacific Northwest. It will be fitted out with the very-low-frequency (VLF) transmitting equipment to be described. Signals from this station will provide world-wide radio coverage in the lower half of the 15- to 35-kc band. Utmost reliability and continuity of service is ensured through careful planning and duplication of essential major components of the equipment.

Very efficient and economical high-frequency (HF) circuits are capable of handling the bulk of military traffic most of the time. They are, however, occasionally interrupted by magnetic and ionospheric disturbances. HF signals are severely attenuated when their circuit paths traverse relatively large auroral zones surrounding the earth's magnetic poles. VLF transmission over great distances requires the use of very high power to overcome attenuation and inherently poor antenna efficiencies. Its prime virtue is its ability to get through when higher frequencies are blacked out. VLF transmission has proved extremely reliable in the high latitudes.

Equipment

The basic transmitter equipment is known as the model *AN/FRT-3* radio transmitting set. It consists of the following principal apparatus:

1. Transmitter units in compartmented shielding;
2. Unified front enclosure;
3. Supervisory console;

Paper 53-199, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15-19, 1953. Manuscript submitted December 26, 1951; made available for printing March 30, 1953.

J. C. Walter is with the Radio Corporation of America, Camden, N. J.

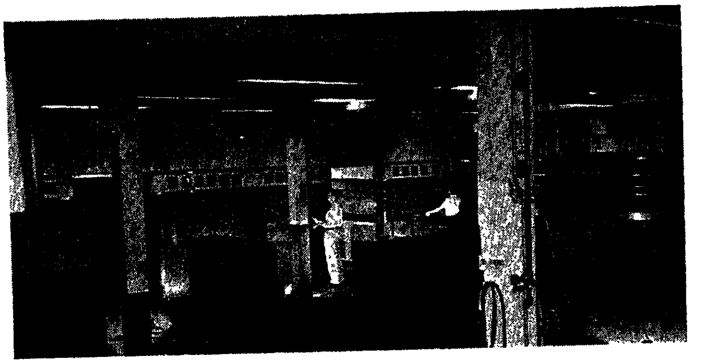

Fig. 1. Transmitter in test position at the factory showing supervisory console, and port and starboard frequency generator-monitors

4. Frequency generator-monitor;
5. Centralized control and distribution unit;
6. Metal-clad switchgear;
7. A-c load-center apparatus;
8. Cooling system;
9. Water-cooled test load;
10. Antenna tuning equipment

An efficient catenary antenna system was specially designed for suspension between two mountain ridges. A radial system of buried ground conductors contains nearly 200 miles of copper wire. Design of the antenna/ground system and materials for its construction were furnished as part of the equipment contract.

Description of Equipment

A general view of the transmitter in its test position at the factory is shown in Fig. 1. Identical port and starboard units are symmetrically disposed about a central control section. Port and starboard groups each consist of the following:

1. Frequency generator-monitor;
2. Main rectifier;
3. Exciter;
4. Power amplifier.

Port and starboard elements of the supervisory console and the control and distribution unit are consolidated in common assemblies.

For full-power operation both power amplifiers are driven by either exciter, and either frequency generator-monitor may be used to furnish keyed signals to the exciter in use. Main rectifiers have sufficient capacity for either unit to supply plate power to both power amplifiers. Idle units are thus in a ready reserve status and available for maintenance and testing.

Either power amplifier may be operated with either exciter to provide an output of 500 kw. The idle amplifier may be simultaneously operated with its test load up to 500 kw.

The supervisory console, Fig. 2, contains extension controls and instruments for trimming amplifier and antenna circuits. Selector switches in a mimic bus control various cross-switching operations. Mimic bus lamps show which transmitter units are in service and which are in idle or test status.

Port and starboard frequency generator-monitor (FGM) units are grouped with the supervisory console to provide a central operating position from which important instruments may be observed. The function of the FGM is to generate stable radio frequency voltage at a level sufficient to drive the transmitter to full power. Any frequency in the VLF range may be set up on the frequency generator. When the monitor is set to the same frequency, the generated frequency may be continuously monitored and automatically controlled to maintain a frequency stability of better than 0.001 percent. The FGM assembly includes a frequency-shift keyer with plus and minus deviation which is adjustable from zero to 25 cycles. The useful range of frequency shift is restricted by the extremely sharp resonance characteristic of the antenna. It is anticipated that at 25 cycles off resonance the radiated signal will be from three to six decibels below the level at resonance. Provisions are included in the FGM for either on-off or polar keying. The keyed r-f output of the FGM is fed through coaxial cable to the input terminals of the exciters.

Central enclosure master panel instruments include flow, pressure, and temperature indicators for the hydraulic and air systems. Master control switches for duplicate cooling systems are centrally located on this panel. Selector switches control the main rectifier ratio tap adjusters. Nine equal tap positions between 40 per cent and full voltage are registered on selsyn indicators. The ratio taps may be changed under load so that output power is adjustable at will without interruption of service.

Enclosure sections associated with port and starboard transmitter units include observation windows and interlocked access doors. Essential instruments and local controls are appropriately grouped on the various enclosure sections. Safety features include the following: door latch operated switches which trip rectifier circuit breakers and release gravity operated d-c ground devices; barrier door switches which additionally ground d-c buses; and insulated grounding sticks.

Compartmentation and radio-frequency shielding for rectifiers, exciters, and power amplifiers are provided by aluminum panels attached to structural aluminum framing behind the front enclosure. Aluminum interconnection wiring ducts and catwalks are mounted on top of the shielding structure just behind the upper section of the front enclosure.

Fig. 3 shows one of the high-power rectifier units which furnishes plate power for either or both power amplifiers at 11.5 kv. The rectifier is housed in a 10 by 20 foot compartment of the aluminum shielding structure. Seven type-*870A*

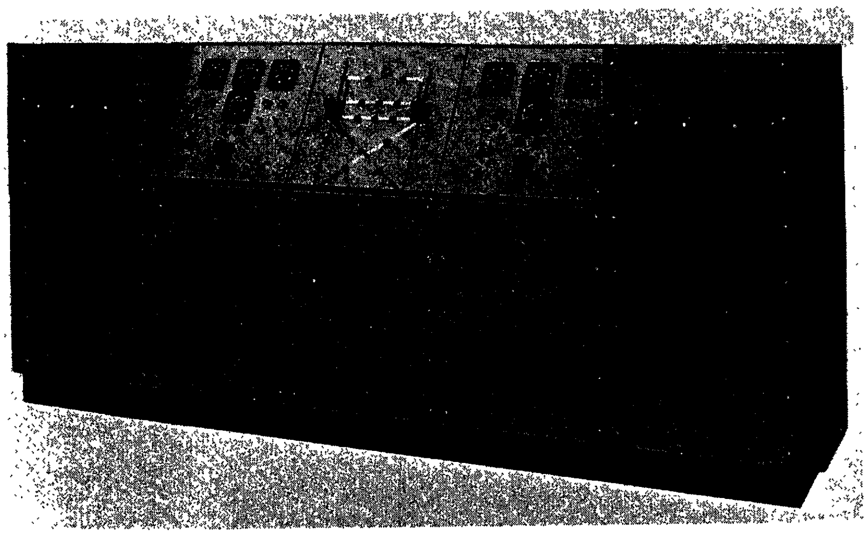

Fig. 2. Supervisory console

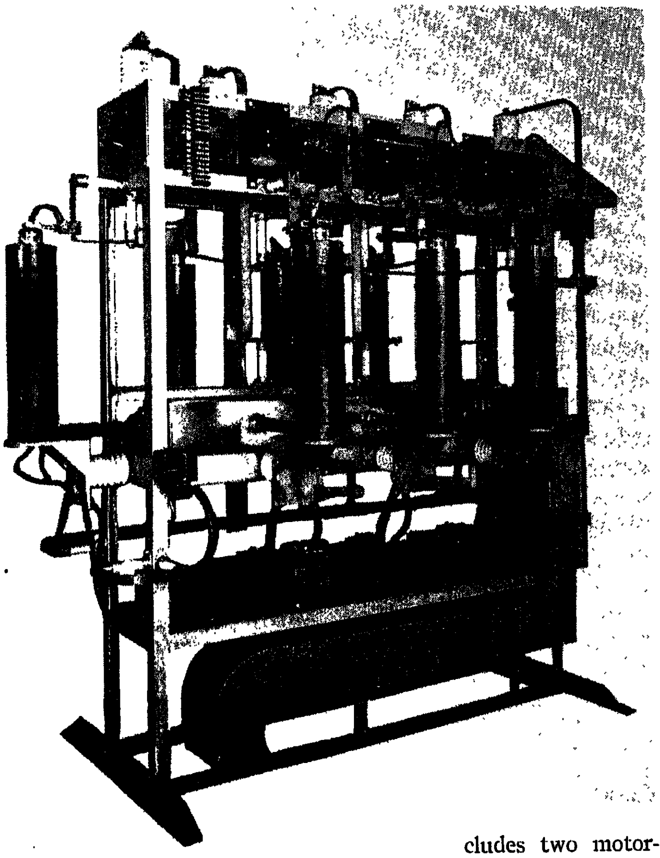

Fig. 3. Main rectifier tube assembly. (Note spare tube mounted on left end)

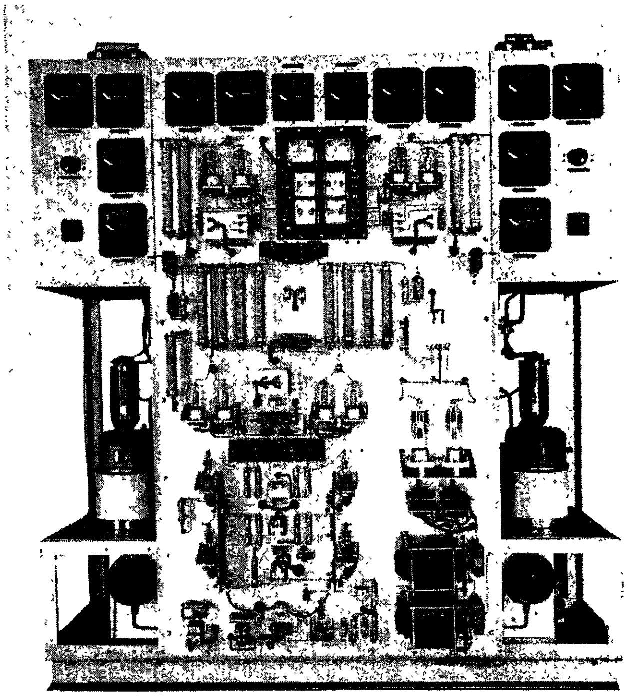

Fig. 4. Untuned radio-frequency exciter

metal-clad hot cathode tubes are mounted with their auxiliary apparatus and air heating and manifolding devices. Six of the tubes are normally connected in a conventional 6-phase double-way rectifier circuit.[1] The seventh is a preheated spare which may be substituted for any active tube by means of sparing switches mounted on a distribution bus. Cooling air is obtained from a station air-duct system located below the deck.

One of the exciters is shown in Fig. 4. This is a broad-band amplifier requiring no tuning over the entire VLF band. The output stage is coupled to either or both power amplifiers through an iron-core oil-cooled transformer. The unit is located within a 10- by 20-foot shielding compartment together with its plate supply rectifier and test load. The exciter rectifier unit consists of 6 type-*673* hot-cathode tubes in a conventional 6-phase double-way circuit and 4 type-*8008* hot-cathode tubes in two conventional diametric-rectifier circuits. The test load consists of a bank of wire-wound resistors mounted in a cabinet. Cooling air for the type-*892R* output tubes, the rectifier, and the test load is obtained from the station air system.

A general view of the port power amplifier radio-frequency circuit elements is shown in Fig. 5. The coil assembly includes two motor-operated variometers and manually adjustable output coupling inductors. The windings are low-loss Litzendraht conductor consisting of 16,128 strands of 5-mil enameled copper cabled around a jute core. The diameter over the glass braid is approximately 2 inches. Porcelain shafts mounting the variometer rotors are turned by motors located in shielded pits below the assembly. Stator windings are lashed to porcelain tubes supported in aluminum castings. Aluminum supporting columns are grounded at the bottom and bolted to bus-support insulators at the top to minimize coupled-in losses. All special porcelains and the Litzendraht conductor used in these assemblies are interchange-

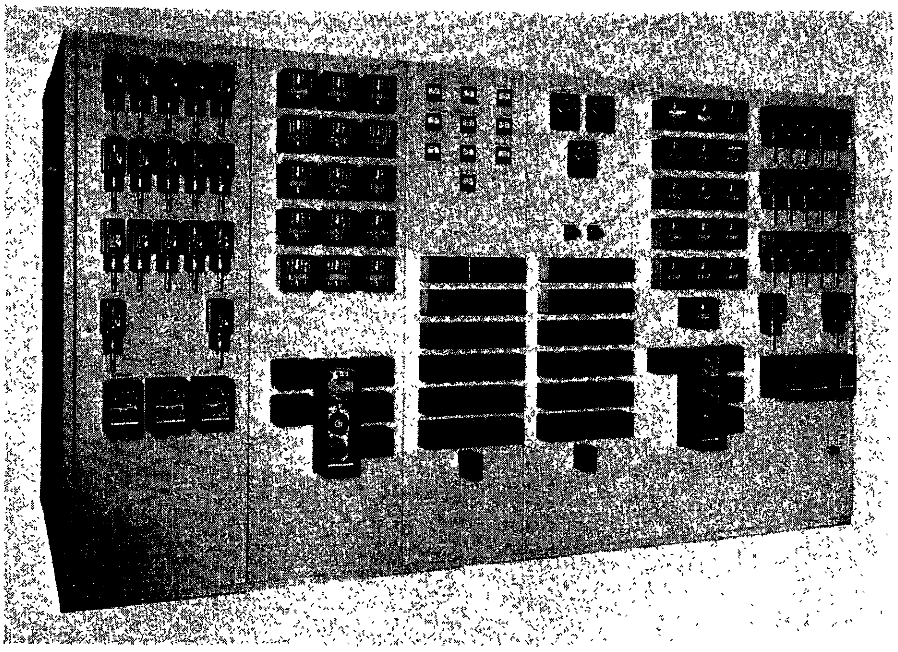

Fig. 6 (above). Control panel showing port and starboard relay groups. Distribution contactors and circuit breakers are on opposite face of the metal-clad cubicle

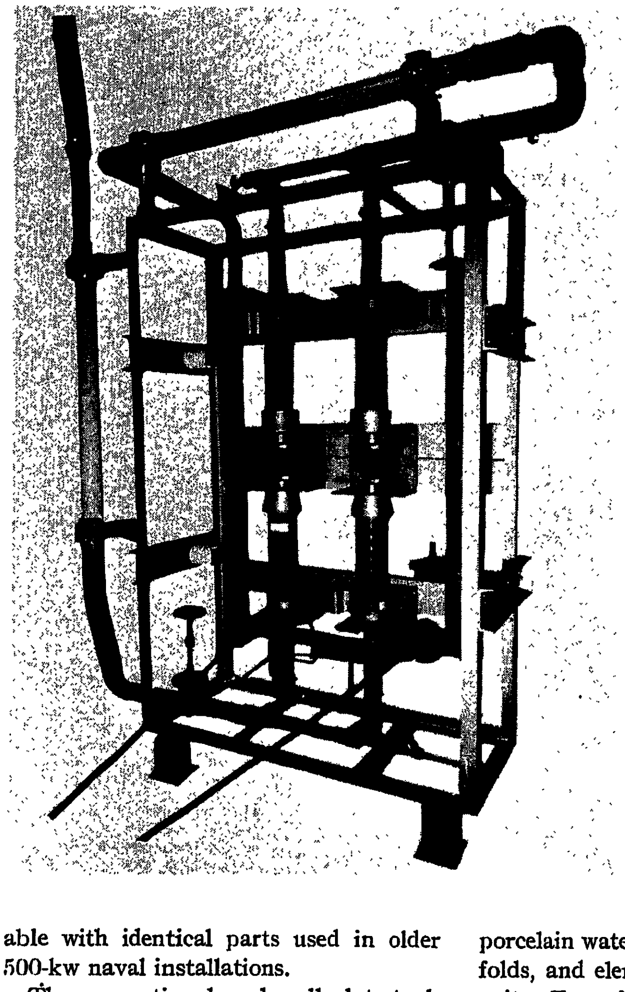

Fig. 7 (left). Water-cooled test load which dissipates 600 kw at radio frequencies

able with identical parts used in older 500-kw naval installations.

The conventional push-pull plate-tank circuit is tuned by push-button control of the plate variometers. Selection of 12 discreet frequency ranges over the 14.5 to 35 kc band is provided by air disconnects mounted on a tank capacitor bus. Forty oil-mica fixed capacitors are used in each power amplifier.

The tube frame assembly supports porcelain water coils, cooling water manifolds, and elements of the grid-tank circuit. Two of the three type-*5831* superpower tubes supported in their toroidal filament transformers are connected in push-pull. The third tube is an installed spare which may be quickly switched into service in lieu of either active tube. Motor-driven grid variometers are remotely controlled for push-button tuning of the grid circuit.

The design of the filament transformers embodies a novel application of toroidal construction wherein the concentric cylinders comprising the high current winding are used as the tube socket. These 14-kw units have a nominal voltage ratio of 175-to-6, and are used with reactors in series with their primaries to limit tube-starting currents to 150 per cent of their final value.

The type-*5831* tubes require exceptionally low driving power because of the electron optical principles incorporated in their design. Their use makes possible a considerable saving in both transmitter construction and operating costs by elimination of a 100-kw penultimate amplifier stage. An additional load reduction of over 50 kw is realized by the use of thoriated tungsten filaments.

Other assemblies located within the power amplifier compartment are a filter-capacitor rack, a shielded bias rectifier, and a cabinet housing an electronic-tube protective unit. The bias rectifier uses 6 type-*673* hot-cathode tubes in a conventional 6-phase double-way circuit. The tube protective unit which provides microsecond fault protection for the power amplifier tubes is a new development which will be described in the next section.

A metal-clad control and distribution unit is located behind the enclosure master panel. Control relays are centralized in two groups associated with port and starboard transmitter elements. Distribution contactors and branch-feeder circuit breakers are similarly grouped on the opposite side. A front elevation of the control panel is shown in Fig. 6. Main rectifier feeder overcurrent relays are drawout inverse-time units with instantaneous attachment. Selective automatic reclosure is provided by motor-operated reclose relays. Plunger-type overcurrent relays protect subordinate feeders.

The various equipments thus far described constitute the basic transmitter. When installed as a unit they occupy a floor space 80 feet wide by 50 feet deep. Auxiliary equipment designed for installation at a lower level occupies approximately the same area directly below the transmitter. Functionally important auxiliaries are briefly described in the following.

The a-c load center apparatus consists of air-cooled indoor distribution transformers, phasing transformers and station-type induction regulators. An overhead 460-volt bus from the customer's source is used for primary distribution. Regulated and unregulated 230-volt and

Power factor, lagging				0.87
4,160-Volt Feeder Load, Kw				1,550
Power factor, lagging				0.94
Total Demand, Kw				1,660
Key up load, kw				102
Standby load, kw				95

460-volt secondary cables run to the distribution unit above and to other loads. Starting reactors for high-power filament circuits are mounted in a frame with associated power-factor correction capacitors.

Certain high-voltage d-c apparatus is also located adjacent to the a-c load center. It consists of port and starboard rectifier filter reactors, current-limiting and transient-suppressor resistors, and a motor-operated d-c transfer switch. The latter is used for cross-switching of the main rectifiers. An expanded metal protective fence encloses the area occupied by the a-c load center and high-voltage d-c apparatus.

Port and starboard blowers furnish air to a station air duct previously mentioned. Either blower may be used alone for this purpose. Each is enclosed in a separate room provided with metal intake filters. Approximately 8,000 cubic feet per minute air delivery, at 1.25 inches static pressure, is required for cooling purposes.

Table I. Test Performance Versus Salient Specifications

Performance	Specification	Test
Locked key demand, kw	1,770	1,660
Average load, 20 words per minute keying, kw	1,105	1,037
Standby load, kw	105	95
Rectifier d-c regulation, per cent	10	9.85
Filter output ripple, rms, per cent	0.50	0.41
Output radio-frequency power, 12 frequencies, kw	1140	1,150
Keying speed, dot-cycles per second	75	75
Frequency stability, per cent	0.001	0.0003

Water-cooled test loads for the port and starboard power amplifiers are located in the blower compartments. Each consists of four water cooled elements mounted in the assembly shown in Fig. 7. Each load is rated at 600 kw dissipation with a flow of 180 gallons per minute of raw water coolant.

Pure water used for cooling the power amplifier tubes is stored in two 1,000-gallon copper tanks. A closed circulating system pumps approximately 120 gallons per minute to each power amplifier. Heated water returns by gravity to the storage tanks. Raw water passing through heat exchangers cools the pure water. All pumps are installed in duplicate, and furnished with appropriate valving to provide for maintenance without interruption of service. As a battle-damage precaution against possible loss of the raw water supply a complete air/water heat-exchanger system is provided as an installed stand-by equipment.

Three-phase plate transformers for the main rectifiers are oil-filled units installed in a typical vaults. Each is rated at 1,700 kva, 5.5 per cent impedance, and 4,160 a-c phase voltage. Small plate transformers for the exciter rectifiers are installed in the same vault.

A switchgear cubicle consisting of a metering section and two high-speed air circuit breakers is installed adjacent to the vault. The circuit breakers are in the 4,160-volt feeders to the main rectifier transformers. They are draw-out units rated at 600 amperes, 5,000 volts, with an interrupting capacity of 100,000 kva. The switch-gear unit is designed for installation in line with matching customer's equipment.

Tube Protective Unit

The tube protective unit is a high-speed electronic control device used to protect the power amplifier tubes from damage due to internal gas arcs or similar faults. Whenever there is a sudden rise in power-amplifier tube current above normal, the d-c plate-supply bus is shorted to ground through a type-*5630* ignitron. This protection is applied 7 to 10 microseconds after the fault is initiated.

Fig. 8 shows the fundamental circuits of this unit and its connection to the power amplifier. Under normal operation, the unit is in the ready condition. Should a tube fault occur, a sudden rise in current above normal causes a rise in voltage to appear across the power-amplifier common cathode resistor *R1*. This is applied through pulse transformer *T1* to the grid of thyratron *V1*. When *V1* fires, it, in turn, fires a larger thyratron *V2*. The current through *V2* is of sufficient magnitude and duration to cause ignition of *V3*. Since the main anode of ignitron *V3* is permanently connected to the d-c bus, the power-amplifier tube fault current that initiated this sequence is transferred to the ignitron. At the same time, relay *K1* is energized and trips the circuit breaker in the main rectifier feeder. Backup protection is provided by primary a-c overcurrent relays, whose contacts operate in the same trip circuit. The feeder circuit breaker is opened in approximately 3 cycles on a 60-cycle basis after its trip coil is energized.

The time interval from fault occurrence to the application of protection was determined by electronic methods, and consistently was found to be 7 to 10 microseconds. Transient calculations indicate that this provides a generous margin of safety in preventing the build up of currents that could damage the power-amplifier tubes.

Antenna Tuning Equipment

Port and starboard antenna equipments each consist of a motor-driven variometer, two helix assemblies, an antenna lead-in trunk, and a power-operated grounding switch. The variometer is similar to, but somewhat larger than, one of the power amplifier variometers. Its windings consist of two parallel 2-inch Litzendraht cables supported on porcelain tubes mounted in shielded concrete piers. A tuning motor and reduction gear are installed in a shielded pit below the vertical rotor shaft. The series-loading helices are wound with two parallel Litzendraht cables, and sectionalized to provide appropriate tap points for major changes in the operating frequency. Helix assemblies are approximately 14 feet in diameter by 26 feet high. The winding are assembled on stacked porcelain spacers. An antenna lead-in trunk consists of a fabricated copper spar 82 feet long by 28 inches in diameter. The trunk is supported by suspension insulators above the helix area and extends outdoors through a wall port 20 feet square. The spar is articulated to take care of slight movements of the antenna feeder bus downlead. A rat-tail cage is brought down to the lead-in trunk from the antenna bus which is dead-ended on a nearby tower. A fabricated grounding-switch arm lowers from the overhead shielding to make contact with a pad on the lead-in trunk.

Port and starboard helix rooms are 75 feet square by approximately 60 feet high, and completely copper-lined. Such dimensions are necessary to minimize losses. Currents of approximately 1,000 amperes in each antenna half are anticipated at the lower operating frequencies. Voltage at the top of the helices is expected to approach 200 kv. Low-loss shielding of appropriate thickness is necessary to prevent extreme losses in reinforcing steel. Structural damage to insufficiently shielded buildings housing similar tuning equipment has recently been reported.[2]

Antenna/Ground System

The design of the antenna/ground system was based upon topographic limitations peculiar to the installation site. Each half of the antenna consists of five catenary suspensions supported from 200-foot steel towers erected on opposing mountain ridges. The arrangement provides five separate flat-top capacity elements having an average elevation of approximately 1,000 feet over the valley floor. A downlead from each flat-top section is connected to a common radio-frequency feeder bus connecting the transmitter output to the radiating system. Average spacing between individual catenaries in the port and starboard groups is roughly 400 feet, while the inboard spans of the two groups are separated by about twice this distance. The transmitter building is located between the antenna halves at a point of low elevation. Each catenary suspension consists of an active radio-frequency portion made up of approximately 4,500 feet of 1-inch-diameter stranded copperweld conductor socketed on each end, and attached to appropriate insulator assemblies. Suspension tail cables of 1-inch-diameter galvanized steel strand are dead-ended on the 200-foot towers on opposite sides of the valley. Average length of the catenaries is 7,700 feet; maximum length, 8,800 feet. Nominal working strain is 31,000 pounds stringing tension, and 44,000 pounds fully loaded with 1/2-inch radial ice and a wind pressure of 8 pounds per square foot of projected area. Rated breaking strength is 93,000 pounds. Strain insulator assemblies consist of two quadruple yoke assemblies in tandem at each end of the radio-frequency portion of each span. A quadruple yoke assembly consists of four porcelain tube strain-insulator units in parallel, each 72 inches long by 6 inches diameter. Each end of a tandem group is provided with aluminum corona rings. Tail cables are fitted with conventional vibration dampers near the dead-end attachment point. A downlead taken off near the center of the copperweld section consists of two portions. The upper is lightweight hollow-copper conductor, approximately 1 inch in diameter and averaging 1,000 feet in length. The lower section of 400 feet consists of two parallel conductors spaced to minimize corona loss. A radio-frequency bus, consisting of a group of conductors formed into a cage, is carried on suspension and tangent towers from the building to a point beneath the furthest catenary.

The ground system is common to both antenna halves and consists of buried copper conductors extending radially from the transmitter building. The nominal radius of the ground system is 3,000 feet and each radial wire is bonded to a buried copper screen slightly larger than the transmitter-building area. All shielding and bonding within the transmitter building is connected to the copper screen.

Performance

Tests were conducted during 1950 at Camden, New Jersey, where the transmitter was assembled in its test position. Output powers up to 1,200 kw were dissipated in the water cooled test loads. Test data covering performance against salient specifications are listed in Table I. Typical data recorded during an 8-hour locked-key test are given in Table II.

Final phases of circuit development included a search for parasitic impedances. A wide-range oscillator and cathode-ray oscilloscope were used to seek out grid- and plate-circuit resonances, and to determine whether their reactances were of the proper sign to support oscillations at spurious frequencies. One extremely-low-frequency resonance in the grid circuit was eliminated by substituting series bias feed for the original shunt feed. Most of the parasitic circuits found at frequencies above the operating range were of the shock-excited variety. This was deduced from observations of damped-wave oscillations appearing in the cathode current pulse during dynamic operation. A final arrangement of series-damping resistors in the grid circuits, and a resistor-capacitor series suppressor from each anode to ground, effectively damp these spurious circuits. Full-power keying tests, at speeds up to 160 dot-cycles per second (400 words per minute), revealed no signs of instability.

Integrating Instruments for Simplified Quality-Control Measurements

D. M. LONGENECKER
MEMBER AIEE

Synopsis: In quality control work, it is often necessary to determine the mean and the standard deviation of an important variable. To accomplish this, a measurement system has been developed for applications in which the material is tested while moving continuously, most of the necessary calculating functions being performed by two new integrating instruments. This paper describes the application of such a system to the measurement of yarn thickness.

SINCE VARIATION is virtually inevitable in most manufacturing processes, quality control necessarily includes the three steps of measuring, studying the variations, and controlling the variations. This paper is concerned with the first two steps, which are usually accomplished by making numerous individual measurements of the important parameter, followed by some sort of statistical study of the data. However, this ordinary procedure has three serious disadvantages.

1. It may require appreciable time and expense to make the numerous measurements and to record and compute the results;
2. The computation and interpretation of the data is often not well understood by manufacturing personnel having little or no knowledge of the mathematics of statistics;
3. There is an uncertainty in the results whenever small-lot sampling methods are used, because of normally expected chance differences between the characteristics of a small sample and those of the larger production lot from which the sample was taken.

This third matter depends upon the size of the sample, and it involves the study of sampling distributions, which will be found in most textbooks on statistics.[1]

Undoubtedly there would be a wider application of scientific quality control procedures, if the results of the statistical analysis could be indicated immediately, and if larger samples could be tested economically so there would be a high degree of certainty that the production lot is not significantly different from the sample. To achieve these objectives, a system has been developed to perform an integrated measurement of a dimension of a continuously-moving sample. This measurement system, which will be described in this paper, has been named an Evenness Integrator, and is shown in Fig. 1.

Mean and Standard Deviation

Shewhart[2] has shown that the best simple criteria of quality for a varying parameter are the mean $\overline{X}$, and the standard deviation σ. The purpose of the Evenness Integrator is to provide a quick and convenient means for determining these two important statistics of the sample. To illustrate, consider the testing of yarn and similar materials in the textile industry. The mean thickness of yarn must conform, within certain limits, to the established standards for that particular material. Furthermore, the degree of variation (unevenness) of yarn thickness is another important criterion of quality, and the standard deviation σ is a good measure of this characteristic.

One testing device,[3] which is widely used in textile mills in this country, is known as the Pacific Evenness Tester, and it provides a chart record of the instantaneous thickness of a moving sample of yarn. The yarn passes between two rolls at a substantially constant speed of 12 yards per minute, as shown in the left part of Fig. 2. Since the lower roll is grooved and the upper one has a mating tongue, the material is confined in the lateral direction. Carried on the hinged and weighted arm is the upper roll, which is free to move up or down in response to the varying thickness of material between the rolls. The primary detector is an electric dimension gauge of the variable-inductance type, responding to the continually varying thickness as the material passes between the rolls. A micrometer screw, which is provided on the electric gauge as a means of suppressing the zero, is ordinarily set in advance to the expected or "correct" thickness of the material, thickness deviations being measured from this preset value.

A chart record, such as Fig. 3, will show the general pattern of thickness variation and may provide much useful information, but it does not enable one to express the mean or the amount of the variation in numbers. Therefore, it is necessary to obtain the mean and the standard deviation of the thickness. To accomplish this, two new end devices are provided in the Evenness Integrator.

Integrating Instruments Used

The first of these, a d-c current-integrating instrument, indicates the mean thickness deviation from the preset value. The second, an a-c current-squared integrating instrument, indicates the mean square of the thickness deviation. As will be shown later in this paper, there are simple relations between the readings obtained from such integrating instruments and the desired statistics. They are as follows

$$\text{mean} = \overline{X} = A + G$$

and

$$\text{standard deviation} = \sigma = \sqrt{B - A^2}$$

where

A = the reading of the current-integrating instrument
B = the reading of the current-squared integrating instrument
G = the setting of the gauge micrometer

The foregoing calculation of the mean can usually be done mentally. A nomograph is provided for calculating the standard deviation, so this conversion also becomes a simple matter for the operator. Thus, the integrating technique eliminates virtually all of the laborious data-taking and the computations ordinarily associated with the statistical analysis of a large amount of data obtained from the test of a large sample.

Functional Principles of System

The functional principles of the integrating system are shown schematically in Fig. 2. The windings of the electric dimension gauge are connected to form two arms of an a-c impedance bridge, the zero of this bridge being set for zero voltage output when the micrometer screw is on zero and the rolls are empty. The micrometer is then reset to the approximate thickness expected of the yarn, and the yarn threaded into the rolls and brought up to speed. Any upward mo-

tion of the steel armature has the effect of increasing the inductance of the upper coil while decreasing that of the lower one. This produces a 60-cycle alternating voltage e proportional to the amount of deflection of the armature from its midposition. A downward deflection produces a similar voltage output, but in this case the phase of the voltage differs by 180 degrees.

The voltage e, which is about 10 millivolts per thousandth of an inch of gauge deflection, is amplified by a conventional electronic amplifier to provide an a-c output i, which varies in phase and magnitude according to the thickness deviation from the micrometer setting. The output current i is approximately 7 milliamperes for 0.001-inch gauge deflection, when the attenuator is set to the highest-gain position. Taking the path indicated by heavy lines in Fig. 3, this current flows through the squaring integrator, which moves always in a clockwise direction and at a speed proportional to the square of the current.

Simultaneously, an alternating voltage V, proportional to i, drives a phase-sensitive a-c to d-c converter, which employs germanium rectifiers. It produces a d-c output proportional to V in magnitude, and having a polarity governed by the phase of V. This d-c output I_{DC}, is of the order of 0.7 milliampere for 0.001-inch deviation, assuming the attenuator is set to the highest-gain position. It flows through the current-integrating instrument and an external recorder, as indicated in Fig. 3. The current integrator has a zero-center scale, and moves clockwise or counterclockwise, depending on the polarity of I_{DC}, and at a speed proportional to the current.

An important part of the system is a timer, which controls the duration of the integrating cycle. After a preset time interval, the timer opens contact 1 and closes 2, de-energizing the relays and opening all four of the relay contacts (shown closed in Fig. 3), thereby disconnecting both integrators from the circuit. The pointers of these integrators then stop immediately, and their readings are recorded by the operator.

Closing of the timer contact 2 energizes the reset circuit, which is essential for resetting the instruments to zero prior to starting a new test. "Right" and "left" reset controls are provided to control the d-c reset voltage PQ for the current integrator, which has a zero-center scale. Operation of either of these controls also applies the a-c reset voltage RS to the squaring instrument, producing a counterclockwise rotation of its pointer, which resets against a pin at the zero end of the scale. Resetting can be completed in twenty seconds or less.

To initiate a new integrating cycle, a start button (not shown) is pushed, closing timer contact 1 and energizing the two relays, so that their four contacts again connect the integrators to the circuit, as shown in Fig. 3.

Continuous or timed operation can be selected for the recorder by closing or opening the switch SW, since dummy load resistors N and O are switched into the circuit by the relays, replacing the integrators while the latter are disconnected. The integrating time, which can be preset to any desired value from 15 to 150 seconds, is controlled by the adjustable timer. While the equipment is ordinarily calibrated for a standard interval such as 2 minutes, other time intervals can be used if the instrument readings are multiplied by appropriate factors. A gain control in the amplifier provides the calibrating adjustment for the system.

It should be noted that the two integrating instruments, the end devices of this measurement system, operate differently from the familiar indicating instruments. Having practically no spring torque, their pointers will not move appreciably so long as no current flows, regardless of the position of the pointer. The pointers are set to zero prior to starting the measuring cycle, and the speed of pointer motion is governed by the current. It is the final position of the pointer, at the end of the test, which is read and used.

Continuously Moving Samples Tested

The basic principle of testing continuously-moving samples, while not new, has certain particular advantages in quality control measurements. Since materials can be tested at fairly high speed with this method, relatively large samples can be tested economically. Furthermore, the system responds continuously to the varying thickness, so that mathematically the effect is as though an almost infinite number of thickness measurements were made on the sample. These factors ordinarily make it safe to assume there is no appreciable difference between test results on a single sample and the production lot in question, provided that the sample is unbiased.

Performance

Sensitivity of the equipment used in the textile industry is given in Table I for the most commonly used integrating interval, 2 minutes. In this application, the scale of the current integrator is marked -2 to 0 to $+2$ in thousandths of an inch and the squaring integrator has a scale of 0 to 7, making the equipment direct-reading for the times-1 attenuator setting. The system is used for materials varying from 0.004 to 0.06 inch in mean thickness, with standard deviations ranging from 0.001 to 0.012 inch.

The measuring system has been found to respond satisfactorily to instantaneous values of $X-G$ ranging from 0.05 times to over three times the full scale values listed in column 2 of Table I. This 60-to-1 range provides adequate accuracy of integration for normal random-varying signals, so long as a favorable degree of amplification is used by setting the attenuator properly. Accuracy of ±6 per cent of full scale is achieved, providing

Fig. 3. Chart record, thickness of yarn

high peak values (in excess of the values listed in the second column of Table I) occur relatively infrequently or are of fairly short duration. The signals to be integrated in practical quality measurements usually have these characteristics, so it is not considered necessary to achieve high accuracy in the integration of large peaks.

Current-Integrating Instrument

The current-integrating instrument, Figs. 4 and 5, consists of two mechanisms, the moving parts of these two being connected by a common shaft. The driving mechanism, toward the right in Fig. 5, is of the conventional permanent-magnet moving-coil construction, except there are no control springs, current being brought to the moving coil by very light spirals built to exert as little restoring torque as possible.

Toward the left is the damping mechanism, consisting of an aluminum cup, open at the left end, rotating in the gap between an internal Alnico magnet and a steel outer ring. The objective in design of the damping mechanism was to provide the largest practical damping torque consistent with the space available, and the 4-pole internal magnet construction has been found advantageous.

When current flows in the moving coil of the driving mechanism, a torque is developed which is counteracted by an equal damping torque developed by the rotation of the aluminum cup in its magnetic field. This damping torque is directly proportional to the rotational speed, while the driving mechanism develops a torque proportional to the current. The result is a speed of rotation proportional to the current.

Practical rotational speeds of the moving system vary from 0.02 to 8 angular degrees per second, the former being such a slow speed that the motion cannot be detected except by very careful observation. The current lead-in spirals, which should ideally have no restoring torque, are made of gold ribbon, providing an effective torque as low as 0.4 to 0.8 dyne-centimeter per radian of deflection, for the combined effect of the two spirals. This is of the order of 70 to 140 times less than the restoring torque of conventional instruments similar in general construction to the driving mechanism used in this device.

The current-integrating instrument is rated −85 to 0 to +85 milliampere-seconds full scale, and an accuracy of about ±2 per cent of full scale is realized when integrating random-varying currents over a period of 2 minutes. The device responds adequately to instantaneous current values as low as 0.03 milliampere, and to peaks as high as 6 milliamperes. Approximate constants for a typical instrument are:

Full-scale angle, 4.4 radians
Current required for full-scale pointer travel in 2 minutes, 1.4 milliamperes d-c
Rotational speed, 0.025 radian per second per milliampere
Damping constant, 6,000 dyne-centimeters per radian per second
Internal resistance, 340 ohms

The spiral torque, although made as low as possible, is not negligible. Consequently, the driving torque required for full-scale pointer travel in 2 minutes should preferably be at least 50 times higher than the full-scale spiral torque, in order to minimize drift errors. In the above design, the drift error did not exceed 0.5 per cent of full scale per minute. The effects of pivot friction and unbalance of the moving system also dictate the use of high driving torque and high damping constants, with the general conclusion that greater accuracy necessitates reduced current sensitivity.

Table I. Evenness Integrator Sensitivity, 2-Minute Interval

Attenuator Setting, M	Mean Thickness Deviation in Thousandths, for Full Reading of Current Integrator $\bar{X}-G$	Mean Squared Thickness Deviation in Thousandths, for Full Reading of Squaring Integrator $\overline{(X-G)^2}$
0.5	−1 to 0 to +1	1.75
1	−2 to 0 to +2	7
2	−4 to 0 to +4	28
5	−10 to 0 to +10	175

Note: The symbol *X* represents the instantaneous thickness, and *G* the setting of the gauge micrometer, both in thousandths of an inch.

Current-Squared Integrating Instrument

This instrument, as shown in Figs. 4 and 6, includes the same design of damping mechanism and current lead-in spirals as the current integrator. However, the driving mechanism in this case is of the electrodynamic type, having a fixed-field coil and a moving coil connected in series. The torque developed by such a system is proportional to the square of the current. Consequently, the pointer speed varies as the square of the current, while the total pointer travel is proportional to the integral of the current squared. Some approximate constants for such an instrument are:

Full-scale angle, 4.4 radians
Current,* 10 milliamperes a-c
Driving torque,* 200 dyne-centimeters
Rotational speed,* 0.036 radian per second
Internal resistance, 1,600 ohms
Reactance at 60 cycles, 5,300 ohms

Accuracy of about ±3 per cent of full scale is realized when integrating ordinary random-varying signals over a period of 2 minutes, and the instrument re-

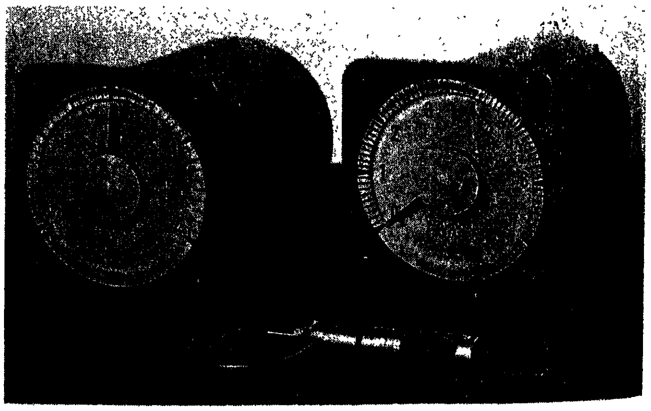

Fig. 4. Left, current-integrating instrument. Right, current-squared integrating instrument

---

* For full-scale pointer travel in two minutes.

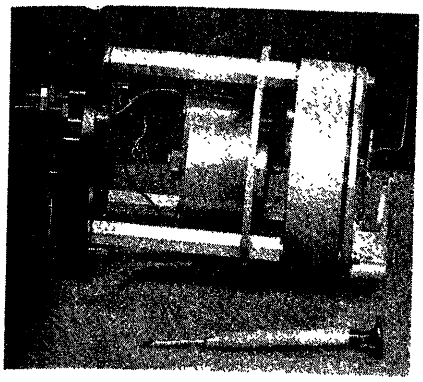

Fig. 5. D-c current-integrating instrument, scale and cover removed

sponds adequately to instantaneous current values ranging from 1.5 to 30 milliamperes. When large peaks, 20 to 30 milliamperes, for example, are integrated, there are instantaneous errors of the pointer speed of the order of 5 to 8 per cent, but the practical effect on the accuracy is slight, since such peaks are ordinarily of short duration, and they constitute only a small portion of the integrated current value. The drift error is about the same as for the current-integrating instrument, 0.5 per cent of full scale per minute.

As shown in Fig. 3, a 0.5-microfarad capacitor C is used with this instrument to provide a low-impedance load at 60 cycles, in order to minimize the volt-ampere burden upon the amplifier. Considerable inverse current feedback is used with the amplifier, greatly reducing the effect of any changes in the output current i occurring from changes in the winding temperatures of the squaring integrator. This feedback also improves the linearity and the gain stability of the system.

Mathematical Basis

Since the purpose of the measuring system is to obtain the mean and the standard deviation, these quantities have been examined mathematically, in order to establish the relation between them and the readings obtained from integrating instruments.

Shewhart[2] defines the mean as follows:

$$\bar{X}=\frac{X_1+X_2+\ldots+X_n}{n} \qquad (1)$$

where X_1, X_2, etc., are individual discreet measurements of the variable, and n the number of such measurements.

When the sample is tested while moving continuously, the signal e, Fig. 3, is a continuously varying voltage proportional to the instantaneous thickness deviation from the preset value. Consequently, n may be considered infinite. The definition may therefore be rewritten as

$$\text{mean}=\bar{X}=\frac{1}{t}\int_0^t X\,dt \qquad (2)$$

where t is the time duration of the test in minutes and X the instantaneous thickness of the material.

Referring to Fig. 3, the a-c output of the amplifier i can be expressed by the relation

$$i=k_1(X-G) \qquad (3)$$

where G is the setting of the micrometer in thousandths of an inch, and k_1 is a constant depending on the amplifier gain and the sensitivity of the primary detector and its associated circuit. The converter produces a direct current I_{DC}, proportional to the alternating current i. This direct current may be either positive or negative, depending on whether X is larger or smaller than G.

If a center-scale instrument responds to the integral of a direct current, its final reading A at the conclusion of the test will be

$$A=k_2\int_0^t i\,dt \qquad (4)$$

where k_2 is the sensitivity constant of the instrument and its converter. Substituting equation 3 into 4, and using the definition of the mean, equation 2, it can be derived that

$$\bar{X}=\frac{A}{tk_1k_2}+G \qquad (5)$$

If a standard test time is used for all samples, it is simple to calibrate the equipment so the product tk_1k_2 is one. Then

$$\bar{X}=A+G \qquad (6)$$

Thus, a d-c current-integrating instrument gives a convenient measure of the mean, if its reading is added to the setting of the micrometer.

Shewhart[2] also defines standard deviation as follows

$$\sigma=\sqrt{\frac{(X_1-\bar{X})^2+(X_2-\bar{X})^2+\ldots+(X_n-\bar{X})^2}{n}}$$

$$=\sqrt{\frac{X_1^2+X_2^2+\ldots+X_n^2}{n}-\bar{X}^2} \qquad (7)$$

For the purpose of this paper, this definition is rewritten in terms of a continuous variable, as was done for the mean. Thus

standard deviation =

$$\sigma=\sqrt{\frac{1}{t}\int_0^t X^2dt-\bar{X}^2} \qquad (8)$$

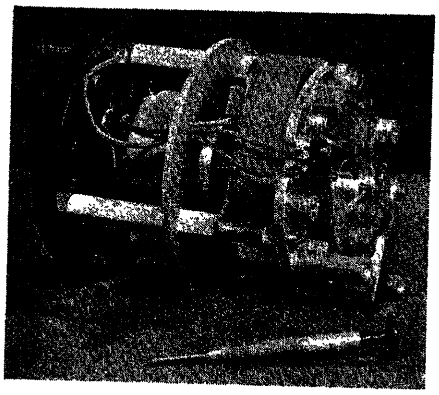

Fig. 6. A-c current-squared integrating instrument, scale and cover removed

It will be recognized that this is a difficult quantity to measure with instruments, since it involves not only an integral of X^2, but also $\bar{X}^2$, a quantity that is unknown prior to the test and which becomes known only upon completing the integrated measurement on the entire sample.

The mathematical expression for the response of a current-squared integrating instrument is the following

$$B=k_3\int_0^t i^2dt \qquad (9)$$

where B is the reading from the scale of the instrument at the conclusion of the test, and k_3 is the sensitivity constant of the instrument. By substituting equation 3 into 9, expanding the resultant expression, and using equations 2, 8, and 5, it can be proved that

$$\sigma=\sqrt{\frac{B}{tk_1^2k_3}-\left(\frac{A}{tk_1k_2}\right)^2} \qquad (10)$$

Constant k_1 is determined by adjusting the gain control so $tk_1^2k_3=1$. A second requirement is to adjust the converter sensitivity, which affects k_2, so that $tk_1k_2=1$, as previously mentioned. Then equation 10 becomes

$$\sigma=\sqrt{B-A^2} \qquad (11)$$

Thus, while it is not possible to indicate standard deviation with the comparatively simple instruments described here, it is possible to obtain the standard deviation from both of the instrument readings, A and B, by performing the calculation of equation 11.

When a variety of materials are to be tested with one equipment it is desirable to provide an attenuator switch, as in Fig. 3, this switch being designed for simple scale-multiplying factors such as 0.5, 1, 2, and 5. The multiplying factor can be designated as M, and it will vary according to the reciprocal of the change in gain effected by the attenuator. For such an arrangement, the modified form of equations 6 and 11 is

$$\bar{X} = MA + G \qquad (12)$$

and

$$\sigma = M\sqrt{B - A^2} \qquad (13)$$

When testing a given type of material, doubling the amplification doubles the reading of the current-integrating instrument, while quadrupling that of the current-squared integrator. The most favorable accuracy is obtained by the use of as much amplification as possible, so long as neither instrument reaches the end of its scale before the end of the time interval.

Conclusions

It is believed that integrating instruments will be found useful in the solution of various specialized measuring problems, of which determining mean and standard deviation is only one example. Obviously, it should be possible to construct instruments for integrating various different quantities by substituting various driving mechanisms for the two described, still using a moving system having essentially no restoring torque and a very high degree of damping. It will be recognized that an integrating instrument is actually a form of computing mechanism, and that the measuring system described herein is a type of analogue computer.

Two new end devices, a current-integrating instrument and a current-squared integrating instrument, have been incorporated, together with conventional parts including an electric dimension gauge, impedance bridge, amplifier, timer, relays, and converter, into a measuring system applicable to dimensional quality measurements for applications where the material is tested while moving continuously. The instruments indicate the mean and the mean-square deviation from a preset value, and mathematical derivations have shown that these readings can be easily converted to the mean and standard deviation of the measured variable.

Although the measurement system described here was developed for testing yarn, similar techniques could presumably be applied to other materials, such as paper, metal strip, wire or plastics, which can be tested while moving at a constant rate of speed. The measured variable could be thickness, width, diameter or any other electrical or nonelectrical quantity, provided that a suitable primary detector is available. It is believed that such instrumentation will reduce the time and effort required to measure certain qualities of manufactured products, encouraging a wider application of scientific quality-control procedures in industry.

An Application of Boolean Algebra to the Design of Electronic Switching Circuits

S. H. WASHBURN
ASSOCIATE MEMBER AIEE

IN THE 15 years since Shannon[1] introduced the Boolean algebra as an aid towards the analysis and synthesis of switching circuits, this algebra has proved to be a worthwhile addition to the procedures available to the switching circuit designer. Although, in its present form, it cannot be employed to solve many of the problems by which the designer is confronted, the switching algebra provides an exceedingly effective technique in those cases where its use is indicated.

The utility of the Boolean algebra is evidenced in two ways. First, the algebraic symbolism is a useful notation for representing the behavior of a switching circuit resulting from various input conditions and its effect on the condition of the output leads which it controls. Second, the theorems of the algebra indicate possible manipulations of circuit configurations, thus allowing the designer to obtain various equivalent circuit forms without fear of the consequences of lapses of logic.

In this paper, a method utilizing the Boolean algebra in the design of electronic switching circuits is presented. This method is analogous to that applicable to the design of relay switching circuits in that it deals with the interconnection of idealized 2-valued building blocks, such as gates and memory units, into so-called logical circuit arrangements. No attempt is made to provide design tools for the synthesis of the building blocks themselves, since such design is outside the province of Boolean algebra.

Although it is not necessary to inclued a complete discussion of the Boolean algebra here, since the literature contains a number of such presentations,[1,2] a brief review of the basic principles may be helpful. The variables of the algebra represent leads or other entities, and can assume only two numerical values corresponding to the two states of these entities; at any given time a variable is equal to either 1 or 0: 1 if the corresponding lead is in an energized, or active, condition, and 0 if the lead is in an unenergized, or passive condition. There are three operations available in the algebra: addi-

J., June 15–19, 1953. Manuscript submitted March 17, 1953; made available for printing April 23, 1953.

S. H. WASHBURN is with the Bell Telephone Laboratories, Inc., New York, N. Y.

The author acknowledges the very considerable part played by W. Keister of the Bell Telephone Laboratories in the formulation of certain of the techniques presented in this paper. In addition, thanks are tendered to other members of the Bell Telephone Laboratories, especially J. H. Felker and W. D. Lewis, whose independent work in defining electronic building blocks and in suggesting means for interconnecting these blocks to satisfy circuit requirements has been of assistance in directing the thoughts of the author, and A. E. Anderson and R. M. Ryder, whose investigation of switching circuit design principles helped to motivate the work leading to this paper.

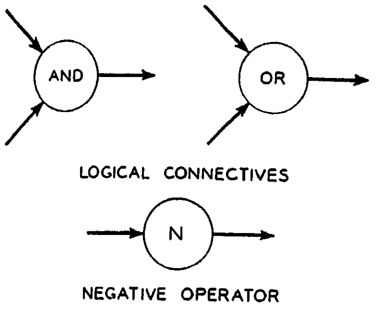

Fig. 1. Symbolic logical operators

tion (+), multiplication (·), and negation ( )′. The addition and multiplication serve to link the variables (or groups of variables already linked), and the negation, or prime, operates on a single variable or group of variables. In the convention to be adopted here multiplication is equivalent to the logical connective AND, and addition is equivalent to the logical connective OR. The operation of negation serves to transform the numerical value of the variables or expression on which it operates; that is, if $X=0$, $X'=1$ and, if $X=1$, $X'=0$; where X can be any algebraic function. It can be shown that the negative of any function can be derived from that function by replacing all products by sums and sums by products, and substituting for each variable its negative, noting that $(X')'=X$.

Fundamentals of Graphical Symbolism

The Boolean algebra is capable of indicating any logical relationship expressible by negation and the connectives AND and OR. Thus, if the requirements for, say, energizing a particular lead in terms of the energization and non-energization of other leads are expressed in these terms, an algebraic equivalent of this situation can be written.

Now, a graphical symbolism may be used which is equivalent to the logical statement, and to the corresponding algebraic expression. The components of this symbolism, shown in Fig. 1, are similar to the neuron symbolism used by J. Von Neumann and others.[3] Each symbol represents a logical operation performed on one input function, as in the case of negation, or on two input functions, as in the case of the connectives AND and OR. These symbols are interconnected in accordance with the logical structure of the particular algebraic expression to be represented. The final configuration is then a diagram graphically indicating the specific operations and their relationships required in the original logical statement.

A number of examples showing symbolic configurations and their corresponding algebraic expressions are shown in Fig. 2. In the first, the algebraic expression represents the statement "X is energized at all times that C is energized, or that A and B are energized"; the diagram shows that A and B are combined by the AND operator and the result is combined with C by an OR operator. In the second illustration, the verbal expression represented is: "X is energized at all times that C is energized together with either B energized or A not energized." Here, the diagram shows that B and the negative of A are combined by OR, and the result is combined with C by the operator AND. The remaining examples can be similarly interpreted.

Since algebraic expressions can be manipulated through the use of the theorems, many equivalent configurations can be drawn to represent equivalent logical statements. For example, consider the statement: "X is energized at those times when B and C are energized or when A or B, but not both, are energized. This is expressed algebraically as

$$f(X)=BC+(A+B)(AB)' \tag{1}$$

since "A or B, but not both" is equivalent to "A or B and not A and B". This expression may be manipulated at will

$$\begin{aligned} f(X)&=BC+(A+B)(A'+B') \\ &=BC+AB'+A'B \\ &=AB'+B(A'+C) \end{aligned} \tag{2}$$

The graphical symbolism for these is shown in Fig. 3.

It is interesting to note that either one of the two connective symbols is not strictly necessary in representing an algebraic expression. This follows from the fact that

$$AB=(A'+B')'$$

and that

$$A+B=(A'B')' \tag{3}$$

It appears that any AND symbol can be replaced by an OR and three negation symbols, and that any OR symbol may be similarly replaced by an AND and three negation symbols. These and other equivalences derived by similar reasoning are shown in Fig. 4. The final equivalence in this figure, showing that two negation operators in tandem are equivalent to the absence of an operator, that is, a direct connection, is justified by the theorem.

$$(X')'=X \tag{4}$$

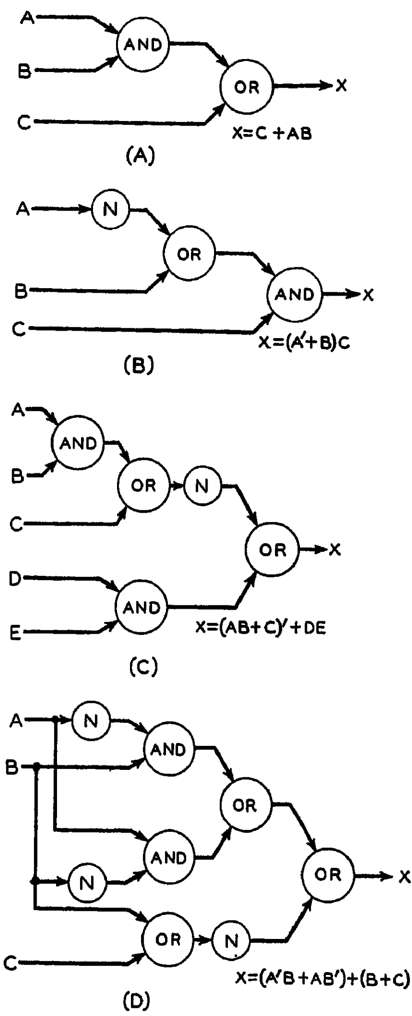

Fig. 2. Typical symbolic configurations

By applying these equivalences, various equivalent graphical configurations can be derived directly.

Application to Electronic Switching Circuits

The basic circuit blocks with which electronic switching circuits are constructed are switching gates, inverters, and memory elements. The gates may be considered as operators similar to the logical connectives, each gate effecting the energization of an output lead depending on the state of its input leads. The inverter is analogous to the logical negation operator. Memory elements, to be considered briefly later in this paper, are two-state devices having the property that, once driven into an active state, an element will remain in that state for some given interval.

In electronic switching circuitry, the difference between energization and non-energization is generally one of potential, although it may be one of current flow. That is, the lead may be at either one of two potentials, one more positive than th

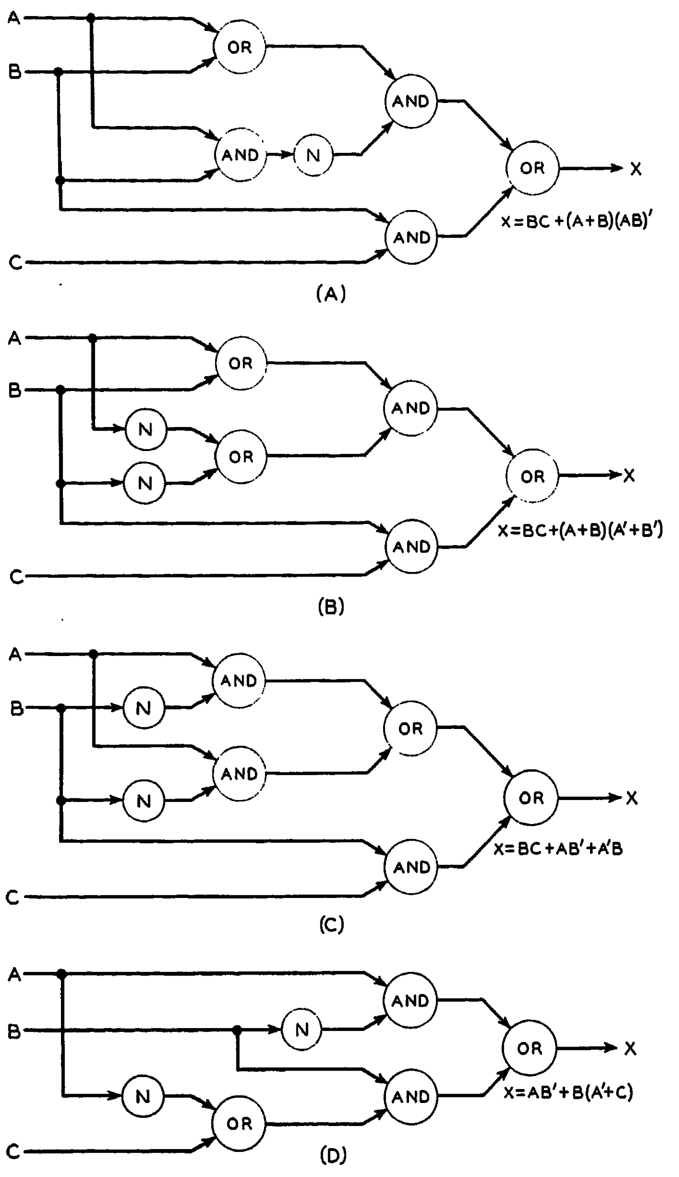

Fig. 3. Equivalent symbolic networks

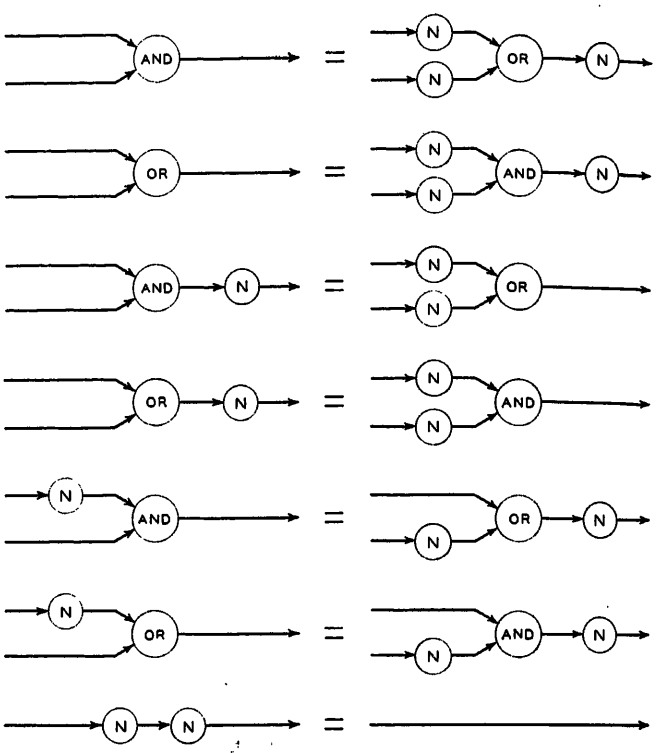

Fig. 4. Table of logical equivalents

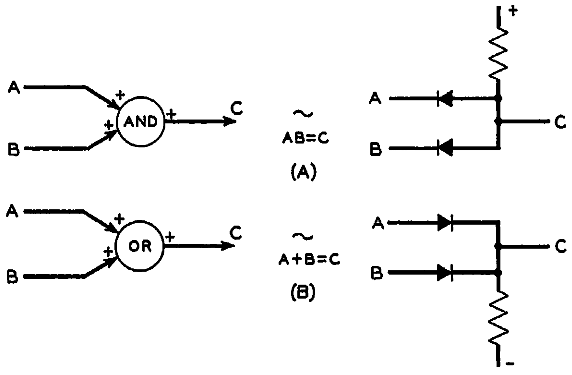

Fig. 5. Simple AND and OR gates

other. As a convention in this paper, these two potentials will be arbitrarily designated "+" and "−," the "+" potential being the more positive of the two. The amplitudes of the two potentials, and also the fact that the potential designated "−" may actually be positive with respect to ground, is of no concern here.

These indications of energization and nonenergization may be used to advantage with the symbolism just described, to clarify the analysis of a symbolic configuration and to specify the operation of the individual gate elements. For example, a particular AND operator, or gate, may have the characteristic that when, and only when, both input leads are "+," the output lead is "+". This gate can be represented as in Fig. 5, with a "+" symbol associated with each input lead and with the output lead. Similarly, the OR gate in the same figure has "+" signs associated with all its leads, indicating that the output lead is "+" when either or both input leads are "+." Typical circuits which operate according to these specifications are also shown in the figure.

Now, for a particular case, either the "+" potential or the "−" potential may be the energized state. For convenience in adopting the Boolean algebra to electronic circuitry, the "+" and "−" potentials will be considered as represented by the numerical constants 1 and 0, respectively. Therefore, the algebraic expressions which describe the operation of the AND and OR gates of Fig. 5 are, in that order

$$AB=C \text{ and } A+B=C \qquad (5)$$

The operation of these gates can be described by an alternative form. For example, for the first gate of Fig. 5, the operation of the gate can be described by the phrase "the output is "+" when, and only when, both inputs are "+"," or by the phrase "the output is "−" when either input is "−"." This, of course, follows from the equivalence of the two algebraic expressions

$$AB=C \text{ and } A'+B'=C' \qquad (6)$$

Both expressions represent exactly the same logical situation. Similarly, since $A+B=C$ and $A'\,B'=C'$ are equivalent to one another, the behavior of the second gate may be stated: "the ouput is "−" when, and only when, the inputs are both "−"." As a result of these equivalences, two different symbols can be used to represent the same operational characteristic, as indicated in Fig. 7.

The "+" and "−" labels may also serve to stress the behavior of the negation operator, or inverter. When the input lead to the inverter is "+," the output lead is "−" or, equivalently,

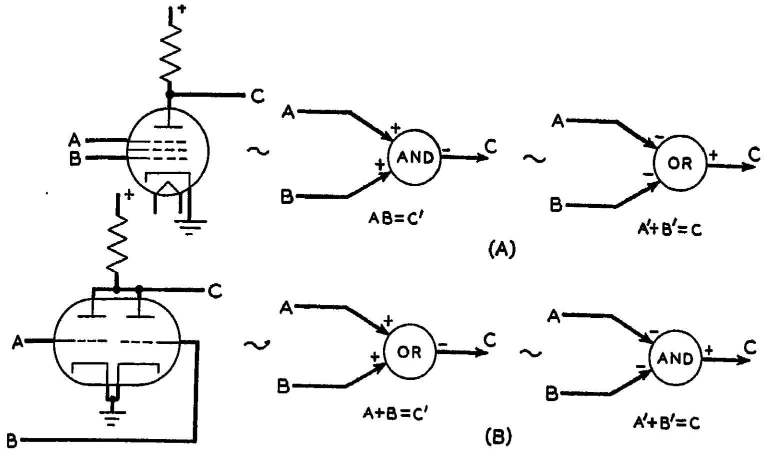

Fig. 6 (above). Gates performing inversion

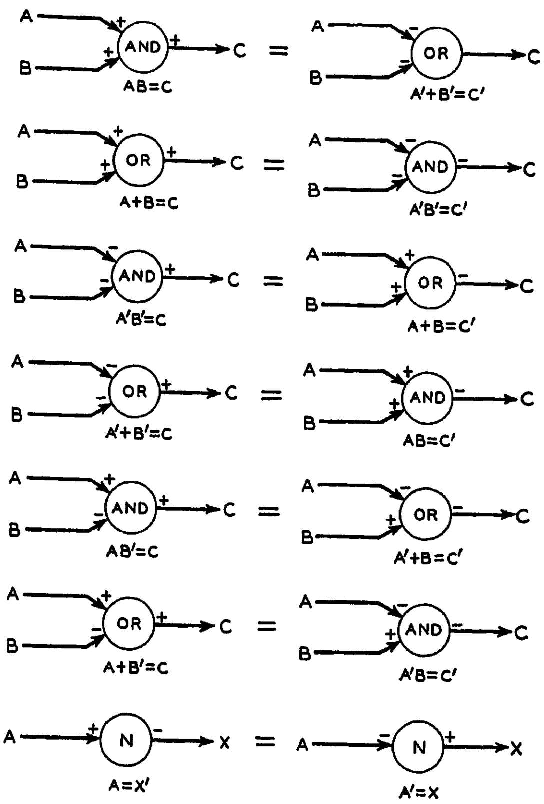

Fig. 7 (right). Table of gate elements for switching circuit application

when the input is "−," the output is "+." As a result, the two symbolic forms shown in Fig. 7 obtain.

Gates and inverters can be combined exactly as were the logical connectives and the negation operator in Fig. 4. However, it is often more convenient to consider the combinations thus obtained as new elemental building blocks rather than as interrelations of the original elements, since in many cases the basic electronic devices used in physical circuits can be described directly by these new blocks. As an illustration, consider the pentode of Fig. 6. With suitably chosen grid biases, a "−" signal on either grid will drive the tube to cut-off; both grids must be "+" to allow the plate potential to fall. The symbolic equivalents for the element and their algebraic expressions are shown in the figure. A second illustration is the pair of plate-connected triodes also shown in Fig. 6. Here, "+" potentials must be applied to either grid to cause the plate potential to assume the "−" potential. Therefore, the element is represented by either of the symbols shown in the figures.

Considering elements of this type as variations of switching gates, it is clear that there are, at most, six operationally unique gates, corresponding to the six logically different combinations of Fig. 4. Four of these have already been introduced. Each gate, as has been seen, can be represented by a pair of equivalent symbols and by the corresponding pair of characteristic equations which define the symbols. These symbolic representations together with their algebraic expressions, as well as those for inversion, are given in Fig. 7.

Synthesis of Switching Networks

The networks to be discussed first are of the type known as combinational circuits. These are circuits in which the state of the circuit output at any time is completely determined by the state of the circuit input at that time. The particular time sequence in which various signal conditions are applied to the circuit input has no effect on this dependency. The design of circuits in which operation is affected by the sequence of application of input signals is considered later in this paper.

A circuit network to produce a given output signal corresponds to a logical statement written in terms of the AND and OR relations between control conditions. It has been seen that such a statement may be represented graphically by a configuration of AND, OR, and negation elements suitably interconnected. Also, the preceding paragraphs have presented switching gates which are defined to operate in a manner equivalent to the logical elements. Therefore, the logical design of the circuit networks consists of selecting and interconnecting these switching gates to correspond to the statement describing the relationship between the output signal and the control conditions.

The technique for carrying out the design procedure is a routine one. First, the circuit requirements are written as an algebraic expression. Any complex expression in Boolean algebra may be separated into two functions related by either multiplication or by addition. This determines whether the gate whose output lead is the output lead for the

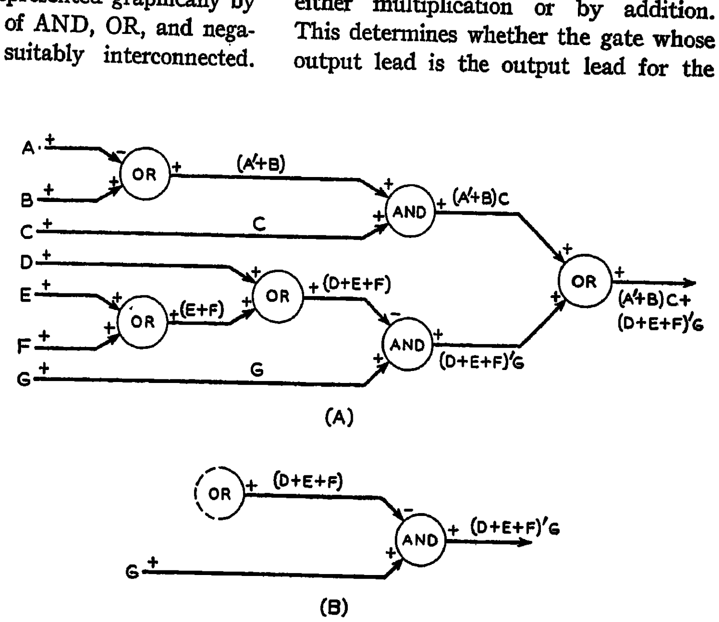

Fig. 8. Typical switching network configuration

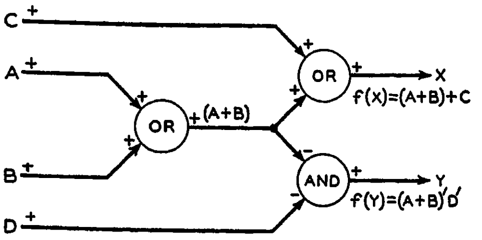

Fig. 9 (left). Network configuration with common circuit elements

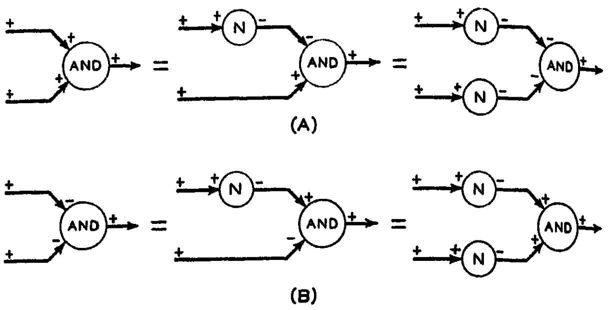

Fig. 10 (right). Circuit manipulation by introduction of inverters

circuit is to be of the AND or the OR type. The two functions into which the original expression is separated form the input to this gate. Where a function is expressed as the negative of another function, a gate with a "−" associated with the input lead corresponding to this function is used; otherwise a "+" is associated with the input lead. Every gate output is labelled "+."

The two functions are then separated to determine the nature of the gates feeding the output gate. The process is continued until only single variables remain. These represent input leads to which the signals controlling the circuit are applied.

In practice, this over-all procedure is very simple—merely a translation from algebraic expression to configuration of gates, replacing each multiplication by an AND gate, each addition by an OR gate, and translating each negation symbol to a "−" sign on the requisite gate input lead. The process is illustrated in Fig. 8(A) for the expression

$$(A'+B)C+(D+E+F)'G \qquad (7)$$

In the figure, the algebraic expression for the signal on each lead is indicated. Input leads for the functions A' and $(D+E+F)'$ have been labelled "−" to provide for the required negation. The assumption that each gate element has only two inputs makes it necessary to produce the expression $(D+E+F)$ in two stages, that is, $D+(E+F)$. Note that the potential labels on the circuit input leads indicate that the active signal on these leads is "+."

Each lead in the symbolic configuration has a potential label on each of its two ends. Where the two polarities are different, a logical negation operation occurs; where they are the same, no negation is carried out. This is clear from an investigation of the behavior of the interconnected gates since the potential labels define the operation of the gates. Consider, for example, the circuit portion shown in Fig. 8(B). The output of the OR gate is "+," as indicated by the label, when D or E or F is "+," the active condition of the input being the "+" potential. Now, the AND gate is defined by its potential symbols as providing a "+" output when its upper input is "−" and its lower input is "+." This means that the output will be "+" when G is "+" and the lead corresponding to $(D+E+F)$ is "−." The active condition at the output of the OR gate is the passive condition for the AND gate and vice versa. Thus, the active condition for the AND gate corresponds to $(D+E+F)'$.

Manipulation of Gate Networks

There may be a number of different circuit arrangements corresponding to a given logical expression. It is often desirable to investigate several of these to determine the one most suitable for a given application. Rearrangement of a circuit without changing its over-all operating characteristics may be accomplished either by manipulation of the corresponding algebraic expressions, in accordance with the fundamental theorems, or by certain transformations which may be made directly on the circuit. Unfortunately, the Boolean algebra in its present state of development can specify no explicit set of operations which will lead to the most economical circuit form.

A fortunate characteristic of the circuitry composing gate elements is the virtual isolation between input leads. That is, a signal or change of signal on one input lead has little or no effect on the other input lead. As a result, input leads to several gates may be directly interconnected and driven from the same source without the fear of back-up paths which bedevil relay circuit designers. The utility of this characteristic is apparent in the example to follow.

Two output leads, X and Y are to be controlled by signals on four input leads, A, B, C, and D, as specified by the expressions

$$\begin{aligned} f(X)&=A+B+C \\ f(Y)&=A'B'D' \end{aligned} \qquad (8)$$

These expressions may be modified as follows

$$\begin{aligned} f(X)&=(A+B)+C \\ f(Y)&=(A+B)'D' \end{aligned} \qquad (9)$$

Note that the term $(A+B)$ is now common to both expressions, and that it can be supplied by a single OR gate in the circuit configuration. The complete network is shown in Fig. 9.

In a practical case, the physical manifestations of certain of the six gates symbolized in Fig. 7 may not be economical or reliable, and the use of these gates may therefore be prohibited. Such gates can be avoided by algebraic manipulation or by the introduction of inverters. The effect of an inverter in the input lead to a gate is that of interchanging active and passive states on that lead or, in terms of the symbolism, of interchanging "+" and "−" labels. This is shown in the typical equivalents of Fig. 10. Note that comparison of the potential symbols at the two ends of each lead still indicates whether or not a logical negation is taking place.

Another technique for avoiding undesirable types of gate elements is that of reversing potential symbols on interconnecting leads. In any network, the potential symbol at the one end of a given lead may be reversed if the symbol at

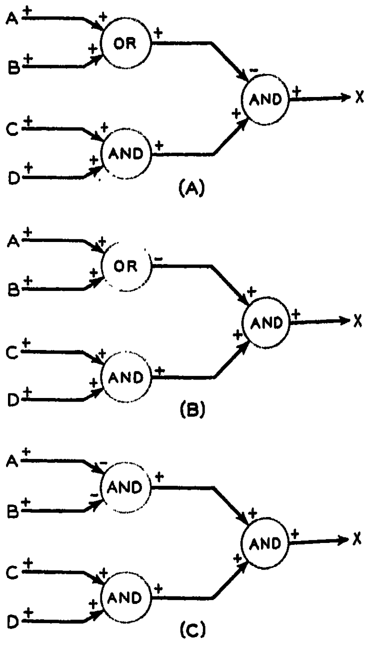

Fig. 11. Circuit manipulation by reversal of potential symbols

the other end is also reversed. This operation has the effect of changing the characteristics of two gate elements: the gate having one end of the given lead as an output, and the gate to which the other end of the lead is an input. A simple illustration of this relabeling is given in Fig. 11. The algebraic expression corresponding to the first network is evidently

$$(A+B)'CD \qquad (10)$$

The potential designations of the two ends of the lead between the OR gate and the AND gate are reversed in the second network. Finally, the OR gate is replaced by the equivalent AND gate in the third network. The network is operationally equivalent to the original network since

$$(A+B)'CD=(A'B')CD \qquad (11)$$

Omission of Gates

In some instances, a gate through which there is no inversion can be replaced by a junction point. These gates are of the characteristic types $A+B=C$, $A'+B'=C'$, $A'B'=C,'$ and $AB=C$. Whether such a gate can be omitted in a particular case depends upon the signal levels and biases associated with the input and output leads, and also upon whether direct connection of these leads at a junction point will introduce unwanted signal conducting paths.

Other Types of Gates

Gates having more than two input terminals and one output terminal require slight modification of the symbolism used thus far in this paper. If, for example, inputs are added to the diode gates of Fig. 5, by employing a diode in series with each new input, multi-input AND and OR gates are obtained. These may be symbolized by AND and OR elements with the requisite number of input leads, each labelled with the appropriate potential symbol. Some gates using vacuum tubes or similar devices may be arranged to deliver both "+" and "−" signals for the active condition by connecting an output lead to both anode and cathode terminals. The symbolic gate elements representing these have two output leads, one labelled "+" and the other labelled "−." The techniques for dealing with these elements are exactly the same as for those elements already discussed.
